The pleasure of authoring a textbook comes from writing about a subject that we enjoy and find exciting. As authors, we hope that we can pass on to the reader not only knowledge but also the excitement that we feel for the subject. In addition, writing about investments brings an added stimulant because the subject can affect the reader during his or her entire business career and beyond. We hope that what readers derive from this course will help them enjoy better lives through managing their financial resources properly.

The purpose of this book is to help you learn how to manage your money so you will derive the maximum benefit from what you earn. To accomplish this purpose, you need to learn about the many investment alternatives that are available today and, what is more important, to develop a way of analyzing and thinking about investments that will remain with you in the years ahead when new and different investment opportunities become available.

Because of its dual purpose, the book mixes description and theory. The descriptive material discusses available investment instruments and considers the purpose and operation of capital markets in the United States and around the world. The theoretical portion details how you should evaluate current investments and future opportunities to develop a portfolio of investments that will satisfy your risk-return objectives.

Preparing this tenth edition has been challenging for two reasons. First, we continue to experience rapid changes in the securities markets in terms of theory, new financial instruments, innovative trading practices, and the fallout from the significant credit and liquidity disruption and the numerous regulatory changes that followed. Second, as mentioned in prior editions, capital markets continue to become very global in nature. Consequently, early in the book we present the compelling case for global investing. Subsequently, to ensure that you are prepared to function in a global environment, almost every chapter discusses how investment practice or theory is influenced by the globalization of investments and capital markets. This completely integrated treatment is to ensure that you develop a broad mindset on investments that will serve you well in the 21st century.

Intended Market

This text is addressed to both graduate and advanced undergraduate students who are looking for an in-depth discussion of investments and portfolio management. The presentation of the material is intended to be rigorous and empirical, without being overly quantitative. A proper discussion of the modern developments in investments and portfolio theory must be rigorous. The discussion of numerous empirical studies reflects the belief that it is essential for alternative investment theories to be exposed to the real world and be judged on the basis of how well they help us understand and explain reality.

Key Features of the Tenth Edition

When planning the tenth edition of Investment Analysis and Portfolio Management, we wanted to retain its traditional strengths and capitalize on new developments in the investments area to make it the most comprehensive investments textbook available.

First, the current edition maintains its unparalleled international coverage. Investing knows no borders, and although the total integration of domestic and global investment opportunities may seem to contradict the need for separate discussions of international issues, it, in fact, makes the need for specific information on non-U.S. markets, instruments, conventions, and techniques even more compelling.

Second, both technology and regulations have caused more significant changes during the last decade in the functioning and organization of global security markets than during the prior 40 years. Chapter 4 contains a detailed discussion of this evolution and the results for global markets.

Third, today’s investing environment includes derivative securities not as exotic anomalies but as standard investment instruments. We felt that Investment Analysis and Portfolio Management must reflect that reality. Consequently, our four chapters on derivatives are written to provide the reader with an intuitive, clear discussion of the different instruments, their markets, valuation, trading strategies, and general use as risk management and return enhancement tools.

Fourth, we have added many new questions and problems to the end-of-chapter material to provide more student practice on executing computations concerned with more sophisticated investment problems.

Fifth, we have updated and enhanced the collection of Thomson ONE: Business School Edition (BSE) exercises in several end-of-chapter problem sets. Thomson ONE: BSE is a professional analytical package used by professionals worldwide. Our text allows one-year access for students to Thomson ONE: BSE, which contains information on firms, including financial statement comparisons with competitors, stock price information, and indexes for comparing firm performance against the market or sector. Thomson ONE: BSE is a great package for hands-on learning, which rivals or exceeds that offered by other textbook publishers.

Major Content Changes in the Tenth Edition

The text has been thoroughly updated for currency. In addition to these time-related revisions, we have also made the following specific changes to individual chapters:

Chapter 3
The updated evidence of returns (through 2010) continues to support global diversification, and an updated study on global assets supports the use of a global measure of systematic risk to explain asset returns. Also, we consider new investment instruments available for global investors, including global index funds and the continued growth of exchange-traded funds (ETFs) for numerous countries and sectors.

Chapter 4
Because of the continuing growth in trading volume handled by electronic communications networks (ECNs), this chapter was heavily rewritten to discuss in detail the significant changes in the market as well as the results of this new environment including the “flash crash” in 2008. This includes a discussion on the continuing changes on the NYSE during 2008–2011. We also consider the rationale for the continuing consolidation of global exchanges across asset classes of stocks, bonds, and derivatives. In addition, we document recent mergers and discuss several proposed and failed mergers. Finally, we note that the corporate bond market continues to experience major changes in how and when trades are reported and the number of bond issues involved.

Chapter 5
This chapter contains a discussion of fundamental weighted stock and bond indexes that use sales and earnings to weight components rather than market value. Also included is an updated analysis of the relationship among indexes.

Chapter 6
New studies that both support the efficient market hypothesis but also provide new evidence of anomalies are examined in this chapter. There is also discussion of behavioral finance and how it explains many of the anomalies. Further, we discuss the implications of the recent changes in the cost of trading (considered in Chapter 4) on some of the empirical results of prior studies.

Chapter 8
This chapter has been revised to enhance the presentation of the important transition between modern portfolio theory and the Capital Asset Pricing Model (CAPM) in a more intuitive way, including section on industry-specific characteristic lines. The discussion contains several examples of how the CAPM is measured and used in practice, in both the United States and global markets.

Chapter 9
The discussion of the theory and practice of using multifactor models of risk and expected return has been updated and expanded. The connection between the Arbitrage Pricing Theory and the Capital Asset Pricing Model (CAPM) is discussed in detail, and the text includes many examples and applications to help students understand how these models can be used in practice.

**Major Content Changes in the Tenth Edition**

The text has been thoroughly updated for currency. In addition to these time-related revisions,
we have also made the following specific changes to individual chapters:

**Chapter 3** The updated evidence of returns (through 2010) continues to support global diver-

and expected return has been updated and expanded. The connection between the Arbitrage
Chapter 10 This chapter contains a detailed comparison of alternative cash flow specifications and how they are used in valuation models and credit analysis. When we apply the extensive ratio analysis to Walgreens, it uncovers several changes in the performance by Walgreens, which highlights the usefulness of the analysis.

Chapter 11 Here we emphasize the two alternative approaches to valuation (present value of cash flows and relative valuation). An updated presentation of the yield spread during the 2008–2010 period enforces the importance of the changing risk premium.

Chapter 12 This chapter both considers the macroeconomic variables that affect capital markets and demonstrates the microvaluation of these markets. The demonstration was very challenging and insightful due to the economic and market environment in 2008–2011.

Chapter 13 We continue to emphasize the importance of the macroanalysis of an industry and the large impact this has on the subsequent valuation of the industry.

Chapter 14 We advocate a two-part analysis that first involves a deep analysis of a company to understand both its business and financial risk and its growth outlook. The second part of the analysis is a stock valuation component that depends upon the company analysis for inputs. The result is two decisions—one on the company and the second on the stock. It is emphasized that these decisions do not have to be the same (e.g., the stock of a good company may be a poor stock—it may be overvalued).

Chapter 15 This chapter contains an enhanced discussion of the relative merits of passive versus active management techniques for equity portfolio management focusing on the important role of tracking error. Expanded material on measuring the tax efficiency of an equity portfolio has been introduced, along with additional analysis of equity portfolio investment strategies, including fundamental and technical approaches, as well as a detailed description of equity style analysis.

Chapter 16 Because of the major credit-liquidity problems encountered in the U.S. bond market during 2007–2009, which continue to impact security markets around the world, several topics in the chapter have been added or adjusted. This includes discussions on governmentsponsored entities (GSEs), bond-rating firms, municipal bond insurance, collateralized debt obligations (CDOs), auction-rate securities, and covered bonds.

Chapter 17 We discuss four specifications of duration including the strengths and problems for each of them. Similarly, we consider three yield spreads—traditional spreads, static yield spreads, and option adjusted spreads (OAS)—and the relationships among them.

Chapter 18 This chapter on bond portfolio management strategies has been enhanced and revised to include an extended discussion comparing active and passive fixed-income strategies, as well as new and updated examples of how the bond immunization process functions. Both new and updated material on how the investment style of a fixed-income portfolio is defined and measured in practice has also been included, along with new examples of active bond management strategies.

Chapter 19 Expanded discussions of the fundamentals associated with using derivative securities (e.g., interpreting price quotations, basic payoff diagrams, basic strategies) are included in this chapter. We also provide updated examples of both basic and intermediate risk management applications using derivative positions, as well as new material on how these contracts trade in the marketplace.

Chapter 20 New and updated examples and applications are provided throughout the chapter, emphasizing the role that forward and futures contracts play in managing exposures to equity, fixed-income, and foreign exchange risk. Also included is an enhanced discussion of how futures and forward markets are structured and operate.

Chapter 21 Here we expand the discussion linking valuation and applications of call and put options in the context of investment management. The chapter contains both new and
updated examples designed to illustrate how investors use options in practice, as well as a discussion of the recent changes to options markets.

**Chapter 23** This chapter includes a revised discussion of several advanced derivative applications (e.g., swap contracting, convertible securities, structured notes, real options), as well as updated examples and applications of each of these applications. An extensive discussion of how credit default derivatives are used in practice has also been updated.

**Chapter 24** Contained in this chapter is a revised and updated discussion of the organization and participants in the professional asset management industry. Of particular note is an extensive update of the structure and strategies employed by hedge funds as well as enhanced analysis of how private equity funds function. The discussion of ethics and regulation in the asset management industry that concludes the chapter has also been updated and expanded.

**Chapter 25** An updated and considerably expanded application of the performance measurement techniques introduced throughout the chapter is provided, including new material regarding the calculation of information ratios. The discussion emphasizes how the concept of “downside” risk can be incorporated into the performance measurement process and the examination of techniques that focus on the security holdings of a manager’s portfolio, rather than the returns that the portfolio generates.

**Supplement Package**

Preparation of the tenth edition provided the opportunity to enhance the supplement products offered to instructors and students who use *Investment Analysis and Portfolio Management*. The result of this examination is a greatly improved package that provides more than just basic answers and solutions. We are indebted to the supplement writers who devoted their time, energy, and creativity to making this supplement package the best it has ever been.

**STOCK-TRAK®** Thousands of students every year use STOCK-TRAK® to practice investment strategies, test theories, practice day trading, and learn about the various markets. A coupon for a price reduction for this optional stock simulation is included with the text.

**Instructor’s Manual** The *Instructor’s Manual* is available on the IRCD. Written by Narendra Rao at Northeastern Illinois University, it contains a brief outline of each chapter’s key concepts and equations, which can be easily copied and distributed to students as a reference tool.

**Test Bank** The *Test Bank*, written by Brian Boccaljon at Penn State University–Erie, includes an extensive set of new questions and problems and complete solutions to the testing material. The *Test Bank* is available on the IRCD. For instructors who would like to prepare their exams electronically, the *ExamView* version contains all the test questions found in the printed version. It is available on the IRCD.

**Solutions Manual** This contains all the answers to the end-of-chapter questions and solutions to end-of-chapter problems. Edgar A. Norton at Illinois State University was ever-diligent in the preparation of these materials, ensuring the most error-free solutions possible. It is available on the IRCD.

**Lecture Presentation Software** A comprehensive set of PowerPoint slides created by Yulong Ma at California State University, Long Beach, is available on the IRCD. Each chapter has a self-contained presentation that covers all the key concepts, equations, and examples within the chapter. The files can be used as is for an innovative, interactive class presentation. Instructors who have access to Microsoft PowerPoint can modify the slides in any way they wish, adding or deleting materials to match their needs.

**Website** The text’s Website can be accessed through http://login.cengage.com/ and includes up-to-date teaching and learning aids for instructors and students. The *Instructor’s Manual, Test Bank*, and PowerPoint slides are available to instructors for download. If they choose to, instructors may post, on a *password-protected site only*, the PowerPoint presentation for their students.

Valuable comments and data support have come from my frequent coauthor, David Wright, University of Wisconsin–Parkside. Once more, we were blessed with bright, dedicated research assistants when we needed them the most. These include David Young, who carried the heavy load with strong support from Aaron Lin. Both of them were extremely careful, dependable, and creative.

Current colleagues have been very helpful: Yu-Chi Chang, Rob Batallio, Mike Hemler, Jerry Langley, and Paul Schultz, University of Notre Dame. As always, some of the best insights and most stimulating comments continue to come during too-infrequent walks with a very good friend, Jim Gentry of the University of Illinois.

We are convinced that professors who want to write a book that is academically respectable and relevant, as well as realistic, require help from the "real world." We continue to benefit from the help and consideration of the dedicated people who are or have been associated with the CFA Institute: Tom Bowman, Whit Broome, Jeff Diermeier, Bob Johnson, Bob Luck, Sue Martin, Katie Sherrerd, and Donald Tuttle.

Professor Reilly would like to thank his assistant, Rachel Karnafel, who had the unenviable task of keeping his office and his life in some sort of order during this project. As always, our greatest gratitude is to our families—past, present, and future. Our parents gave us life and helped us understand love and how to give it. Most important are our wives who provide love, understanding, and support throughout the day and night. We thank God for our children and grandchildren who ensure that our lives are full of love, laughs, and excitement.

Keith C. Brown
Austin, Texas

September 2011
Keith C. Brown holds the position of University Distinguished Teaching Professor of Finance and Fayez Sarofim Fellow at the McCombs School of Business, University of Texas. He received his BA in economics from San Diego State University, where he was a member of the Phi Beta Kappa, Phi Kappa Phi, and Omicron Delta Epsilon honor societies. He received his MS and PhD in financial economics from the Krannert Graduate School of Management at Purdue University. Since leaving school in 1981, he has specialized in teaching investment management, portfolio management and security analysis, capital markets, and derivatives courses at the undergraduate, MBA, and PhD levels, and has received numerous awards for teaching innovation and excellence, including election to the university's prestigious Academy of Distinguished Teachers. In addition to his academic responsibilities, he also serves as President and Chief Executive Officer of The MBA Investment Fund, L.L.C., a privately funded investment company managed by graduate students at the University of Texas.

In August 1988, Professor Brown received his Chartered Financial Analyst designation from the CFA Institute and he has served as a member of that organization’s CFA Candidate Curriculum Committee and Education Committee, and on the CFA Examination Grading staff. For five years, he was the research director of the Research Foundation of the CFA Institute, from which position he guided the development of the research portion of the organization’s worldwide educational mission. For several years, he was also associate editor for Financial Analysts Journal and currently holds that position for Journal of Investment Management and Journal of Behavioral Finance. In other professional service, Professor Brown has been a regional director for the Financial Management Association and has served as the applied research track chairman for that organization’s annual conference.

Professor Brown is the cofounder and senior partner of Fulcrum Financial Group, a portfolio management and investment advisory firm located in Austin, Texas, and Las Vegas, Nevada, that currently oversees portfolios holding a total of $60 million in fixed-income securities. From May 1987 to August 1988 he was based in New York as a senior consultant to the Corporate Professional Development Department at Manufacturers Hanover Trust Company. He has lectured extensively throughout the world on investment and risk management topics in the executive development programs for such companies as Fidelity Investments, JP Morgan Chase, Commonfund, BMO Nesbitt Burns, Merrill Lynch, Chase Manhattan Bank, Chemical Bank, Lehman Brothers, Union Bank of Switzerland, Shearson, Chase Bank of Texas, The Beacon Group, Motorola, and Halliburton. He is an advisor to the boards of the Teachers Retirement System of Texas and the University of Texas Investment Management Company and serves on the Investment Committee of LBJ Asset Management Partners.

Frank K. Reilly is the Bernard J. Hank Professor of Finance and former dean of the Mendoza College of Business at the University of Notre Dame. Holding degrees from the University of Notre Dame (BBA), Northwestern University (MBA), and the University of Chicago (PhD), Professor Reilly has taught at the University of Illinois, the University of Kansas, and the University of Wyoming in addition to the University of Notre Dame. He has several years of experience as a senior securities analyst, as well as experience in stock and bond trading. A chartered financial analyst (CFA), he has been a member of the Council of Examiners, the Council on Education and Research, the grading committee, and was chairman of the board of trustees of the Institute of Chartered Financial Analysts and chairman of the board of the Association of Investment Management and Research (AIMR, now the CFA Institute). Professor Reilly has been president of the Financial Management Association, the Midwest Business Administration Association, the Eastern Finance Association, the Academy of Financial Services, and the Midwest Finance Association. He is or has been on the board of directors of the First Interstate Bank of Wisconsin, Norwest Bank of Indiana, the Investment Analysts Society of Chicago, UBS Global Funds (chairman), Fort Dearborn Income Securities (chairman), Discover Bank, NIBCO, Inc., the International Board of Certified Financial Planners, Battery Park High Yield Bond Fund, Inc., Morgan Stanley Trust FSB, the CFA Institute Research Foundation (chairman), the Financial Analysts Seminar, the Board of Certified Safety Professionals, and the University Club at the University of Notre Dame.

Professor Reilly was named on the list of Outstanding Educators in America and has received the University of Illinois Alumni Association Graduate Teaching Award, the Outstanding Educator Award from the MBA class at the University of Illinois, and the Outstanding Teacher Award from the MBA class and the senior class at Notre Dame. He also received from the CFA Institute both the C. Stewart Sheppard Award for his contribution to the educational mission of the Association and the Daniel J. Forrestal III Leadership Award for Professional Ethics and Standards of Investment Practice. He also received the Hortense Friedman Award for Excellence from the CFA Society of Chicago and a Lifetime Achievement Award from the Midwest Finance Association. He was part of the inaugural group selected as a fellow of the Financial Management Association International. He is or has been a member of the editorial boards of Financial Management, The Financial Review, International Review of Economics and Finance, Journal of Financial Education, Quarterly Review of Economics and Finance, and the European Journal of Finance. He is included in Who’s Who in Finance and Industry, Who’s Who in America, Who’s Who in American Education, and Who’s Who in the World.

The chapters in this section will provide a background for your study of investments by answering the following questions:

1. Why do people invest?
2. How do you measure the returns and risks for alternative investments?
3. What factors should you consider when you make asset allocation decisions?
4. What investments are available?
5. How do securities markets function?
6. How and why are securities markets in the United States and around the world changing?
7. What are the major uses of security-market indexes?
8. How can you evaluate the market behavior of common stocks and bonds?
9. What factors cause differences among stock- and bond-market indexes?

In the first chapter, we consider why an individual would invest, how to measure the rates of return and risk for alternative investments, and what factors determine an investor’s required rate of return on an investment. The latter point will be important in subsequent analyses when we work to understand investor behavior, the markets for alternative securities, and the valuation of various investments.

Because the ultimate decision facing an investor is the makeup of his or her portfolio, Chapter 2 deals with the all-important asset allocation decision. This includes specific steps in the portfolio management process and factors that influence the makeup of an investor’s portfolio over his or her life cycle.

To minimize risk, investment theory asserts the need to diversify. Chapter 3 begins our exploration of investments available to investors by making an overpowering case for investing globally rather than limiting choices to only U.S. securities. Building on this premise, we discuss several investment instruments found in global markets. We conclude the chapter with a review of the historical rates of return and measures of risk for a number of alternative asset groups.

In Chapter 4, we examine how markets work in general, and then specifically focus on the purpose and function of primary and secondary bond and stock markets. During the last 15 years, significant changes have occurred in the operation of the securities market, including a trend toward a global capital market, electronic trading markets, and substantial worldwide consolidation. After discussing these changes and the rapid development of new capital markets around the world, we speculate about how global markets will continue to consolidate and will increase available investment alternatives.

Investors, market analysts, and financial theorists generally gauge the behavior of securities markets by evaluating the return and risk implied by various market indexes and evaluate portfolio performance by comparing a portfolio’s results to an appropriate benchmark. Because these indexes are used to make asset allocation decisions and then to evaluate portfolio performance, it is important to have a deep understanding of how they are constructed and the numerous alternatives available. Therefore, in Chapter 5, we examine and compare a number of stock-market and bond-market indexes available for the domestic and global markets.

This initial section provides the framework for you to understand various securities, how to allocate among alternative asset classes, the markets where these securities are bought and sold, the indexes that reflect their performance, and how you might manage a collection of investments in a portfolio. Specific portfolio management techniques are described in later chapters.

Specific portfolio management techniques are described in later chapters.
Another possibility is that they can give up the immediate possession of these savings for a future larger amount of money that will be available for future consumption. This trade-off of present consumption for a higher level of future consumption is the reason for saving. What you do with the savings to make them increase over time is investment.

Those who give up immediate possession of savings (that is, defer consumption) expect to receive in the future a greater amount than they gave up. Conversely, those who consume more than their current income (that is, borrow) must be willing to pay back in the future more than they borrowed. The rate of exchange between future consumption (future dollars) and current consumption (current dollars) is the pure rate of interest. Both people’s willingness to pay this difference for borrowed funds and their desire to receive a surplus on their savings (i.e., some rate of return) give rise to an interest rate referred to as the pure time value of money. This interest rate is established in the capital market by a comparison of the supply of excess income available (savings) to be invested and the demand for excess consumption (borrowing) at a given time. If you can exchange $100 of certain income today for $104 of certain income one year from today, then the pure rate of exchange on a risk-free investment (that is, the time value of money) is said to be 4 percent ($104/100 − 1).

The investor who gives up $100 today expects to consume $104 of goods and services in the future. This assumes that the general price level in the economy stays the same. This price stability has rarely been the case during the past several decades when inflation rates have varied from 1.1 percent in 1986 to as much as 13.3 percent in 1979, with a geometric average of 4.4 percent a year from 1970 to 2010. If investors expect a change in prices, they will require a higher rate of return to compensate for it. For example, if an investor expects a rise in prices (that is, he or she expects inflation) at the annual rate of 2 percent during the period of investment, he or she will increase the required interest rate by 2 percent. In our example, the investor would require $106 in the future to defer the $100 of consumption during an inflationary period (a 6 percent nominal, risk-free interest rate will be required instead of 4 percent).

Further, if the future payment from the investment is not certain, the investor will demand an interest rate that exceeds the nominal risk-free interest rate. The uncertainty of the payments from an investment is the investment risk. The additional return added to the nominal, risk-free interest rate is called a risk premium. In our previous example, the investor would require more than $106 one year from today to compensate for the uncertainty. As an example, if the required amount were $110, $4 (4 percent) would be considered a risk premium.

### 1.1 What Is an Investment?

For most of your life, you will be earning and spending money. Rarely, though, will your current money income exactly balance with your consumption desires. Sometimes, you may have more money than you want to spend; at other times, you may want to purchase more than you can afford based on your current income. These imbalances will lead you either to borrow or to save to maximize the long-run benefits from your income.

When current income exceeds current consumption desires, people tend to save the excess. They can do any of several things with these savings. One possibility is to put the money under a mattress or bury it in the backyard until some future time when consumption desires exceed current income. When they retrieve their savings from the mattress or backyard, they have the same amount they saved.
Another possibility is that they can give up the immediate possession of these savings for a future larger amount of money that will be available for future consumption. This trade-off of present consumption for a higher level of future consumption is the reason for saving. What you do with the savings to make them increase over time is investment.¹

Those who give up immediate possession of savings (that is, defer consumption) expect to receive in the future a greater amount than they gave up. Conversely, those who consume more than their current income (that is, borrow) must be willing to pay back in the future more than they borrowed.

The rate of exchange between future consumption (future dollars) and current consumption (current dollars) is the pure rate of interest. Both people’s willingness to pay this difference for borrowed funds and their desire to receive a surplus on their savings (i.e., some rate of return) give rise to an interest rate referred to as the pure time value of money. This interest rate is established in the capital market by a comparison of the supply of excess income available (savings) to be invested and the demand for excess consumption (borrowing) at a given time. If you can exchange $100 of certain income today for $104 of certain income one year from today, then the pure rate of exchange on a risk-free investment (that is, the time value of money) is said to be 4 percent (104/100 − 1).

The investor who gives up $100 today expects to consume $104 of goods and services in the future. This assumes that the general price level in the economy stays the same. This price stability has rarely been the case during the past several decades when inflation rates have varied from 1.1 percent in 1986 to as much as 13.3 percent in 1979, with a geometric average of 4.4 percent a year from 1970 to 2010. If investors expect a change in prices, they will require a higher rate of return to compensate for it. For example, if an investor expects a rise in prices (that is, he or she expects inflation) at the annual rate of 2 percent during the period of investment, he or she will increase the required interest rate by 2 percent. In our example, the investor would require $106 in the future to defer the $100 of consumption during an inflationary period (a 6 percent nominal, risk-free interest rate would be required instead of 4 percent).

Further, if the future payment from the investment is not certain, the investor will demand an interest rate that exceeds the nominal risk-free interest rate. The uncertainty of the payments from an investment is the investment risk. The additional return added to the nominal risk-free interest rate is called a risk premium. In our previous example, the investor would require more than $106 one year from today to compensate for the uncertainty. As an example, if the required amount were $110, $4 (4 percent) would be considered a risk premium.

### 1.1.1 Investment Defined

From our discussion, we can specify a formal definition of an investment. Specifically, an investment is the current commitment of dollars for a period of time in order to derive future payments that will compensate the investor for (1) the time the funds are committed, (2) the expected rate of inflation during this time period, and (3) the uncertainty of the future payments. The “investor” can be an individual, a government, a pension fund, or a corporation. Similarly, this definition includes all types of investments, including investments by corporations in plant and equipment and investments by individuals in stocks, bonds, commodities, or real estate. This text emphasizes investments by individual investors. In all cases, the investor is trading a known dollar amount today for some expected future stream of payments that will be greater than the current dollar amount today.

At this point, we have answered the questions about why people invest and what they want from their investments. They invest to earn a return from savings due to their deferred consumption. They want a rate of return that compensates them for the time period of the investment, the expected rate of inflation, and the uncertainty of the future cash flows. This return, the investor’s required rate of return, is discussed throughout this book. A central question of this book is how investors select investments that will give them their required rates of return.

¹In contrast, when current income is less than current consumption desires, people borrow to make up the difference. Although we will discuss borrowing on several occasions, the major emphasis of this text is how to invest savings.
The next section of this chapter describes how to measure the expected or historical rate of return on an investment and also how to quantify the uncertainty (risk) of expected returns. You need to understand these techniques for measuring the rate of return and the uncertainty of these returns to evaluate the suitability of a particular investment. Although our emphasis will be on financial assets, such as bonds and stocks, we will refer to other assets, such as art and antiques. Chapter 3 discusses the range of financial assets and also considers some nonfinancial assets.

1.2 Measures of Return and Risk

The purpose of this book is to help you understand how to choose among alternative investment assets. This selection process requires that you estimate and evaluate the expected risk-return trade-offs for the alternative investments available. Therefore, you must understand how to measure the rate of return and the risk involved in an investment accurately. To meet this need, in this section we examine ways to quantify return and risk. The presentation will consider how to measure both historical and expected rates of return and risk.

We consider historical measures of return and risk because this book and other publications provide numerous examples of historical average rates of return and risk measures for various assets, and understanding these presentations is important. In addition, these historical results are often used by investors when attempting to estimate the expected rates of return and risk for an asset class.

The first measure is the historical rate of return on an individual investment over the time period the investment is held (that is, its holding period). Next, we consider how to measure the average historical rate of return for an individual investment over a number of time periods. The third subsection considers the average rate of return for a portfolio of investments.

Given the measures of historical rates of return, we will present the traditional measures of risk for a historical time series of returns (that is, the variance and standard deviation). Following the presentation of measures of historical rates of return and risk, we turn to estimating the expected rate of return for an investment. Obviously, such an estimate contains a great deal of uncertainty, and we present measures of this uncertainty or risk.

1.2.1 Measures of Historical Rates of Return

When you are evaluating alternative investments for inclusion in your portfolio, you will often be comparing investments with widely different prices or lives. As an example, you might want to compare a $10 stock that pays no dividends to a stock selling for $150 that pays dividends of $5 a year. To properly evaluate these two investments, you must accurately compare their historical rates of returns. A proper measurement of the rates of return is the purpose of this section.

When we invest, we defer current consumption in order to add to our wealth so that we can consume more in the future. Therefore, when we talk about a return on an investment, we are concerned with the change in wealth resulting from this investment. This change in wealth can be either due to cash inflows, such as interest or dividends, or caused by a change in the price of the asset (positive or negative).

If you commit $200 to an investment at the beginning of the year and you get back $220 at the end of the year, what is your return for the period? The period during which you own an investment is called its holding period, and the return for that period is the holding period return \(HPR\). In this example, the \(HPR\) is 1.10, calculated as follows:

\[
1.1 \quad HPR = \frac{\text{Ending Value of Investment}}{\text{Beginning Value of Investment}} = \frac{$220}{\$200} = 1.10
\]
In contrast, consider an investment of $100 held for only six months that earned a return of $12:

\[
HPR = \frac{112}{100} = 1.12
\]

Annual HPR = \(1.12^{\frac{1}{0.5}}\)

Annual HPY = \(1.12^{\frac{1}{2}} - 1 = 0.12\)

\(= 12\%\)

Note that we made some implicit assumptions when converting the six-month HPY to an annual basis. This annualized holding period yield computation assumes a constant annual yield for each year. In the two-year investment, we assumed an 18.32 percent rate of return each year, compounded. In the partial year HPR that was annualized, we assumed that the return is compounded for the whole year. That is, we assumed that the rate of return earned during the first half of the year is likewise earned on the value at the end of the first six months. The 12 percent rate of return for the initial six months compounds to 25.44 percent for the full year.

Because of the uncertainty of being able to earn the same return in the future six months, institutions will typically not compound partial year results.

Remember one final point: The ending value of the investment can be the result of a positive or negative change in price for the investment alone (for example, a stock going from $20 a share to $22 a share), income from the investment alone, or a combination of price change and income. Ending value includes the value of everything related to the investment.

1.2.2 Computing Mean Historical Returns

Now that we have calculated the HPY for a single investment for a single year, we want to consider mean rates of return for a single investment and for a portfolio of investments. Over a number of years, a single investment will likely give high rates of return during some years and low rates of return, or possibly negative rates of return, during others. Your analysis should consider each of these returns, but you also want a summary figure that indicates this investment’s typical experience, or the rate of return you might expect to receive if you owned this investment over an extended period of time. You can derive such a summary figure by computing the mean annual rate of return (its HPY) for this investment over some period of time.

Alternatively, you might want to evaluate a portfolio of investments that might include similar investments (for example, all stocks or all bonds) or a combination of investments (for example, stocks, bonds, and real estate). In this instance, you would calculate the mean rate of return for this portfolio of investments for an individual year or for a number of years.

Single Investment

Given a set of annual rates of return (HPYs) for an individual investment, there are two summary measures of return performance. The first is the arithmetic mean return, the second is the geometric mean return. To find the arithmetic mean (AM), the sum (\(\Sigma\)) of annual HPYs is divided by the number of years (\(n\)) as follows:

\[
AM = \frac{\Sigma \text{HPY}}{n}
\]

where:

\(\Sigma\) HPY = the sum of annual holding period yields

An alternative computation, the geometric mean (GM), is the \(n\)th root of the product of the HPRs for \(n\) years minus one.

To check that you understand the calculations, determine the annual HPY for a three-year HPR of 1.50. (Answer: 14.47 percent.) Compute the annual HPY for a three-month HPR of 1.06. (Answer: 26.25 percent.)
In contrast, consider an investment of $100 held for only six months that earned a return of $12:

\[ HPR = \frac{112}{100} = 1.12 \quad (n = 0.5) \]

Annual \( HPR = 1.12^{1/5} \)

\[ = 1.12 \]

\[ = 1.2544 \]

Annual \( HPY = 1.2544 - 1 = 0.2544 \)

\[ = 25.44\% \]

Note that we made some implicit assumptions when converting the six-month \( HPY \) to an annual basis. This annualized holding period yield computation assumes a constant annual yield for each year. In the two-year investment, we assumed an 18.32 percent rate of return each year, compounded. In the partial year \( HPR \) that was annualized, we assumed that the return is compounded for the whole year. That is, we assumed that the rate of return earned during the first half of the year is likewise earned on the value at the end of the first six months. The 12 percent rate of return for the initial six months compounds to 25.44 percent for the full year.\(^7\) Because of the uncertainty of being able to earn the same return in the future six months, institutions will typically \textit{not} compound partial year results.

Remember one final point: The ending value of the investment can be the result of a positive or negative change in price for the investment alone (for example, a stock going from $20 a share to $22 a share), income from the investment alone, or a combination of price change and income. Ending value includes the value of everything related to the investment.

### 1.2.2 Computing Mean Historical Returns

Now that we have calculated the \( HPY \) for a single investment for a single year, we want to consider mean rates of return for a single investment and for a portfolio of investments. Over a number of years, a single investment will likely give high rates of return during some years and low rates of return, or possibly negative rates of return, during others. Your analysis should consider each of these returns, but you also want a summary figure that indicates this investment’s typical experience, or the rate of return you might expect to receive if you owned this investment over an extended period of time. You can derive such a summary figure by computing the mean annual rate of return (its \( HPY \)) for this investment over some period of time.

Alternatively, you might want to evaluate a portfolio of investments that might include similar investments (for example, all stocks or all bonds) or a combination of investments (for example, stocks, bonds, and real estate). In this instance, you would calculate the mean rate of return for this portfolio of investments for an individual year or for a number of years.

**Single Investment** Given a set of annual rates of return (\( HPYs \)) for an individual investment, there are two summary measures of return performance. The first is the arithmetic mean return, the second is the geometric mean return. To find the arithmetic mean (AM), the sum (\( \Sigma \)) of annual \( HPYs \) is divided by the number of years (\( n \)) as follows:

\[
AM = \Sigma HPY/n
\]

where:

\[ \Sigma HPY = \text{the sum of annual holding period yields} \]

An alternative computation, the geometric mean (GM), is the \( n \)th root of the product of the \( HPRs \) for \( n \) years minus one.

---

\(^7\)To check that you understand the calculations, determine the annual \( HPY \) for a three-year \( HPR \) of 1.50. (Answer: 14.47 percent.) Compute the annual \( HPY \) for a three-month \( HPR \) of 1.06. (Answer: 26.25 percent.)
When rates of return are the same for all years, the GM will be equal to the AM. If the rates of return vary over the years, the GM will always be lower than the AM. The difference between the two mean values will depend on the year-to-year changes in the rates of return. Larger annual changes in the rates of return—that is, more volatility—will result in a greater difference between the alternative mean values. We will point out examples of this in subsequent chapters.

An awareness of both methods of computing mean rates of return is important because most published accounts of long-run investment performance or descriptions of financial research will use both the AM and the GM as measures of average historical returns. We will also use both throughout this book with the understanding that the AM is best used as an expected value for an individual year, while the GM is the best measure of long-term performance since it measures the compound annual rate of return for the asset being measured.

A Portfolio of Investments

The mean historical rate of return (HPY) for a portfolio of investments is measured as the weighted average of the HPYs for the individual investments in the portfolio, or the overall percent change in value of the original portfolio. The weights used in computing the averages are the relative beginning market values for each investment; this is referred to as dollar-weighted or value-weighted mean rate of return. This technique is demonstrated by the examples in Exhibit 1.1. As shown, the HPY is the same (9.5 percent) whether you compute the weighted average return using the beginning market value weights or if you compute the overall percent change in the total value of the portfolio.

Although the analysis of historical performance is useful, selecting investments for your portfolio requires you to predict the rates of return you expect to prevail. The next section discusses how you would derive such estimates of expected rates of return. We recognize the great uncertainty regarding these future expectations, and we will discuss how one measures this uncertainty, which is referred to as the risk of an investment.

1.2.3 Calculating Expected Rates of Return

Risk is the uncertainty that an investment will earn its expected rate of return. In the examples in the prior section, we examined realized historical rates of return. In contrast, an investor who is evaluating a future investment alternative expects or anticipates a certain rate of return. The investor might say that he or she expects the investment will provide a rate of return of 10 percent, but this is actually the investor’s most likely estimate, also referred to as a point estimate. Pressed further, the investor would probably acknowledge the uncertainty of this point estimate return and admit the possibility that, under certain conditions, the annual rate of return on this investment might go as low as −10 percent or as high as 25 percent. The point is, the specification of a larger range of possible returns from an investment reflects the investor’s uncertainty.

</tbody>
</table>

HPR = [21,900,000 / 20,000,000] − 1 = 0.095

GM = [(1.20) × (1.05) × (1.10)]^{1/3} − 1

= (1.03353)^{1/3} − 1

= 1.03353 − 1

= 0.03353 = 3.353%

Investors are typically concerned with long-term performance when comparing alternative investments. GM is considered a superior measure of the long-term mean rate of return because it indicates the compound annual rate of return based on the ending value of the investment versus its beginning value. Specifically, using the prior example, if we compounded 3.353 percent for three years, (1.03353)^3, we would get an ending wealth value of 1.104.

Although the arithmetic average provides a good indication of the expected rate of return for an investment during a future individual year, it is biased upward if you are attempting to measure an asset’s long-term performance. This is obvious for a volatile security. Consider, for example, a security that increases in price from $50 to $100 during year 1 and drops back to $50 during year 2. The annual HPYs would be:

<table>
<thead>
<tr>
<th>Year</th>
<th>Beginning Value</th>

<td>1.00</td>
</tr>
<tr>
<td>2</td>
<td>100</td>
<td>50</td>
<td>0.50</td>
<td>−0.50</td>
</tr>
</tbody>
</table>

This would give an AM rate of return of:

[((1.00) + (−0.50))/2 = .50/2

= 0.25 = 25%]

This investment brought no change in wealth and therefore no return, yet the AM rate of return is computed to be 25 percent.

The GM rate of return would be:

(2.00 × 0.50)^{1/2} − 1 = (1.00)^{1/2} − 1

= 1.00 − 1 = 0%

This answer of a 0 percent rate of return accurately measures the fact that there was no change in wealth from this investment over the two-year period.

Note that the GM is the same whether you compute the geometric mean of the individual annual holding period yields or the annual HPY for a three-year period, comparing the ending value to the beginning value, as discussed earlier under annual HPY for a multiperiod case.
When rates of return are the same for all years, the GM will be equal to the AM. If the rates of return vary over the years, the GM will always be lower than the AM. The difference between the two mean values will depend on the year-to-year changes in the rates of return. Larger annual changes in the rates of return—that is, more volatility—will result in a greater difference between the alternative mean values. We will point out examples of this in subsequent chapters.

We will also use both throughout this book with the understanding that the AM is best used as an expected value for an individual year, while the GM is the best measure of long-term performance since it measures the compound annual rate of return for the asset being measured.

uncertainty regarding what the actual return will be. Therefore, a larger range of possible returns implies that the investment is riskier.

An investor determines how certain the expected rate of return on an investment is by analyzing estimates of possible returns. To do this, the investor assigns probability values to all possible returns. These probability values range from zero, which means no chance of the return, to one, which indicates complete certainty that the investment will provide the specified rate of return. These probabilities are typically subjective estimates based on the historical performance of the investment or similar investments modified by the investor’s expectations for the future. As an example, an investor may know that about 30 percent of the time the rate of return on this particular investment was 10 percent. Using this information along with future expectations regarding the economy, one can derive an estimate of what might happen in the future.

The expected return from an investment is defined as:

\[
E(R_i) = \sum_{i=1}^{n} (P_i)(R_i) = \left[ (P_1)(R_1) + (P_2)(R_2) + (P_3)(R_3) + \ldots + (P_n)(R_n) \right]
\]

Let us begin our analysis of the effect of risk with an example of perfect certainty wherein the investor is absolutely certain of a return of 5 percent. Exhibit 1.2 illustrates this situation. Perfect certainty allows only one possible return, and the probability of receiving that return is 1.0. Few investments provide certain returns and would be considered risk-free investments. In the case of perfect certainty, there is only one value for \( P_i R_i \):

\[
E(R_i) = (1.0)(0.05) = 0.05 = 5\%
\]

In an alternative scenario, suppose an investor believed an investment could provide several different rates of return depending on different possible economic conditions. As an example, in a strong economic environment with high corporate profits and little or no inflation, the investor might expect the rate of return on common stocks during the next year to reach as high
as 20 percent. In contrast, if there is an economic decline with a higher-than-average rate of inflation, the investor might expect the rate of return on common stocks during the next year to be −20 percent. Finally, with no major change in the economic environment, the rate of return during the next year would probably approach the long-run average of 10 percent.

The investor might estimate probabilities for each of these economic scenarios based on past experience and the current outlook as follows:

<table>
<thead>
<tr>
<th>Economic Conditions</th>
<th>Probability</th>
<th>Rate of Return</th>
</tr>
</thead>
<tbody>
<tr>
<td>Strong economy, no inflation</td>
<td>0.15</td>
<td>0.20</td>
</tr>
<tr>
<td>Weak economy, above-average inflation</td>
<td>0.15</td>
<td>−0.20</td>
</tr>
<tr>
<td>No major change in economy</td>
<td>0.70</td>
<td>0.10</td>
</tr>
</tbody>
</table>

This set of potential outcomes can be visualized as shown in Exhibit 1.3.

The computation of the expected rate of return \( E(R_i) \) is as follows:

\[
E(R_i) = \left[ (0.15)(0.20) \right] + \left[ (0.15)(-0.20) \right] + \left[ (0.70)(0.10) \right]
\]

\[
E(R_i) = 0.07
\]

Obviously, the investor is less certain about the expected return from this investment than about the return from the prior investment with its single possible return.

A third example is an investment with 10 possible outcomes ranging from −40 percent to 50 percent with the same probability for each rate of return. A graph of this set of expectations would appear as shown in Exhibit 1.4.

In this case, there are numerous outcomes from a wide range of possibilities. The expected rate of return \( E(R_i) \) for this investment would be:

\[
E(R_i) = (0.10)(-0.40) + (0.10)(-0.30) + (0.10)(-0.20) + (0.10)(-0.10) + (0.10)(0.0)
\]

\[
+ (0.10)(0.10) + (0.10)(0.20) + (0.10)(0.30) + (0.10)(0.40) + (0.10)(0.50)
\]

\[
= (-0.04) + (-0.03) + (-0.02) + (-0.01) + (0.00) + (0.01) + (0.02) + (0.03)
\]

\[
+ (0.04) + (0.05)
\]

\[
= 0.05
\]

The expected rate of return for this investment is the same as the certain return discussed in the first example; but, in this case, the investor is highly uncertain about the actual rate of return.
Note that, in perfect certainty, there is no variance of return because there is no deviation from expectations and, therefore, no risk or uncertainty. The variance for the second example would be:

\[ \sigma^2 = \sum_{i=1}^{n} (P_i)(R_i - E(R))^2 \]

\[ = (0.15)(0.05 - 0.07)^2 + (0.10)(0.15 - 0.07)^2 + (0.05)(0.10 - 0.07)^2 \]

\[ = 0.010935 + 0.002535 + 0.00063 \]

\[ = 0.0141 \]

The standard deviation is the square root of the variance:

\[ \text{Standard Deviation} = \sqrt{0.0141} = 0.11874 \]

Therefore, when describing this investment example, you would contend that you expect a return of 7 percent, but the standard deviation of your expectations is 11.87 percent.

### 1.2.4 Measuring the Risk of Expected Rates of Return

We have shown that we can calculate the expected rate of return and evaluate the uncertainty, or risk, of an investment by identifying the range of possible returns from that investment and assigning each possible return a weight based on the probability that it will occur. Although the graphs help us visualize the dispersion of possible returns, most investors want to quantify this dispersion using statistical techniques. These statistical measures allow you to compare the return and risk measures for alternative investments directly. Two possible measures of risk (uncertainty) have received support in theoretical work on portfolio theory: the **variance** and the **standard deviation** of the estimated distribution of expected returns.

In this section, we demonstrate how variance and standard deviation measure the dispersion of possible rates of return around the expected rate of return. We will work with the examples discussed earlier. The formula for variance is as follows:

\[ \text{Variance} \ (\sigma^2) = \sum_{i=1}^{n} (P_i)(R_i - E(R))^2 \]

\[ = \sum_{i=1}^{n} P_i[R_i - E(R_i)]^2 \]

**Variance** The larger the variance for an expected rate of return, the greater the dispersion of expected returns and the greater the uncertainty, or risk, of the investment. The variance for the perfect-certainty (risk-free) example would be:

\[ (\sigma^2) = \sum_{i=1}^{n} P_i[R_i - E(R_i)]^2 \]

\[ = 1.0(0.05 - 0.05)^2 = 1.0(0.0) = 0 \]
1.2.5 Risk Measures for Historical Returns

To measure the risk for a series of historical rates of returns, we use the same measures as for expected returns (variance and standard deviation) except that we consider the historical holding period yields (HPYs) as follows:

\[
\sigma^2 = \frac{1}{n} \sum_{i=1}^{n} (P_i [R_i - E(R_i)])^2
\]

where:
- \( \sigma^2 \) is the variance of the series
- \( HPY_i \) is the holding period yield during period \( i \)
- \( E(HPY) \) is the expected value of the holding period yield that is equal to the arithmetic mean (AM) of the series
- \( n \) is the number of observations

The standard deviation is the square root of the variance. Both measures indicate how much the individual HPYs over time deviated from the expected value of the series. An example computation is contained in the appendix to this chapter. As is shown in subsequent chapters where we present historical rates of return for alternative asset classes, presenting the standard deviation as a measure of risk (uncertainty) for the series or asset class is fairly common.

1.3 Determinants of Required Rates of Return

In this section, we continue our discussion of factors that you must consider when selecting securities for an investment portfolio. You will recall that this selection process involves finding securities that provide a rate of return that compensates you for: (1) the time value of money during the period of investment, (2) the expected rate of inflation during the period, and (3) the risk involved.

The summation of these three components is called the required rate of return. This is the minimum rate of return that you should accept from an investment to compensate you for deferring consumption. Because of the importance of the required rate of return to the total investment selection process, this section contains a discussion of the three components and what influences each of them.

The analysis and estimation of the required rate of return are complicated by the behavior of market rates over time. First, a wide range of rates is available for alternative investments at any time. Second, the rates of return on specific assets change dramatically over time. Third, the difference between the rates available (that is, the spread) on different assets changes over time. The yield data in Exhibit 1.5 for alternative bonds demonstrate these three characteristics. First, even though all these securities have promised returns based upon bond contracts, the promised annual yields during any year differ substantially. As an example, during 2009 the average yields on alternative assets ranged from 0.15 percent on T-bills to 7.29 percent for Baa corporate bonds. Second, the changes in yields for a specific asset are shown by the three-month Treasury bill rate that went from 4.48 percent in 2007 to 0.15 percent in 2009. Third, an example of a change in the difference between yields over time (referred to as a spread) is shown by the Baa – Aaa spread. The yield spread in 2007 was 91 basis points (6.47 – 5.56), but the spread in 2009 increased to 198 basis points (7.29 – 5.31). (A basis point is 0.01 percent.)

4 Bonds are rated by rating agencies based upon the credit risk of the securities, that is, the probability of default. Aaa is the top rating Moody’s (a prominent rating service) gives to bonds with almost no probability of default. (Only U.S. Treasury bonds are considered to be of higher quality.) Baa is a lower rating Moody’s gives to bonds of generally high quality that have some possibility of default under adverse economic conditions.
Because differences in yields result from the riskiness of each investment, you must understand the risk factors that affect the required rates of return and include them in your assessment of investment opportunities. Because the required returns on all investments change over time, and because large differences separate individual investments, you need to be aware of the several components that determine the required rate of return, starting with the risk-free rate. In this chapter we consider the three components of the required rate of return and briefly discuss what affects these components. The presentation in Chapter 11 on valuation theory will discuss the factors that affect these components in greater detail.

1.3.1 The Real Risk-Free Rate

The real risk-free rate (\(RRFR\)) is the basic interest rate, assuming no inflation and no uncertainty about future flows. An investor in an inflation-free economy who knew with certainty what cash flows he or she would receive at what time would demand the \(RRFR\) on an investment. Earlier, we called this the pure time value of money, because the only sacrifice the investor made was deferring the use of the money for a period of time. This \(RRFR\) of interest is the price charged for the risk-free exchange between current goods and future goods. Two factors, one subjective and one objective, influence this exchange price. The subjective factor is the time preference of individuals for the consumption of income. When individuals give up $100 of consumption this year, how much consumption do they want a year from now to compensate for that sacrifice? The strength of the human desire for current consumption influences the rate of compensation required. Time preferences vary among individuals, and the market creates a composite rate that includes the preferences of all investors. This composite rate changes gradually over time because it is influenced by all the investors in the economy, whose changes in preferences may offset one another.

The objective factor that influences the \(RRFR\) is the set of investment opportunities available in the economy. The investment opportunities available are determined in turn by the long-run real growth rate of the economy. A rapidly growing economy produces more and better opportunities to invest funds and experience positive rates of return. A change in the economy’s long-run real growth rate causes a change in all investment opportunities and a change in the required rates of return on all investments. Just as investors supplying capital should demand a higher rate of return when growth is higher, those looking to borrow funds to invest should be willing and able to pay a higher rate of return to use the funds for investment because of the higher growth rate and better opportunities. Thus, a positive relationship exists between the real growth rate in the economy and the \(RRFR\).

1.3.2 Factors Influencing the Nominal Risk-Free Rate (\(NRFR\))

Earlier, we observed that an investor would be willing to forgo current consumption in order to increase future consumption at a rate of exchange called the risk-free rate of interest. This rate of exchange was measured in real terms because we assume that investors want to

1.2.5 Risk Measures for Historical Returns

To measure the risk for a series of historical rates of returns, we use the same measures as for expected returns (variance and standard deviation) except that we consider the historical holding period yields (\(HPYs\)) as follows:

\[
\sigma^2 = \frac{\sum_{i=1}^{n} (HPY_i - E(HPY))^2}{n}

- \(E(HPY)\) = the expected value of the holding period yield that is equal to the arithmetic mean (AM) of the series
- \(n\) = the number of observations

The standard deviation is the square root of the variance. Both measures indicate how much the individual \(HPYs\) over time deviated from the expected value of the series. increase the consumption of actual goods and services rather than consuming the same amount that had come to cost more money. Therefore, when we discuss rates of interest, we need to differentiate between real rates of interest that adjust for changes in the general price level, as opposed to nominal rates of interest that are stated in money terms. That is, nominal rates of interest that prevail in the market are determined by real rates of interest, plus factors that will affect the nominal rate of interest, such as the expected rate of inflation and the monetary environment. It is important to understand these factors.

Notably, the variables that determine the RRFR change only gradually because we are concerned with long-run real growth. Therefore, you might expect the required rate on a risk-free investment to be quite stable over time. As discussed in connection with Exhibit 1.5, rates on three-month T-bills were not stable over the period from 2004 to 2010. This is demonstrated with additional observations in Exhibit 1.6, which contains yields on T-bills for the period 1987–2010.

Investors view T-bills as a prime example of a default-free investment because the government has unlimited ability to derive income from taxes or to create money from which to pay interest. Therefore, one could expect that rates on T-bills should change only gradually. In fact, the data in Exhibit 1.6 show a highly erratic pattern. Specifically, there was an increase in yields from 4.64 percent in 1999 to 5.82 percent in 2000 before declining by over 80 percent in three years to 1.01 percent in 2003, followed by an increase to 4.73 percent in 2006, and concluding at 0.14 percent in 2010. Clearly, the nominal rate of interest on a default-free investment is not stable in the long run or the short run, even though the underlying determinants of the RRFR are quite stable. As noted, two other factors influence the nominal risk-free rate (NRFR): (1) the relative ease or tightness in the capital markets, and (2) the expected rate of inflation.

Conditions in the Capital Market

You will recall from prior courses in economics and finance that the purpose of capital markets is to bring together investors who want to invest savings with companies or governments who need capital to expand or to finance budget deficits. The cost of funds at any time (the interest rate) is the price that equates the current supply and demand for capital. Beyond this long-run equilibrium, change in the relative ease or tightness in the capital market is a short-run phenomenon caused by a temporary disequilibrium in the supply and demand of capital.

As an example, disequilibrium could be caused by an unexpected change in monetary policy (for example, a change in the target federal funds rate) or fiscal policy (for example, a change in the federal deficit). Such a change in monetary policy or fiscal policy will produce a change in the NRFR of interest, but the change should be short-lived because, in the longer

In this chapter we consider the three components of the required rate of return and briefly discuss what affects these components. The presentation in Chapter 11 on valuation theory will discuss the factors that affect these components in greater detail.

1.3.1 The Real Risk-Free Rate

The real risk-free rate (RRFR) is the basic interest rate, assuming no inflation and no uncertainty about future flows. An investor in an inflation-free economy who knew with certainty what cash flows he or she would receive at what time would demand the RRFR on an investment. Earlier, we called this the pure time value of money, because the only sacrifice the investor made was deferring the use of the money for a period of time. This RRFR of interest is the price charged for the risk-free exchange between current goods and future goods.

Two factors, one subjective and one objective, influence this exchange price. The subjective factor is the time preference of individuals for the consumption of income. When individuals give up $100 of consumption this year, how much consumption do they want a year from now to compensate for that sacrifice? The strength of the human desire for current consumption influences the rate of compensation required. Time preferences vary among individuals, and the market creates a composite rate that includes the preferences of all investors. This composite rate changes gradually over time because it is influenced by all the investors in the economy, whose changes in preferences may offset one another.

The objective factor that influences the RRFR is the set of investment opportunities available in the economy. The investment opportunities available are determined in turn by the long-run real growth rate of the economy. A rapidly growing economy produces more and better opportunities to invest funds and experience positive rates of return. A change in the economy’s long-run real growth rate causes a change in all investment opportunities and a change in the required rates of return on all investments. Just as investors supplying capital should demand a higher rate of return when growth is higher, those looking to borrow funds to invest should be willing and able to pay a higher rate of return to use the funds for investment because of the higher growth rate and better opportunities. Thus, a positive relationship exists between the real growth rate in the economy and the RRFR.

1.3.2 Factors Influencing the Nominal Risk-Free Rate (NRFR)

Earlier, we observed that an investor would be willing to forgo current consumption in order to increase future consumption at a rate of exchange called the risk-free rate of interest. This rate of exchange was measured in real terms because we assume that investors want to

run, the higher or lower interest rates will affect capital supply and demand. As an example, an increase in the federal deficit caused by an increase in government spending (easy fiscal policy) will increase the demand for capital and increase interest rates. In turn, this increase in interest rates should cause an increase in savings and a decrease in the demand for capital by corporations or individuals. These changes in market conditions should bring rates back to the long-run equilibrium, which is based on the long-run growth rate of the economy.

**Expected Rate of Inflation** Previously, it was noted that if investors expected the price level to increase (an increase in the inflation rate) during the investment period, they would require the rate of return to include compensation for the expected rate of inflation. Assume that you require a 4 percent real rate of return on a risk-free investment but you expect prices to increase by 3 percent during the investment period. In this case, you should increase your required rate of return by this expected rate of inflation to about 7 percent \((1.04 \times 1.03 - 1)\). If you do not increase your required return, the $104 you receive at the end of the year will represent a real return of about 1 percent, not 4 percent. Because prices have increased by 3 percent during the year, what previously cost $100 now costs $103, so you can consume only about 1 percent more at the end of the year \((104/103 - 1)\). If you had required a 7.12 percent nominal return, your real consumption could have increased by 4 percent \((107.12/103 - 1)\). Therefore, an investor’s nominal required rate of return on a risk-free investment should be:

\[
NRFR = [(1 + RRFR) \times (1 + \text{Expected Rate of Inflation})] - 1
\]

Rearranging the formula, you can calculate the **RRFR** of return on an investment as follows:

\[
RRFR = \left(\frac{(1 + NRFR \text{ of Return})}{(1 + \text{Rate of Inflation})}\right) - 1
\]

To see how this works, assume that the nominal return on U.S. government T-bills was 9 percent during a given year, when the rate of inflation was 5 percent. In this instance, the **RRFR** of return on these T-bills was 3.8 percent, as follows:

\[
RRFR = [(1 + 0.09)/(1 + 0.05)] - 1
\]

\[
= 1.038 - 1
\]

\[
= 0.038 = 3.8\%
\]

This discussion makes it clear that the nominal rate of interest on a risk-free investment is not a good estimate of the **RRFR**, because the nominal rate can change dramatically in the short run in reaction to temporary ease or tightness in the capital market or because of changes in the expected rate of inflation. As indicated by the data in Exhibit 1.6, the significant changes in the average yield on T-bills typically were related to large changes in the rates of inflation. Notably, 2009–2010 were different due to the quantitative easing by the Federal Reserve.

**The Common Effect** All the factors discussed thus far regarding the required rate of return affect all investments equally. Whether the investment is in stocks, bonds, real estate, or machine tools, if the expected rate of inflation increases from 2 percent to 6 percent, the investor’s required rate of return for all investments should increase by 4 percent. Similarly, if a decline in the expected real growth rate of the economy causes a decline in the **RRFR** of 1 percent, the required return on all investments should decline by 1 percent.

### 1.3.3 Risk Premium

A risk-free investment was defined as one for which the investor is certain of the amount and timing of the expected returns. The returns from most investments do not fit this pattern. An
investor typically is not completely certain of the income to be received or when it will be received. Investments can range in uncertainty from basically risk-free securities, such as T-bills, to highly speculative investments, such as the common stock of small companies engaged in high-risk enterprises.

Most investors require higher rates of return on investments if they perceive that there is any uncertainty about the expected rate of return. This increase in the required rate of return over the NFR is the risk premium (RP). Although the required risk premium represents a composite of all uncertainty, it is possible to consider several fundamental sources of uncertainty. In this section, we identify and discuss briefly the major sources of uncertainty, including: (1) business risk, (2) financial risk (leverage), (3) liquidity risk, (4) exchange rate risk, and (5) country (political) risk.

Business risk is the uncertainty of income flows caused by the nature of a firm’s business. The less certain the income flows of the firm, the less certain the income flows to the investor. Therefore, the investor will demand a risk premium that is based on the uncertainty caused by the basic business of the firm. As an example, a retail food company would typically experience stable sales and earnings growth over time and would have low business risk compared to a firm in the auto or airline industry, where sales and earnings fluctuate substantially over the business cycle, implying high business risk.

Financial risk is the uncertainty introduced by the method by which the firm finances its investments. If a firm uses only common stock to finance investments, it incurs only business risk. If a firm borrows money to finance investments, it must pay fixed financing charges (in the form of interest to creditors) prior to providing income to the common stockholders, so the uncertainty of returns to the equity investor increases. This increase in uncertainty because of fixed-cost financing is called financial risk or financial leverage, and it causes an increase in the stock’s risk premium. For an extended discussion on this, see Brigham (2010).

Liquidity risk is the uncertainty introduced by the secondary market for an investment. When an investor acquires an asset, he or she expects that the investment will mature (as with a bond) or that it will be salable to someone else. In either case, the investor expects to be able to convert the security into cash and use the proceeds for current consumption or other investments. The more difficult it is to make this conversion to cash, the greater the liquidity risk. An investor must consider two questions when assessing the liquidity risk of an investment: How long will it take to convert the investment into cash? How certain is the price to be received? Similar uncertainty faces an investor who wants to acquire an asset: How long will it take to acquire the asset? How uncertain is the price to be paid?2

Uncertainty regarding how fast an investment can be bought or sold, or the existence of uncertainty about its price, increases liquidity risk. A U.S. government Treasury bill has almost no liquidity risk because it can be bought or sold in seconds at a price almost identical to the quoted price. In contrast, examples of illiquid investments include a work of art, an antique, or a parcel of real estate in a remote area. For such investments, it may require a long time to find a buyer and the selling prices could vary substantially from expectations. Investors will increase their required rates of return to compensate for this uncertainty regarding timing and price. Liquidity risk can be a significant consideration when investing in foreign securities depending on the country and the liquidity of its stock and bond markets.

Exchange rate risk is the uncertainty of returns to an investor who acquires securities denominated in a currency different from his or her own. The likelihood of incurring this risk is becoming greater as investors buy and sell assets around the world, as opposed to only assets within their own countries. A U.S. investor who buys Japanese stock denominated in yen must

2You will recall from prior courses that the overall capital market is composed of the primary market and the secondary market. Securities are initially sold in the primary market, and all subsequent transactions take place in the secondary market. These concepts are discussed in Chapter 4.
1.3.4 Risk Premium and Portfolio Theory

An alternative view of risk has been derived from extensive work in portfolio theory and capital market theory by Markowitz (1952, 1959) and Sharpe (1964). These theories are dealt with in greater detail in Chapter 7 and Chapter 8 but their impact on a stock’s risk premium should be mentioned briefly at this point. These prior works by Markowitz and Sharpe indicated that investors should use an external market measure of risk. Under a specified set of assumptions, all rational, profit-maximizing investors want to hold a completely diversified market portfolio of risky assets, and they borrow or lend to arrive at a risk level that is consistent with their risk preferences. Under these conditions, they showed that the relevant risk measure for an individual asset is its comovement with the market portfolio. This comovement, which is measured by an asset’s covariance with the market portfolio, is referred to as an asset’s systematic risk, the portion of an individual asset’s total variance that is attributable to the variability of the total market portfolio. In addition, individual assets have variance that is unrelated to the market portfolio (the asset’s nonmarket variance) that is due to the asset’s unique features. This nonmarket variance is called unsystematic risk, and it is generally considered unimportant because it is eliminated in a large, diversified portfolio. Therefore, under these assumptions, the risk premium for an individual earning asset is a function of the asset’s systematic risk with the aggregate market portfolio of risky assets. The measure of an asset’s systematic risk is referred to as its beta:

\[
\text{Risk Premium} = f(\text{Systematic Market Risk})
\]

1.3.5 Fundamental Risk versus Systematic Risk

Some might expect a conflict between the market measure of risk (systematic risk) and the fundamental determinants of risk (business risk, and so on). A number of studies have examined the relationship between the market measure of risk (systematic risk) and accounting variables used to measure the fundamental risk factors, such as business risk, financial risk, and liquidity risk. The authors of these studies (especially Thompson, 1976) have generally concluded that a significant relationship exists between the market measure of risk and the fundamental measures of risk. Therefore, the two measures of risk can be complementary. This consistency seems reasonable because one might expect the market measure of risk to reflect the fundamental risk characteristics of the asset. For example, you might expect a firm that has high business risk and financial risk to have an above-average beta. At the same time, as we discuss in Chapter 8, a firm that has a high level of fundamental risk and a large standard deviation of returns can have a lower level of systematic risk simply because the variability of its earnings and its stock price is not related to the aggregate economy or the aggregate market, i.e., a large component of its total risk is due to unique unsystematic risk. Therefore, one can specify the risk premium for an asset as either:

\[
\text{Risk Premium} = f(\text{Business Risk, Financial Risk, Liquidity Risk, Exchange Rate Risk, Country Risk})
\]

\[
\text{Risk Premium} = f(\text{Systematic Market Risk})
\]

1.3.6 Summary of Required Rate of Return

The overall required rate of return on alternative investments is determined by three variables: (1) the economy’s RRFR, which is influenced by the investment opportunities in the economy (that is, the long-run real growth rate); (2) variables that influence the NRFR, which include short-run ease or tightness in the capital market and the expected rate of inflation. Notably, these variables, which determine the NRFR, are the same for all investments; and (3) the risk premium on the investment. In turn, this risk premium can be related to fundamental factors, including business risk, financial risk, liquidity risk, exchange rate risk, and country risk, or it can be a function of an asset’s systematic market risk (beta).
1.3.4 Risk Premium and Portfolio Theory

An alternative view of risk has been derived from extensive work in portfolio theory and capital market theory by Markowitz (1952, 1959) and Sharpe (1964). These theories are dealt with in greater detail in Chapter 7 and Chapter 8 but their impact on a stock’s risk premium should be mentioned briefly at this point. These prior works by Markowitz and Sharpe indicated that investors should use an *external market* measure of risk. Under a specified set of assumptions, all rational, profit-maximizing investors want to hold a completely diversified market portfolio of risky assets, and they borrow or lend to arrive at a risk level that is consistent with their risk preferences. Under these conditions, they showed that the relevant risk measure for an individual asset is its *comovement with the market portfolio*. This comovement, which is measured by an asset’s covariance with the market portfolio, is referred to as an asset’s **systematic risk**, the portion of an individual asset’s total variance that is attributable to the variability of the total market portfolio. In addition, individual assets have variance that is unrelated to the market portfolio (the asset’s nonmarket variance) that is due to the asset’s unique features. This nonmarket variance is called **unsystematic risk**, and it is generally considered unimportant because it is eliminated in a large, diversified portfolio. Therefore, under these assumptions, the risk *premium for an individual earning asset is a function of the asset’s systematic risk with the aggregate market portfolio of risky assets*. The measure of an asset’s systematic risk is referred to as its **beta**:

\[
\text{Risk Premium} = f (\text{Systematic Market Risk})

The authors of these studies (especially Thompson, 1976) have generally concluded that a **significant relationship exists between the market measure of risk and the fundamental measures of risk**. Therefore, the two measures of risk can be complementary. This consistency seems reasonable because one might expect the market measure of risk to reflect the fundamental risk characteristics of the asset. 1.3.6 Summary of Required Rate of Return

The overall required rate of return on alternative investments is determined by three variables: (1) the economy’s **RRFR**, which is influenced by the investment opportunities in the economy (that is, the long-run real growth rate); (2) variables that influence the **NRRF**, which include short-run ease or tightness in the capital market and the expected rate of inflation. Notably, these variables, which determine the **NRRF**, are the same for all investments; and (3) the risk premium on the investment. In turn, this risk premium can be related to fundamental factors, including business risk, financial risk, liquidity risk, exchange rate risk, and country risk, or it can be a function of an asset’s systematic market risk (beta).
Beginning with an initial SML, three changes in the SML can occur. First, individual investments can change positions on the SML because of changes in the perceived risk of the investments. Second, the slope of the SML can change because of a change in the attitudes of investors toward risk; that is, investors can change the returns they require per unit of risk. Third, the SML can experience a parallel shift due to a change in the RRFR or the expected rate of inflation—i.e., anything that can change in the NRFR. These three possibilities are discussed in this section.

1.4.1 Movements along the SML

Investors place alternative investments somewhere along the SML based on their perceptions of the risk of the investment. Obviously, if an investment’s risk changes due to a change in one of its fundamental risk sources (business risk, and such), it will move along the SML. For example, if a firm increases its financial risk by selling a large bond issue that increases its financial leverage, investors will perceive its common stock as riskier and the stock will move up the SML to a higher risk position implying that investors will require a higher rate of return. As the common stock becomes riskier, it changes its position on the SML. Any change in an asset that affects its fundamental risk factors or its market risk (that is, its beta) will cause the asset to move along the SML as shown in Exhibit 1.8. Note that the SML does not change, only the position of specific assets on the SML.

1.4.2 Changes in the Slope of the SML

The slope of the SML indicates the return per unit of risk required by all investors. Assuming a straight line, it is possible to select any point on the SML and compute a risk premium (RP) for an asset through the equation:

\[
RP_i = E(R_i) - NRFR
\]

where:
- \(RP_i\) = risk premium for asset \(i\)
- \(E(R_i)\) = the expected return for asset \(i\)
- \(NRFR\) = the nominal return on a risk-free asset

Exhibit 1.8 Changes in the Required Rate of Return Due to Movements along the SML

### 1.4 Relationship between Risk and Return

Previously, we showed how to measure the risk and rates of return for alternative investments and we discussed what determines the rates of return that investors require. This section discusses the risk-return combinations that might be available at a point in time and illustrates the factors that cause changes in these combinations.

Exhibit 1.7 graphs the expected relationship between risk and return. It shows that investors increase their required rates of return as perceived risk (uncertainty) increases. The line that reflects the combination of risk and return available on alternative investments is referred to as the security market line (SML). The SML reflects the risk-return combinations available for all risky assets in the capital market at a given time. Investors would select investments that are consistent with their risk preferences; some would consider only low-risk investments, whereas others welcome high-risk investments.

**Exhibit 1.7 Relationship between Risk and Return**

![Exhibit 1.7 Relationship between Risk and Return](image-url)
Beginning with an initial SML, three changes in the SML can occur. First, individual investments can change positions on the SML because of changes in the perceived risk of the investments. Second, the slope of the SML can change because of a change in the attitudes of investors toward risk; that is, investors can change the returns they require per unit of risk. Third, the SML can experience a parallel shift due to a change in the RRFR or the expected rate of inflation—i.e., anything that can change in the NRFR. These three possibilities are discussed in this section.

1.4.1 Movements along the SML
Investors place alternative investments somewhere along the SML based on their perceptions of the risk of the investment. Obviously, if an investment’s risk changes due to a change in one of its fundamental risk sources (business risk, and such), it will move along the SML. For example, if a firm increases its financial risk by selling a large bond issue that increases its financial leverage, investors will perceive its common stock as riskier and the stock will move up the SML to a higher risk position implying that investors will require a higher rate of return. As the common stock becomes riskier, it changes its position on the SML. Any change in an asset that affects its fundamental risk factors or its market risk (that is, its beta) will cause the asset to move along the SML as shown in Exhibit 1.8. Note that the SML does not change, only the position of specific assets on the SML.

1.4.2 Changes in the Slope of the SML
The slope of the SML indicates the return per unit of risk required by all investors. Assuming a straight line, it is possible to select any point on the SML and compute a risk premium (RP) for an asset through the equation:

\[ RP_i = E(R_i) - NRFR \]

where:
- \( RP_i \) = risk premium for asset \( i \)
- \( E(R_i) \) = the expected return for asset \( i \)
- \( NRFR \) = the nominal return on a risk-free asset

**Exhibit 1.8 Changes in the Required Rate of Return Due to Movements along the SML**

![Diagram showing the SML with NRFR and risk on the axes. The slope of the SML is indicated as movements along the curve reflect changes in the risk of the asset.](image-url)
If a point on the SML is identified as the portfolio that contains all the risky assets in the market (referred to as the market portfolio), it is possible to compute a market RP as follows:

\[ RP_m = E(R_m) - NRFR \]

where:

- \( RP_m \) = the risk premium on the market portfolio
- \( E(R_m) \) = the expected return on the market portfolio
- \( NRFR \) = the nominal return on a risk-free asset

This market RP is not constant because the slope of the SML changes over time. Although we do not understand completely what causes these changes in the slope, we do know that there are changes in the yield differences between assets with different levels of risk even though the inherent risk differences are relatively constant.

These differences in yields are referred to as yield spreads, and these yield spreads change over time. As an example, if the yield on a portfolio of Aaa-rated bonds is 7.50 percent and the yield on a portfolio of Baa-rated bonds is 9.00 percent, we would say that the yield spread is 1.50 percent. This 1.50 percent is referred to as a credit risk premium because the Baa-rated bond is considered to have higher credit risk—that is, it has a higher probability of default. This Baa–Aaa yield spread is not constant over time, as shown by the substantial volatility in the yield spreads shown in Exhibit 1.9.

Although the underlying business and financial risk characteristics for the portfolio of bonds in the Aaa-rated bond index and the Baa-rated bond index would probably not change dramatically over time, it is clear from the time-series plot in Exhibit 1.9 that the difference in yields (i.e., the yield spread) has experienced changes of more than 100 basis points (1 percent) in a short period of time (for example, see the yield spread increases in 1974–1975, 1981–1983, 2001–2002, 2008–2009, and the dramatic declines in yield spread during 1975, 1983–1984, 2003–2004, and the second half of 2009). Such a significant change in the yield spread during a period where there is no major change in the fundamental risk characteristics of Baa bonds.

2. A change in the slope of the SML occurs in response to a change in the attitudes of investors toward risk. Such a change demonstrates that investors want either higher or lower rates of return for the same intrinsic risk. This is also described as a change in the market risk premium (\( R_m - NRFR \)). A change in the market risk premium will affect all risky investments.

3. A shift in the SML reflects a change in expected real growth, a change in market conditions (such as ease or tightness of money), or a change in the expected rate of inflation. Again, such a change will affect all investments.

**SUMMARY**

The purpose of this chapter is to provide background that can be used in subsequent chapters. To achieve that goal, we covered several topics:

1. We discussed why individuals save part of their income and why they decide to invest their savings. We defined investment as the current commitment of these savings for a period of time to derive a rate of return that compensates for the time involved, the expected rate of inflation, and the uncertainty.

2. We examined ways to quantify historical return and risk to help analyze alternative investment opportunities. We considered two measures of mean return (arithmetic and geometric) and applied these to a historical series for an individual investment and to a portfolio of investments during a period of time.

3. We considered the concept of uncertainty and alternative measures of risk (the variance, standard deviation, and a relative measure of risk—the coefficient of variation).

4. Before discussing the determinants of the required rate of return for an investment, we noted that the estimation of the required rate of return is complicated because the rates on individual investments change over time, because there is a wide range of rates of return available on alternative investments, and because the differences between required returns on alternative investments (for example, the yield spreads) likewise change over time.

relative to Aaa bonds would imply a change in the market RP. Specifically, although the intrinsic financial risk characteristics of the bonds remain relatively constant, investors changed the yield spreads (i.e., the credit risk premiums) they demand to accept this difference in financial risk.

This change in the RP implies a change in the slope of the SML. Such a change is shown in Exhibit 1.10. The exhibit assumes an increase in the market risk premium, which means an increase in the slope of the market line. Such a change in the slope of the SML (the market risk premium) will affect the required rate of return for all risky assets. Irrespective of where an investment is on the original SML, its required rate of return will increase, although its intrinsic risk characteristics remain unchanged.

### 1.4.3 Changes in Capital Market Conditions or Expected Inflation

The graph in Exhibit 1.11 shows what happens to the SML when there are changes in one of the following factors: (1) expected real growth in the economy, (2) capital market conditions, or (3) the expected rate of inflation. For example, an increase in expected real growth, temporary tightness in the capital market, or an increase in the expected rate of inflation will cause the SML to experience a parallel shift upward as shown in Exhibit 1.11. The parallel shift occurs because changes in expected real growth or changes in capital market conditions or a change in the expected rate of inflation affect the economy’s nominal risk-free rate (NRFR) that impacts all investments, irrespective of their risk levels.

### 1.4.4 Summary of Changes in the Required Rate of Return

The relationship between risk and the required rate of return for an investment can change in three ways:

1. A movement along the SML demonstrates a change in the risk characteristics of a specific investment, such as a change in its business risk, its financial risk, or its systematic risk (its beta). This change affects only the individual investment.
We examined the specific factors that determine the required rate of return: (1) the real risk-free rate, which is based on the real rate of growth in the economy, (2) the nominal risk-free rate, which is influenced by capital market conditions and the expected rate of inflation, and (3) a risk premium, which is a function of fundamental factors, such as business risk, or the systematic risk of the asset relative to the market portfolio (that is, its beta).

We discussed the risk-return combinations available on alternative investments at a point in time (illustrated by the SML) and the three factors that can cause changes in this relationship. First, a change in the inherent risk of an individual investment (that is, its fundamental risk or market risk) will cause a movement along the SML. Second, a change in investors’ attitudes toward risk will cause a change in the required return per unit of risk—that is, a change in the market risk premium. Such a change will cause a change in the slope of the SML. Finally, a change in expected real growth, in capital market conditions, or in the expected rate of inflation will cause a parallel shift of the SML.

Based on this understanding of the investment environment, you are prepared to consider the asset allocation decision, which is discussed in Chapter 2.

1. Discuss the overall purpose people have for investing. Define investment.
2. As a student, are you saving or borrowing? Why?
3. Divide a person’s life from ages 20 to 70 into 10-year segments and discuss the likely saving or borrowing patterns during each period.
4. Discuss why you would expect the saving-borrowing pattern to differ by occupation (for example, for a doctor versus a plumber).
5. The Wall Street Journal reported that the yield on common stocks is about 2 percent, whereas a study at the University of Chicago contends that the annual rate of return on common stocks since 1926 has averaged about 10 percent. Reconcile these statements.
6. Some financial theorists consider the variance of the distribution of expected rates of return to be a good measure of uncertainty. Discuss the reasoning behind this measure of risk and its purpose.
7. Discuss the three components of an investor’s required rate of return on an investment.
8. Discuss the two major factors that determine the market nominal risk-free rate (NRFR). Explain which of these factors would be more volatile over the business cycle.
9. Briefly discuss the five fundamental factors that influence the risk premium of an investment.
10. You own stock in the Gentry Company, and you read in the financial press that a recent bond offering has raised the firm’s debt/equity ratio from 35 percent to 55 percent. Discuss the effect of this change on the variability of the firm’s net income stream, other factors being constant. Discuss how this change would affect your required rate of return on the common stock of the Gentry Company.
11. Draw a properly labeled graph of the security market line (SML) and indicate where you would expect the following investments to fall along that line. Discuss your reasoning.
   a. Common stock of large firms
   b. U.S. government bonds
   c. U.K. government bonds
   d. Low-grade corporate bonds

Compute the expected return \( E(R_i) \) on Lauren Computer stock.

8. Without any formal computations, do you consider Madison Beer in Problem 6 or Lauren Computer in Problem 7 to present greater risk? Discuss your reasoning.

9. During the past year, you had a portfolio that contained U.S. government T-bills, long-term government bonds, and common stocks. The rates of return on each of them were as follows:

- U.S. government T-bills: 5.50%
- U.S. government long-term bonds: 7.50%
- U.S. common stocks: 11.60%

During the year, the consumer price index, which measures the rate of inflation, went from 160 to 172 (1982 – 1984 = 100). Compute the rate of inflation during this year. Compute the real rates of return on each of the investments in your portfolio based on the inflation rate.

10. You read in *BusinessWeek* that a panel of economists has estimated that the long-run real growth rate of the U.S. economy over the next five-year period will average 3 percent. In addition, a bank newsletter estimates that the average annual rate of inflation during this five-year period will be about 4 percent. What nominal rate of return would you expect on U.S. government T-bills during this period?

11. What would your required rate of return be on common stocks if you wanted a 5 percent risk premium to own common stocks given what you know from Problem 10? If common stock investors became more risk averse, what would happen to the required rate of return on common stocks? What would be the impact on stock prices?

12. Assume that the consensus required rate of return on common stocks is 14 percent. In addition, you read in *Fortune* that the expected rate of inflation is 5 percent and the estimated long-term real growth rate of the economy is 3 percent. What interest rate...
would you expect on U.S. government T-bills? What is the approximate risk premium for common stocks implied by these data?

On what stock markets are the firms traded? How do their growth rates in sales and earnings compare? How have their stocks performed over the past few months? Are stock analysts recommending investors buy or sell each of the two firm’s stocks?
Computation of Variance and Standard Deviation

Variance and standard deviation are measures of how actual values differ from the expected values (arithmetic mean) for a given series of values. In this case, we want to measure how rates of return differ from the arithmetic mean value of a series. There are other measures of dispersion, but variance and standard deviation are the best known because they are used in statistics and probability theory. Variance is defined as:

\[ \text{Variance} (\sigma^2) = \sum_{i=1}^{n} (\text{Probability})(\text{Possible Return} - \text{Expected Return})^2 = \sum_{i=1}^{n} (P_i)(R_i - E(R_i))^2 \]

Consider the following example, as discussed in the chapter:

<table>
<thead>
<tr>
<th>Probability of Possible Return ((P_i))</th>
<th>Possible Return ((R_i))</th>
<th>(P_iR_i)</th>
<th>(P_i(R_i - E(R_i))^2)</th>
</tr>
</thead>
<tbody>
<tr>
<td>0.15</td>
<td>0.20</td>
<td>0.03</td>
<td>0.0169</td>
</tr>
<tr>
<td>0.15</td>
<td>-0.20</td>
<td>-0.03</td>
<td>0.00729</td>
</tr>
<tr>
<td>0.70</td>
<td>0.10</td>
<td>0.07</td>
<td>0.00009</td>
</tr>
</tbody>
</table>

This gives an expected return \([E(R_i)]\) of 7 percent. The dispersion of this distribution as measured by variance is:

<table>
<thead>
<tr>
<th>Probability ((P_i))</th>
<th>Return ((R_i))</th>
<th>(R_i - E(R_i))</th>
<th>([R_i - E(R_i)]^2)</th>
<th>(P_i[R_i - E(R_i)]^2)</th>
</tr>
</thead>
<tbody>
<tr>
<td>0.15</td>
<td>0.20</td>
<td>0.13</td>
<td>0.0169</td>
<td>0.002535</td>
</tr>
<tr>
<td>0.15</td>
<td>-0.20</td>
<td>-0.27</td>
<td>0.0729</td>
<td>0.010935</td>
</tr>
<tr>
<td>0.70</td>
<td>0.10</td>
<td>0.03</td>
<td>0.00009</td>
<td>0.0000630</td>
</tr>
</tbody>
</table>

\[ \Sigma = 0.014100 \]

The variance \((\sigma^2)\) is equal to 0.0141. The standard deviation is equal to the square root of the variance:

\[ \text{Standard Deviation} (\sigma) = \sqrt{\sum_{i=1}^{n} P_i[R_i - E(R_i)]^2} \]

Consequently, the standard deviation for the preceding example would be:

\[ \sigma_i = \sqrt{0.0141} = 0.11874 \]

In this example, the standard deviation is approximately 11.87 percent. Therefore, you could describe this distribution as having an expected value of 7 percent and a standard deviation of 11.87 percent.

In many instances, you might want to compute the variance or standard deviation for a historical series in order to evaluate the past performance of the investment. Assume that you are given the following information on annual rates of return \((HPY)\) for common stocks listed on the New York Stock Exchange (NYSE):

<table>
<thead>
<tr>
<th>Year</th>
<th>Annual Rate of Return</th>
</tr>
</thead>
<tbody>
<tr>
<td>2012</td>
<td>0.07</td>
</tr>
<tr>
<td>2013</td>
<td>0.11</td>
</tr>
<tr>
<td>2014</td>
<td>-0.04</td>
</tr>
<tr>
<td>2015</td>
<td>0.12</td>
</tr>
<tr>
<td>2016</td>
<td>-0.06</td>
</tr>
</tbody>
</table>
In this case, we are not examining expected rates of return but actual returns. Therefore, we assume equal probabilities, and the expected value (in this case the mean value, \( \bar{R} \)) of the series is the sum of the individual observations in the series divided by the number of observations, or 0.04 (0.20/5). The variances and standard deviations are:

\[
\begin{array}{ccc}
\text{Year} & R_i & (R_i - \bar{R})^2 \\
2012 & 0.07 & 0.0009 & 0.02865 \\
2013 & 0.11 & 0.0049 & 0.00572 \\
2014 & -0.04 & 0.0064 \\
2015 & 0.12 & 0.0064 \\
2016 & -0.06 & 0.0110 & 0.0756 \\
\end{array}
\]

We can interpret the performance of NYSE common stocks during this period of time by saying that the average rate of return was 4 percent and the standard deviation of annual rates of return was 7.56 percent.

**Coefficient of Variation**

In some instances, you might want to compare the dispersion of two different series. The variance and standard deviation are absolute measures of dispersion. That is, they can be influenced by the magnitude of the original numbers. To compare series with very different values, you need a relative measure of dispersion. A measure of relative dispersion is the coefficient of variation, which is defined as:

\[
\text{Coefficient of Variation (CV) =} \frac{\text{Standard Deviation of Returns}}{\text{Expected Rate of Return}}
\]

A larger value indicates greater dispersion relative to the arithmetic mean of the series. For the previous example, the CV would be:

\[
CV = \frac{0.0756}{0.0400} = 1.89
\]

It is possible to compare this value to a similar figure having a markedly different distribution. As an example, assume you wanted to compare this investment to another investment that had an average rate of return of 10 percent and a standard deviation of 9 percent. The standard deviations alone tell you that the second series has greater dispersion (9 percent versus 7.56 percent) and might be considered to have higher risk. In fact, the relative dispersion for this second investment is much less.

\[
CV_1 = \frac{0.0756}{0.0400} = 1.89
\]

\[
CV_2 = \frac{0.0900}{0.1000} = 0.90
\]

Considering the relative dispersion and the total distribution, most investors would probably prefer the second investment.

The Asset Allocation Decision*

1. What is involved in the asset allocation process?
2. What are the four steps in the portfolio management process?
3. What is the role of asset allocation in investment planning?
4. Why is a policy statement important to the planning process?
5. What objectives and constraints should be detailed in a policy statement?
6. How and why do investment goals change over a person’s lifetime?
7. Why do asset allocation strategies differ across national boundaries?

The previous chapter informed us that risk drives return. Therefore, the practice of investing funds and managing portfolios should focus primarily on managing risk rather than on managing returns. This chapter examines some of the practical implications of risk management in the context of asset allocation.

Asset allocation is the process of deciding how to distribute an investor’s wealth among different countries and asset classes for investment purposes. An asset class is comprised of securities that have similar characteristics, attributes, and risk/return relationships. A broad asset class, such as "bonds," can be divided into smaller asset classes, such as Treasury bonds, corporate bonds, and high-yield bonds. We will see that, in the long run, the highest compounded returns will most likely accrue to those investors with larger exposures to risky assets. We will also see that although there are no shortcuts or guarantees to investment success, maintaining a reasonable and disciplined approach to investing will increase the likelihood of investment success over time.

The asset allocation decision is not an isolated choice; rather, it is a component of a structured four-step portfolio management process that we present in this chapter. As we will see, the first step in the process is to develop an investment policy statement, or plan, that will guide all future decisions. Much of an asset allocation strategy depends on the investor’s policy statement, which includes the investor’s goals or objectives, constraints, and investment guidelines.

What we mean by an "investor" can range from an individual account to trustees overseeing a corporation’s multibillion-dollar pension fund, a university endowment, or an insurance company portfolio. Regardless of who the investor is or how simple or complex the investment needs, he or she should develop a policy statement before...

2.1 Investment Strategies over an Investor’s Lifetime

Assuming the basic insurance and cash reserve needs are met, individuals can start a serious investment program with their savings. Because of changes in their net worth and risk tolerance, individuals’ investment strategies will change over their lifetime. In the following sections, we review various phases in the investment life cycle. Although each individual’s needs and preferences are different, some general traits affect most investors over the life cycle.

The four life-cycle phases are shown in Exhibit 2.1 (the third and fourth phases—spending and gifting—are shown as concurrent) and described here.

Accumulation Phase

Individuals in the early-to-middle years of their working careers are in the accumulation phase. As the name implies, these individuals are attempting to accumulate assets to satisfy fairly immediate needs (for example, a down payment for a house) or longer-term goals (children’s college education, retirement). Typically, their net worth is small, and debt from car loans or their own past college loans may be heavy. As a result of their typically long investment time horizon and their future earning ability, individuals in the accumulation phase are willing to make relatively high-risk investments in the hopes of making above-average nominal returns over time.

Here we emphasize the wisdom of investing early and regularly in one’s life. Funds invested in early life cycle phases, with returns compounding over time, will reap significant financial benefits during later phases. Exhibit 2.2 shows growth from an initial $10,000 investment over 20, 30, and 40 years at assumed annual returns of 7 and 8 percent. The middle-aged person who invests $10,000 "when he or she can afford it" will only reap the benefits of compounding for 20 years or so before retirement. In contrast, a person who begins saving at a younger age will reap the much higher benefits of funds invested for 30 or 40 years. Regularly investing as little as $2,000 a year reaps large benefits over time, as well. As shown in Exhibit 2.2, a person who has invested a total of $90,000—an initial $10,000 investment followed by $2,000 annual investments over 40 years—will have over half a million dollars accumulated assuming the 7 percent return. If the funds are invested more aggressively and earn the 8 percent return, the accumulation will be nearly three-quarters of a million dollars.

2.1 Individual Investor Life Cycle

Financial plans and investment needs are as different as each individual. Investment needs change over a person’s life cycle. How individuals structure their financial plan should be related to their age, financial status, future plans, risk aversion characteristics, and needs.

2.1.1 The Preliminaries

Before embarking on an investment program, we need to make sure other needs are satisfied. No serious investment plan should be started until a potential investor has adequate income to cover living expenses and has a safety net should the unexpected occur.

Insurance Life insurance should be a component of any financial plan. Life insurance protects loved ones against financial hardship should death occur before our financial goals are met. The death benefit paid by the insurance company can help pay medical bills and funeral expenses and provide cash that family members can use to maintain their lifestyle, retire debt, or invest for future needs (for example, children’s education, spouse retirement). Therefore, one of the first steps in developing a financial plan is to purchase adequate life insurance coverage.

Insurance can also serve more immediate purposes, including being a means to meet long-term goals, such as retirement planning. On reaching retirement age, you can receive the cash or surrender value of your life insurance policy and use the proceeds to supplement your retirement lifestyle or for estate planning purposes.

Insurance coverage also provides protection against other uncertainties. Health insurance helps to pay medical bills. Disability insurance provides continuing income should you become unable to work. Automobile and home (or rental) insurance provides protection against accidents and damage to cars or residences.

Although nobody ever expects to use his or her insurance coverage, a first step in a sound financial plan is to have adequate coverage “just in case.” Lack of insurance coverage can ruin the best-planned investment program.

Cash Reserve Emergencies, job layoffs, and unforeseen expenses happen, and good investment opportunities emerge. It is important to have a cash reserve to help meet these occasions. In addition to providing a safety cushion, a cash reserve reduces the likelihood of being forced to sell investments at inopportune times to cover unexpected expenses. Most experts recommend a cash reserve equal to about six months’ living expenses. Calling it a “cash” reserve does not mean the funds should be in cash; rather, the funds should be in investments you can easily convert to cash with little chance of a loss in value. Money market or short-term bond mutual funds and bank accounts are appropriate vehicles for the cash reserve.

Similar to the financial plan, an investor’s insurance and cash reserve needs will change over his or her life. The need for disability insurance declines when a person retires. In contrast, other insurance, such as supplemental Medicare coverage or long-term-care insurance, may become more important.
2.1.2 Investment Strategies over an Investor’s Lifetime

Assuming the basic insurance and cash reserve needs are met, individuals can start a serious investment program with their savings. Because of changes in their net worth and risk tolerance, individuals’ investment strategies will change over their lifetime. In the following sections, we review various phases in the investment life cycle. Although each individual’s needs and preferences are different, some general traits affect most investors over the life cycle.

2.1.3 Life Cycle Investment Goals

During an individual’s investment life cycle, he or she will have a variety of financial goals. Near-term, high-priority goals are shorter-term financial objectives that individuals set to fund purchases that are personally important to them, such as accumulating funds to make a house down payment, buy a new car, or take a trip. Parents with teenage children may have a near-term, high-priority goal to accumulate funds to help pay college expenses. Because of the emotional importance of these goals and their short time horizon, high-risk investments are not usually considered suitable for achieving them.

Long-term, high-priority goals typically include some form of financial independence, such as the ability to retire at a certain age. Because of their long-term nature, higher-risk investments can be used to help meet these objectives.

Lower-priority goals are just that—it might be nice to meet these objectives, but it is not critical. Examples include the ability to purchase a new car every few years, redecorate the home with expensive furnishings, or take a long, luxurious vacation. A well-developed policy statement considers these diverse goals over an investor’s lifetime. The following sections detail the process for constructing an investment policy, creating a portfolio that is consistent with the policy and the environment, managing the portfolio, and monitoring its performance relative to its goals and objectives over time.

2.2 The Portfolio Management Process

The process of managing an investment portfolio never stops. Once the funds are initially invested according to the plan, the real work begins in evaluating the portfolio’s performance and updating the portfolio based on changes in the economic environment and the investor’s needs.

The first step in the portfolio management process, as seen in Exhibit 2.3, is for the investor, either alone or with the assistance of an investment advisor, to construct a portfolio.

*This section and the one that follows benefited from insights contained in Maginn, Tuttle, Pinto, and McLeavey (2007), especially Chapters 1 and 2.

**Consolidation Phase** Individuals in the consolidation phase are typically past the midpoint of their careers, have paid off much or all of their outstanding debts, and perhaps have paid, or have the assets to pay, their children’s college bills. Earnings exceed expenses, so the excess can be invested to provide for future retirement or estate planning needs. The typical investment horizon for this phase is still long (20 to 30 years), so moderately high risk investments are attractive. At the same time, because individuals in this phase are concerned about capital preservation, they do not want to take abnormally high risks that may put their current nest egg in jeopardy.

**Spending Phase** The spending phase typically begins when individuals retire. Living expenses are covered by social security income and income from prior investments, including employer pension plans. Because their earning years have concluded (although some retirees take part-time positions or do consulting work), they are very conscious of protecting their capital. At the same time, they must balance their desire to preserve the nominal value of their savings with the need to protect themselves against a decline in the real value of their savings due to inflation. The average 65-year-old person in the United States has a life expectancy of about 20 years. Thus, although their overall portfolio may be less risky than in the consolidation phase, they still need some risky growth investments, such as common stocks, for inflation (purchasing power) protection.

The transition into the spending phase requires a sometimes difficult change in mindset; throughout our working life we are trying to save; suddenly we can spend. We tend to think that if we spend less, say 4 percent of our accumulated funds annually instead of 5, 6, or 7 percent, our wealth will last far longer. Although this is correct, a bear market early in our retirement can greatly reduce our accumulated funds. Fortunately, there are planning tools that can give a realistic view of what can happen to our retirement funds should markets fall early in our retirement years; this insight can assist in budgeting and planning to minimize the chance of spending (or losing) all the saved retirement funds. Annuities, which transfer risk from the individual to the annuity firm (most likely an insurance company), are another possibility. With an annuity, the recipient receives a guaranteed, lifelong stream of income. Options can allow for the annuity to continue until both a husband and wife die.

**Gifting Phase** The gifting phase is similar to, and may be concurrent with, the spending phase. In this stage, individuals may believe they have sufficient income and assets to cover their current and future expenses while maintaining a reserve for uncertainties. In such a case, excess assets can be used to provide financial assistance to relatives or friends, to establish charitable trusts, or to fund trusts as an estate planning tool to minimize estate taxes.
2.1.3 Life Cycle Investment Goals

During an individual’s investment life cycle, he or she will have a variety of financial goals. Near-term, high-priority goals are shorter-term financial objectives that individuals set to fund purchases that are personally important to them, such as accumulating funds to make a house down payment, buy a new car, or take a trip. 2.2 The Portfolio Management Process*

The process of managing an investment portfolio never stops. Once the funds are initially invested according to the plan, the real work begins in evaluating the portfolio’s performance and updating the portfolio based on changes in the economic environment and the investor’s needs.

The first step in the portfolio management process, as seen in Exhibit 2.3, is for the investor, either alone or with the assistance of an investment advisor, to construct a

policy statement. The policy statement is a road map; in it, investors specify the types of risks they are willing to take and their investment goals and constraints. All investment decisions are based on the policy statement to ensure that these decisions are appropriate for the investor. We examine the process of constructing a policy statement in the following section. Because investor needs, goals, and constraints change over time, the policy statement must be periodically reviewed and updated.

The process of investing involves assessing the future and deriving strategies that offer the best possibility of meeting the policy statement guidelines. In the second step of the portfolio management process, the portfolio manager studies current financial and economic conditions and forecasts future trends. The investor’s needs, as reflected in the policy statement, and financial market expectations will jointly determine investment strategy. Economies are dynamic; they are affected by numerous industry struggles, politics, and changing demographics and social attitudes. Thus, the portfolio will require constant monitoring and updating to reflect changes in financial market expectations. We examine the process of evaluating and forecasting economic trends in Chapter 12.

The third step of the portfolio management process is to construct the portfolio. With the investor’s policy statement and financial market forecasts as input, the advisors implement the investment strategy and determine how to allocate available funds across different countries, asset classes, and securities. This involves constructing a portfolio that will minimize the investor’s risks while meeting the needs specified in the policy statement. Financial theory frequently assists portfolio construction, which is discussed in Part 2 of this book. Some of the practical aspects of selecting investments for inclusion in a portfolio are discussed in Part 4 and Part 5.

The fourth step in the portfolio management process is the continual monitoring of the investor’s needs and capital market conditions and, when necessary, updating the policy statement. Based upon all of this, the investment strategy is modified accordingly. An important component of the monitoring process is to evaluate a portfolio’s performance and compare the relative results to the expectations and the requirements listed in the policy statement. The evaluation of portfolio performance is discussed in Chapter 25. Once you have completed the four steps, it is important to recognize that this is a continuous process—it is essential to revisit all the steps to ensure that the policy statement is still valid, that the economic outlook has not changed, and so forth.

2.3 The Need for a Policy Statement

As noted in the previous section, a policy statement is a road map that guides the investment process. Constructing a policy statement is an invaluable planning tool that will help the investor understand his or her needs better as well as assist an advisor or portfolio manager in managing a client’s funds. While it does not guarantee investment success, a policy statement will provide discipline for the investment process and reduce the possibility of making hasty, inappropriate decisions. There are two important reasons for constructing a policy statement: First, it helps the investor decide on realistic investment goals after learning about the financial markets and the risks of investing; second, it creates a standard by which to judge the performance of the portfolio manager.

2.3.1 Understand and Articulate Realistic Investor Goals

When asked about their investment goal, people often say, “to make a lot of money,” or some similar response. Such a goal has two drawbacks: First, it may not be appropriate for the investor, and second, it is too open-ended to provide guidance for specific investments and time
frames. Such an objective is well suited for someone going to the racetrack or buying lottery tickets, but it is inappropriate for someone investing funds in financial and real assets for the long term.

An important purpose of writing a policy statement is to help investors understand their own needs, objectives, and investment constraints. As part of this, investors need to learn about financial markets and the risks of investing. This background will help prevent them from making inappropriate investment decisions in the future based on unrealistic expectations and increase the possibility that they will satisfy their specific, measurable financial goals.

Thus, the policy statement helps the investor to specify realistic goals and become more informed about the risks and costs of investing. Market values of assets, whether they be stocks, bonds, or real estate, can fluctuate dramatically. For example, during the October 1987 crash, the Dow Jones Industrial Average (DJIA) fell more than 20 percent in one day; in October 1997, the Dow fell “only” 7 percent. A review of market history shows that it is not unusual for asset prices to decline by 10 percent to 20 percent over several months—for example, the months following the market peak in March 2000, and the major decline when the market reopened after September 11, 2001. The most recent “bloodbath” was the market decline of over 30 percent during 2008—and this decline was global. The problem is, investors typically focus on a single statistic, such as an 11 percent average annual rate of return on stocks, and expect the market to rise 11 percent every year. Such thinking ignores the risk of stock investing. Part of the process of developing a policy statement is for the investor to become familiar with the risks of investing, because we know that a strong positive relationship exists between risk and return.

One expert in the field recommends that investors should think about the following set of questions and explain their answers as part of the process of constructing a policy statement:

1. What are the real risks of an adverse financial outcome, especially in the short run?
2. What probable emotional reactions will I have to an adverse financial outcome?
3. How knowledgeable am I about investments and financial markets?
4. What other capital or income sources do I have? How important is this particular portfolio to my overall financial position?
5. What, if any, legal restrictions may affect my investment needs?
6. How would any unanticipated fluctuations in my portfolio value affect my investment policy?

In summary, constructing a policy statement is mainly the investor’s responsibility. It is a process whereby investors articulate their realistic needs and goals and become familiar with financial markets and investing risks. Without this information, investors cannot adequately communicate their needs to the portfolio manager. Without this input from investors, the portfolio manager cannot construct a portfolio that will satisfy clients’ needs. The result of bypassing this step will most likely be future aggravation, dissatisfaction, and disappointment.

2.3.2 Standards for Evaluating Portfolio Performance

The policy statement also assists in judging the performance of the portfolio manager. Performance cannot be judged without an objective standard; the policy statement provides that objective standard. The portfolio’s performance should be compared to guidelines specified in the policy statement, not on the portfolio’s overall return. For example, if an investor has a low
tolerance for risky investments, the portfolio manager should not be fired simply because the portfolio does not perform as well as the risky S&P 500 stock index. The point is, because risk drives returns, the investor’s lower-risk investments, as specified in the investor’s policy statement, will probably earn lower returns than if all the investor’s funds were placed in the aggregate stock market.

The policy statement will typically include a benchmark portfolio, or comparison standard. The risk of the benchmark, and the assets included in the benchmark, should agree with the client’s risk preferences and investment needs. Notably, both the client and the portfolio manager must agree that the benchmark portfolio reflects the risk preferences and appropriate return requirements of the client. In turn, the investment performance of the portfolio manager should be compared to this benchmark portfolio. For example, an investor who specifies low-risk investments in the policy statement should compare the portfolio manager’s performance against a low-risk benchmark portfolio. Likewise, an investor seeking high-risk, high-return investments should compare the portfolio’s performance against a high-risk benchmark portfolio.

Because it sets an objective performance standard, the policy statement acts as a starting point for periodic portfolio review and client communication with managers. Questions concerning portfolio performance should be addressed in the context of the written policy guidelines. Managers should mainly be judged by whether they consistently followed the client’s policy guidelines. The portfolio manager who makes unilateral deviations from policy is not working in the best interests of the client. Therefore, even significant deviations that result in higher portfolio returns can and should be grounds for the manager’s dismissal.

Thus, we see the importance of constructing the policy statement: The client must first understand his or her own needs before communicating them to the portfolio manager who in turn, must implement the client’s desires by following the investment guidelines. As long as policy is followed, shortfalls in performance should not be a major concern. Remember that the policy statement is designed to impose an investment discipline on the client and on the portfolio manager. The less knowledgeable they are, the more likely clients are to inappropriately judge the performance of the portfolio manager.

2.3.3 Other Benefits

A sound policy statement helps to protect the client against a portfolio manager’s inappropriate investments or unethical behavior. Without clear, written guidance, some managers may consider investing in high-risk investments, hoping to earn a quick return. Such actions are probably counter to the investor’s specified needs and risk preferences. Though legal recourse is a possibility against such action, writing a clear and unambiguous policy statement should reduce the possibility of such inappropriate manager behavior.

Just because a specific manager currently manages your account does not mean that person will always manage your funds. Because your portfolio manager may be promoted, dismissed or take a better job, your funds may come under the management of an individual you do not know and who does not know you. To prevent costly delays during this transition, you can ensure that the new manager “hits the ground running” with a clearly written policy statement. A policy statement should prevent delays in monitoring and rebalancing your portfolio and contribute to a seamless transition from one money manager to another.

To sum up, a clearly written policy statement helps avoid potential problems. When the client clearly specifies his or her needs and desires, the portfolio manager can more effectively construct an appropriate portfolio. The policy statement provides an objective measure for evaluating portfolio performance, helps guard against ethical lapses by the portfolio manager, and aids in the transition between money managers. Therefore, the first step before beginning any investment program is to construct a policy statement.
An appropriate policy statement should satisfactorily answer the following questions:

1. Is the policy carefully designed to meet the specific needs and objectives of this particular investor? (Cookie-cutter or one-size-fits-all policy statements are generally inappropriate.)
2. Is the policy written so clearly and explicitly that a competent stranger could use it to manage the portfolio in conformance with the client’s needs? In case of a manager transition, could the new manager use this policy statement to handle your portfolio in accordance with your needs?
3. Would the client have been able to remain committed to the policies during the capital market experiences of the past 60 to 70 years? That is, does the client fully understand investment risks and the need for a disciplined approach to the investment process?
4. Would the portfolio manager have been able to maintain the policies specified over the same period? (Discipline is a two-way street; we do not want the portfolio manager to change strategies because of a disappointing market.)
5. Would the policy, if implemented, have achieved the client’s objectives? (Bottom line: Would the policy have worked to meet the client’s needs?)

### 2.4 Input to the Policy Statement

Before an investor and advisor can construct a policy statement, they need to have an open and frank exchange of information, ideas, fears, and goals. Specifically, the client and advisor need to discuss the client’s investment objectives and constraints. To illustrate this framework, we discuss the investment objectives and constraints that may confront “typical” 25-year-old and 65-year-old investors.

#### 2.4.1 Investment Objectives

The investor’s **objectives** are his or her investment goals expressed in terms of both risk and returns. The relationship between risk and returns requires that goals not be expressed only in terms of returns. Expressing goals only in terms of returns can lead to inappropriate investment practices by the portfolio manager, such as the use of high-risk investment strategies or account “churning,” which involves moving quickly in and out of investments in an attempt to buy low and sell high.

For example, a person may have a stated return goal such as “double my investment in five years.” Before such a statement becomes part of the policy statement, the client must become fully informed of investment risks associated with such a goal, including the possibility of loss. **A careful analysis of the client’s risk tolerance should precede any discussion of return objectives.** It makes little sense for a person who is risk averse to have his/her funds invested in high-risk assets. Investment firms survey clients to gauge their risk tolerance. Sometimes investment magazines or books contain tests that individuals can take to help them evaluate their risk tolerance (see Exhibit 2.4). Subsequently, an advisor will use the results of this evaluation to categorize a client’s risk tolerance and suggest an initial asset allocation such as those contained in Exhibit 2.5.

Risk tolerance is more than a function of an individual’s psychological makeup; it is affected by other factors, including a person’s current insurance coverage and cash reserves. Risk tolerance is also affected by an individual’s family situation (for example, marital status and the number and ages of children) and by his or her age. We know that older persons generally have shorter investment time frames within which to make up any losses; they also have years of experience, including living through various market gyrations and “corrections”
Exhibit 2.4 How Much Risk Is Right for You?

You’ve heard the expression “no pain, no gain”? In the investment world, the comparable phrase would be “no risk, no reward.”

How you feel about risking your money will drive many of your investment decisions. The risk-comfort scale extends from very conservative (you don’t want to risk losing a penny regardless of how little your money earns) to very aggressive (you’re willing to risk much of your money for the possibility that it will grow tremendously). As you might guess, most investors’ tolerance for risk falls somewhere in between.

If you’re unsure of what your level of risk tolerance is, this quiz should help.

1. You win $300 in an office football pool. You: (a) spend it on groceries, (b) purchase lottery tickets, (c) put it in a money market account, (d) buy some stock.
2. Two weeks after buying 100 shares of a $20 stock, the price jumps to over $30. You decide to: (a) buy more stock; it’s obviously a winner, (b) sell it and take your profits, (c) sell half to recoup some costs and hold the rest, (d) sit tight and wait for it to advance even more.
3. On days when the stock market jumps way up, you: (a) wish you had invested more, (b) call your financial advisor and ask for recommendations, (c) feel glad you’re not in the market because it fluctuates too much, (d) pay little attention.
4. You’re planning a vacation trip and can either lock in a fixed room-and-meals rate of $150 per day or book standby and pay anywhere from $100 to $300 per day. You: (a) take the fixed-rate deal, (b) talk to people who have been there about the availability of last-minute accommodations, (c) book standby and also arrange vacation insurance because you’re leery of the tour operator, (d) take your chances with standby.
5. The owner of your apartment building is converting the units to condominiums. You can buy your unit for $75,000 or an option on a unit for $15,000. (Units have recently sold for close to $100,000, and prices seem to be going up.) For financing, you’ll have to borrow the down payment and pay mortgage and condo fees higher than your present rent. You: (a) buy your unit, (b) buy your unit and look for another to buy, (c) sell the option and arrange to rent the unit yourself, (d) sell the option and move out because you think the conversion will attract couples with small children.

6. You have been working three years for a rapidly growing company. As an executive, you are offered the option of buying up to 2% of company stock: 2,000 shares at $10 a share. Although the company is privately owned (its stock does not trade on the open market), its majority owner has made handsome profits selling three other businesses and intends to sell this one eventually. You: (a) purchase all the shares you can and tell the owner you would invest more if allowed, (b) purchase all the shares, (c) purchase half the shares, (d) purchase a small amount of shares.

7. You go to a casino for the first time. You choose to play: (a) quarter slot machines, (b) $5 minimum-bet roulette, (c) dollar slot machines, (d) $25 minimum-bet blackjack.

8. You want to take someone out for a special dinner in a city that’s new to you. How do you pick a place? (a) read restaurant reviews in the local newspaper, (b) ask coworkers if they know of a suitable place, (c) call the only other person you know in this city, who eats out a lot but only recently moved there, (d) visit the city sometime before your dinner to check out the restaurants yourself.

9. The expression that best describes your lifestyle is: (a) no guts, no glory, (b) just do it! (c) look before you leap, (d) all good things come to those who wait.

10. Your attitude toward money is best described as: (a) a dollar saved is a dollar earned, (b) you’ve got to spend money to make money, (c) cash and carry only, (d) whenever possible, use other people’s money.

SCORING SYSTEM: Score your answers this way: (1) a-1, b-4, c-2, d-3 (2) a-4, b-1, c-3, d-2 (3) a-3, b-4, c-2, d-1 (4) a-2, b-3, c-1, d-4 (5) a-3, b-4, c-2, d-1 (6) a-4, b-3, c-2, d-1 (7) a-1, b-3, c-2, d-4 (8) a-2, b-3, c-4, d-1 (9) a-4, b-3, c-2, d-1 (10) a-2, b-3, c-1, d-4.

What your total score indicates:

- 10–17: You’re not willing to take chances with your money, even though it means you can’t make big gains.
- 18–25: You’re semi-conservative, willing to take a small chance with enough information.
- 26–32: You’re semi-aggressive, willing to take chances if you think the odds of earning more are in your favor.
- 33–40: You’re aggressive, looking for every opportunity to make your money grow, even though in some cases the odds may be quite long. You view money as a tool to make more money.
A euphemism for downtrends or crashes) that younger people have not experienced or whose effect they do not fully appreciate. Risk tolerance is also influenced by one's current net worth and income expectations. All else being equal, individuals with higher incomes have a greater propensity to undertake risk because their incomes can help cover any shortfall. Likewise, individuals with larger portfolios can afford to place some assets in risky investments while the remaining assets provide a cushion against losses.

A person’s return objective may be stated in terms of an absolute or a relative percentage return, but it may also be stated in terms of a general goal, such as capital preservation, current income, capital appreciation, or total return. Capital preservation means that investors want to minimize their risk of loss, usually in real terms: They seek to maintain the purchasing power of their investment. In other words, the return needs to be no less than the rate of inflation. Generally, this is a strategy for strongly risk-averse investors or for funds needed in the short run, such as for next year’s tuition payment or a down payment on a house.

Capital appreciation is an appropriate objective when the investors want the portfolio to grow in real terms over time to meet some future need. Under this strategy, growth mainly occurs through capital gains. This is an aggressive strategy for investors willing to take on risk to meet their objective. Generally, longer-term investors seeking to build a retirement or college education fund may have this goal.

When current income is the return objective, the investors want the portfolio to concentrate on generating income rather than capital gains. This strategy sometimes suits investors who want to supplement their earnings with income generated by their portfolio to meet their living expenses. Retirees may favor this objective for part of their portfolio to help generate spendable funds.

The objective for the total return strategy is similar to that of capital appreciation; namely, the investors want the portfolio to grow over time to meet a future need. Whereas the capital appreciation strategy seeks to do this primarily through capital gains, the total return strategy seeks to increase portfolio value by both capital gains and reinvesting current income. Because the total return strategy has both income and capital gains components, its risk exposure lies between that of the current income and capital appreciation strategies.

Investment Objective: 25-Year-Old

What is an appropriate investment objective for our typical 25-year-old investor? Assume he holds a steady job, is a valued employee, has adequate insurance coverage, and has enough money in the bank to provide a cash reserve. Let’s also assume that his current long-term, high-priority investment goal is to build a retirement fund. Depending on his risk preferences, he can select a strategy carrying moderate to high amounts of risk because the income stream from his job will probably grow over time. Further, given his young age and income growth potential, a low-risk strategy, such as capital preservation or current income, is inappropriate for his retirement fund goal; a total return or capital appreciation objective would be most appropriate. Here’s a possible objective statement:

Invest funds in a variety of moderate- to higher-risk investments. The average risk of the equity portfolio should exceed that of a broad stock market index, such as the NYSE stock index. Foreign and domestic equity exposure should range from 80 percent to 95 percent of the total portfolio. Remaining funds should be invested in short- and intermediate-term notes and bonds.

Investment Objective: 65-Year-Old

Assume our typical 65-year-old investor likewise has adequate insurance coverage and a cash reserve. Let’s also assume she is retiring this year. This individual will want less risk exposure than the 25-year-old investor because her earning power from employment will soon be ending; she will not be able to recover any investment losses by saving more out of her paycheck. Depending on her income from social security and a pension plan, she may need some current income from her retirement portfolio to meet living expenses. Given that she can be expected to live an average of another 20 years, she will...

need protection against inflation. A risk-averse investor will choose a combination of current
income and capital preservation strategy; a more risk-tolerant investor will choose a combina-
tion of current income and total return in an attempt to have principal growth outpace infla-
tion. Here’s an example of such an objective statement:
Invest in stock and bond investments to meet income needs (from bond income and stock
dividends) and to provide for real growth (from equities). Fixed-income securities should
comprise 55–65 percent of the total portfolio; of this, 5–15 percent should be invested in
short-term securities for extra liquidity and safety. The remaining 35–45 percent of the port-
folio should be invested in high-quality stocks whose risk is similar to the S&P 500 index.

More detailed analyses for our 25-year-old and our 65-year-old would make more specific
assumptions about the risk tolerance of each, as well as clearly enumerate their investment
goals, return objectives, the funds they have to invest at the present, the funds they expect to
invest over time, and the benchmark portfolio that will be used to evaluate performance.

2.4.2 Investment Constraints
In addition to the investment objective that sets limits on risk and return, certain other con-
straints also affect the investment plan. Investment constraints include liquidity needs, an in-
vestment time horizon, tax factors, legal and regulatory constraints, and unique needs and
preferences.

Liquidity Needs
An asset is liquid if it can be quickly converted to cash at a price close to
fair market value. Generally, assets are more liquid if many traders are interested in a fairly
standardized product. Treasury bills are a highly liquid security, and real estate and venture
capital are not.

Investors may have liquidity needs that the investment plan must consider. For example,
although an investor may have a primary long-term goal, several near-term goals may require
available funds. Wealthy individuals with sizable tax obligations need adequate liquidity to pay
their taxes without upsetting their investment plan. Some retirement plans may need funds for
shorter-term purposes, such as buying a car or a house or making college tuition payments.

Our typical 25-year-old investor probably has little need for liquidity as he focuses on his
long-term retirement fund goal. This constraint may change, however, should he face a period
of unemployment or should near-term goals, such as honeymoon expenses or a house down
payment, enter the picture. Should any changes occur, the investor needs to revise his policy
statement and financial plans accordingly.

Our soon-to-be-retired 65-year-old investor has a greater need for liquidity. Although she
may receive regular checks from her pension plan and social security, it is not likely that they
will equal her working paycheck. She will want some of her portfolio in liquid securities to
meet unexpected expenses, bills, or special needs such as trips or cruises.

Time Horizon
Time horizon as an investment constraint briefly entered our earlier discussion
of near-term and long-term high-priority goals. A close (but not perfect) relationship exists be-
tween an investor’s time horizon, liquidity needs, and ability to handle risk. Investors with long
investment horizons generally require less liquidity and can tolerate greater portfolio risk: less
liquidity because the funds are not usually needed for many years; greater risk tolerance because
any shortfalls or losses can be overcome by earnings and returns in subsequent years.

Investors with shorter time horizons generally favor more liquid and less risky investments
because losses are harder to overcome during a short time frame.

Because of life expectancies, our 25-year-old investor has a longer investment time horizon than
our 65-year-old investor. But, as discussed earlier, this does not mean the 65-year-old should place
all her money in short-term CDs; she needs the inflation protection that long-term investments
would provide.

Investment Objective: 25-Year-Old
What is an appropriate investment objective for our

Wealthy individuals with sizable tax obligations need adequate liquidity to pay their taxes without upsetting their investment plan. Some retirement plans may need funds for shorter-term purposes, such as buying a car or a house or making college tuition payments.

Our typical 25-year-old investor probably has little need for liquidity as he focuses on his long-term retirement fund goal. This constraint may change, however, should he face a period of unemployment or should near-term goals, such as honeymoon expenses or a house down payment, enter the picture. Should any changes occur, the investor needs to revise his policy statement and financial plans accordingly.

Our soon-to-be-retired 65-year-old investor has a greater need for liquidity. Although she may receive regular checks from her pension plan and social security, it is not likely that they will equal her working paycheck. She will want some of her portfolio in liquid securities to meet unexpected expenses, bills, or special needs such as trips or cruises.

Time Horizon Time horizon as an investment constraint briefly entered our earlier discussion of near-term and long-term high-priority goals. A close (but not perfect) relationship exists between an investor’s time horizon, liquidity needs, and ability to handle risk. Investors with long investment horizons generally require less liquidity and can tolerate greater portfolio risk: less liquidity because the funds are not usually needed for many years; greater risk tolerance because any shortfalls or losses can be overcome by earnings and returns in subsequent years.

Investors with shorter time horizons generally favor more liquid and less risky investments because losses are harder to overcome during a short time frame.

Because of life expectancies, our 25-year-old investor has a longer investment time horizon than our 65-year-old investor. But, as discussed earlier, this does not mean the 65-year-old should place all her money in short-term CDs; she needs the inflation protection that long-term investments
The first $17,000 of income has a 10 percent marginal tax rate; the next $33,000 has a 15 percent marginal tax rate:

$17,000 \times 0.10 + \$33,000 \times 0.15 = \$13,500$, or the average tax rate of 13.9 percent.

Another tax factor is that some sources of investment income are exempt from federal and state taxes. For example, interest on federal securities, such as Treasury bills, notes, and bonds, is exempt from state taxes. Interest on municipal bonds (bonds issued by a state or other local governing body) is exempt from federal taxes. Further, if investors purchase municipal bonds issued by a local governing body of the state in which they live, the interest may be exempt from both state and federal income tax. Thus, high-income individuals have an incentive to purchase municipal bonds to reduce their tax liabilities.

The after-tax return on taxable investment income is

\[
\text{After-Tax Income Return} = \text{Pre-Tax Income Return} \times (1 - \text{Marginal Tax Rate})
\]

Thus, the after-tax return on a taxable bond investment should be compared to that of municipals before deciding which security a tax-paying investor should purchase.

Alternatively, we could compute a municipal’s equivalent taxable yield, which is what a taxable bond investment would have to offer to produce the same after-tax return as the municipal. It is given by

\[
\text{ Equivalent Taxable Yield} = (\text{Municipal Yield}) \times (1 - \text{Marginal Tax Rate})
\]

To illustrate, if an investor is in the 28 percent marginal tax bracket, a taxable investment yield of 8 percent has an after-tax yield of 8 percent \times (1 - 0.28) or 5.76 percent; an equivalent-risk municipal security offering a yield greater than 5.76 percent offers the investor greater after-tax returns. On the other hand, a municipal bond yielding 6 percent has an equivalent taxable yield of: 6 percent \div (1 - 0.28) = 8.33 percent; to earn more money after taxes, an equivalent-risk taxable investment has to offer a return greater than 8.33 percent.

There are other means of reducing investment tax liabilities. Contributions to an IRA (individual retirement account) may qualify as a tax deduction if certain income limits are met. Even without that deduction, taxes on any investment returns of an IRA, including any income, are deferred until the funds are withdrawn from the account. Any funds withdrawn from an IRA are taxable as current income, regardless of whether growth in the IRA occurs as a result of capital gains, income, or both. For this reason, to minimize taxes advisors recommend investing in stocks in taxable accounts and in bonds in tax-deferred accounts such as IRAs. When funds are withdrawn from a tax-deferred account such as a regular IRA, assets are taxed (at most) at a 35 percent income tax rate (Exhibit 2.6) — even if the source of the stock return is primarily capital gains. In a taxable account, capital gains are taxed at the maximum 15 percent capital gains rate. Decisions regarding IRAs (including Roth IRAs) are very important, but the details of such decisions are beyond the purpose of this book. Therefore, we recommend that investors discuss these decisions with a tax consultant or financial planner.

### Legal and Regulatory Factors

Both the investment process and the financial markets are highly regulated and subject to numerous laws. At times, these legal and regulatory factors constrain the investment strategies of individuals and institutions.

For example, funds removed from a regular IRA, Roth IRA, or 401(k) plan before age 59½ are taxable and subject to an additional 10 percent withdrawal penalty. You may also be.

such as common stock can provide. Still, because of the time horizon constraint, the 25-year-old can have a greater proportion of his portfolio in equities—including stocks in small firms, as well as international and emerging market firms—than the 65-year-old.

**Tax Concerns** Investment planning is complicated by the tax code; taxes complicate the situation even more if international investments are part of the portfolio. Taxable income from interest, dividends, or rents is taxable at the investor’s marginal tax rate. The marginal tax rate is the proportion of the next one dollar in income paid as taxes. Exhibit 2.6 shows the marginal tax rates for different levels of taxable income. As of 2011, the top federal marginal tax rate was 35 percent.

Capital gains or losses arise from asset price changes. They are taxed differently than income. Income is taxed when it is received; capital gains or losses are taxed only when an asset is sold and the gain or loss, relative to its initial cost or basis, is realized. **Unrealized capital gains** (or losses) reflect the price change in currently held assets that have not been sold; the tax liability on unrealized capital gains can be deferred indefinitely. If appreciated assets are passed on to an heir upon the investor’s death, the basis of the assets is considered to be their value on the date of the holder’s death. The heirs can then sell the assets and pay lower capital gains taxes if they wish. **Realized capital gains** occur when an appreciated asset is sold; taxes are due on the realized capital gains only. As of 2011, the maximum tax rate on stock dividends and long-term capital gains is 15 percent.

Some find the difference between average and marginal income tax rates confusing. The **marginal tax rate** is the part of each additional dollar in income that is paid as tax. Thus, a married person, filing jointly, with an income of $50,000 will have a marginal tax rate of 15 percent. The 15 percent marginal tax rate should be used to determine after-tax returns on investments.

The **average tax rate** is simply a person’s total tax payment divided by their total income. It represents the average tax paid on each dollar the person earned. From Exhibit 2.6, a married person, filing jointly, will pay $6,650 in tax on a $50,000 income [$1,700 + 0.15($50,000 – $17,000)]. This average tax rate is $6,650/$50,000 or 13.3 percent. Note that the average tax rate is a weighted average of the person’s marginal tax rates paid on each dollar of income.
The first $17,000 of income has a 10 percent marginal tax rate; the next $33,000 has a 15 percent marginal tax rate.

\[
\frac{17,000}{50,000} \times 0.10 + \frac{33,000}{50,000} \times 0.15 = 0.133, \text{ or the average tax rate of } 13.3 \text{ percent}
\]

Another tax factor is that some sources of investment income are exempt from federal and state taxes. For example, interest on federal securities, such as Treasury bills, notes, and bonds, is exempt from state taxes. Interest on municipal bonds (bonds issued by a state or other local governing body) is exempt from federal taxes. Further, if investors purchase municipal bonds issued by a local governing body of the state in which they live, the interest may be exempt from both state and federal income tax. Thus, high-income individuals have an incentive to purchase municipal bonds to reduce their tax liabilities.

The after-tax return on taxable investment income is

\[
\text{After-Tax Income Return} = \text{Pre-Tax Income Return} \times (1 - \text{Marginal Tax Rate})
\]

Thus, the after-tax return on a taxable bond investment should be compared to that of municipals before deciding which security a tax-paying investor should purchase. Alternatively, we could compute a municipal's equivalent taxable yield, which is what a taxable bond investment would have to offer to produce the same after-tax return as the municipal. It is given by

\[
\text{Equivalent Taxable Yield} = \frac{\text{Municipal Yield}}{1 - \text{Marginal Tax Rate}}
\]

To illustrate, if an investor is in the 28 percent marginal tax bracket, a taxable investment yield of 8 percent has an after-tax yield of 8 percent \((1 - 0.28)\) or 5.76 percent; an equivalent-risk municipal security offering a yield greater than 5.76 percent offers the investor greater after-tax returns. On the other hand, a municipal bond yielding 6 percent has an equivalent taxable yield of: 6 percent/(1 – 0.28) = 8.33 percent; to earn more money after taxes, an equivalent-risk taxable investment has to offer a return greater than 8.33 percent.

There are other means of reducing investment tax liabilities. Contributions to an IRA (individual retirement account) may qualify as a tax deduction if certain income limits are met. Even without that deduction, taxes on any investment returns of an IRA, including any income, are deferred until the funds are withdrawn from the account. Any funds withdrawn from an IRA are taxable as current income, regardless of whether growth in the IRA occurs as a result of capital gains, income, or both. For this reason, to minimize taxes advisors recommend investing in stocks in taxable accounts and in bonds in tax-deferred accounts such as IRAs. When funds are withdrawn from a tax-deferred account such as a regular IRA, assets are taxed (at most) at a 35 percent income tax rate (Exhibit 2.6)—even if the source of the stock return is primarily capital gains. In a taxable account, capital gains are taxed at the maximum 15 percent capital gains rate. Decisions regarding IRAs (including Roth IRAs) are very important, but the details of such decisions are beyond the purpose of this book. Therefore, we recommend that investors discuss these decisions with a tax consultant or financial planner.

**Legal and Regulatory Factors** Both the investment process and the financial markets are highly regulated and subject to numerous laws. At times, these legal and regulatory factors constrain the investment strategies of individuals and institutions.

For example, funds removed from a regular IRA, Roth IRA, or 401(k) plan before age 59½ are taxable and subject to an additional 10 percent withdrawal penalty. You may also be

familiar with the tag line in many bank CD advertisements—“substantial interest penalty upon early withdrawal.” Regulations and rules such as these may make such investments unattractive for investors with substantial liquidity needs in their portfolios.

Regulations can also constrain the investment choices available to someone in a fiduciary role. A fiduciary, or trustee, supervises an investment portfolio of a third party, such as a trust account or discretionary account. The fiduciary must make investment decisions in accordance with the owner’s wishes; a properly written policy statement assists this process. In addition, trustees of a trust account must meet the prudent-man standard, which means that they must invest and manage the funds as a prudent person would manage his or her own affairs. Notably, the prudent-man standard is based on the composition of the entire portfolio, not each individual asset.

All investors must respect certain laws, such as insider trading prohibitions against the purchase and sale of securities on the basis of important information that is not publicly known. Typically, the people possessing such private, or insider, information are the firm’s managers, who have a fiduciary duty to their shareholders. Security transactions based on access to insider information violates the fiduciary trust the shareholders have placed with management because the managers seek personal financial gain from their privileged position as agents for the shareholders.

For our typical 25-year-old investor, legal and regulatory matters will be of little concern, with the possible exception of insider trading laws and the penalties associated with early withdrawal of funds from tax-deferred retirement accounts. Should he seek a financial advisor to assist him in constructing a financial plan, that advisor would have to obey the regulations pertinent to a client-advisor relationship. Similar concerns confront our 65-year-old investor. In addition, as a retiree, if she wants to do estate planning and set up trust accounts, she should seek legal and tax advice to ensure that her plans are properly implemented.

**Unique Needs and Preferences** This category covers the individual and sometimes idiosyncratic concerns of each investor. Some investors may want to exclude certain investments from their portfolio solely on the basis of personal preference or for social consciousness reasons. For example, they may request that no firms that manufacture or sell tobacco, alcohol, pornography, or environmentally harmful products be included in their portfolio. Some mutual funds screen according to this type of social responsibility criterion.

Another example of a personal constraint is the time and expertise a person has for managing his or her portfolio. Busy executives may prefer to relax during nonworking hours and let a trusted advisor manage their investments. Retirees, on the other hand, may have the time but believe they lack the expertise to choose and monitor investments, so they also may seek professional advice.

In addition, a business owner with a large portion of her wealth—and emotion—tied up in her firm’s stock may be reluctant to sell even when it may be financially prudent to do so and then reinvest the proceeds for diversification purposes. Further, if the stock holdings are in a private company, it may be difficult to find a buyer unless shares are sold at a discount from their fair market value. Because each investor is unique, the implications of this final constraint differ for each person; there is no “typical” 25-year-old or 65-year-old investor. The point is, each individual will have to decide on—and then communicate—specific needs and preferences in a well-constructed policy statement.

---

2 A discretionary account is one in which the fiduciary, many times a financial planner or stockbroker, has the authority to purchase and sell assets in the owner’s portfolio without first receiving the owner’s approval.

3 As we will discuss in Chapter 7, it is sometimes wise to hold assets that are individually risky in the context of a well-diversified portfolio, even if the investor is strongly risk averse.
2.5 Constructing the Policy Statement

As we have seen, the policy statement allows the investor to communicate his or her objectives (risk and return) and constraints (liquidity, time horizon, tax, legal and regulatory, and unique needs and preferences). This communication gives the advisor a better chance of implementing an investment strategy that will satisfy the investor. Even if an advisor is not used, each investor needs to take this first important step of the investment process and develop a financial plan to guide the investment strategy. To do without a plan or to plan poorly is to place the success of the financial plan in jeopardy.

2.5.1 General Guidelines

Constructing a policy statement is the investor’s responsibility, but investment advisors often assist in the process. Here, for both the investor and the advisor, are guidelines for good policy statement construction.

In the process of constructing a policy statement, investors should think about the set of questions suggested previously on page 39.

When working with an investor to create a policy statement, an advisor should ensure that the policy statement satisfactorily answers the questions suggested previously on page 41.

2.5.2 Some Common Mistakes

When constructing their policy statements, participants in employer-sponsored retirement plans need to realize that in many such plans 30–40 percent of their retirement funds may be invested in their employer’s stock. Having so much money invested in one asset violates diversification principles and could be costly. To put this in context, most mutual funds are limited by law to having no more than 5 percent of their assets in any one company’s stock; a firm’s pension plan can invest no more than 10 percent of their funds in its own stock. As noted by Schulz (1996), individuals are unfortunately doing what government regulations prevent many institutional investors from doing. In addition, some studies point out that the average stock allocation in many retirement plans is lower than it should be if the investor wants growth of principal over time—that is, investors tend to be too conservative.

Another consideration is the issue of stock trading. A number of studies by Barber and Odean (1999, 2000, 2001) and Odean (1998, 1999) have shown that individual investors typically trade stocks too often (driving up commissions), sell stocks with gains too early (prior to further price increases), and hold on to losers too long (as the price continues to fall). These costly mistakes are especially true for men and online traders.

Investors, in general, seem to neglect that important first step to achieve financial success: They do not plan for the future. Studies of retirement plans discussed by Ruffinach (2001) and Clements (1997a, b, c) show that Americans are not saving enough to finance their retirement years and they are not planning sufficiently for what will happen to their savings after they retire. Around 25 percent of workers have saved less than $50,000 for their retirement. Finally, about 60 percent of workers surveyed confessed they were “behind schedule” in planning and saving for retirement.

2.6 The Importance of Asset Allocation

A major reason why investors develop policy statements is to provide guidance for an overall investment strategy. Though a policy statement does not indicate which specific securities to purchase and when they should be sold, it should provide guidelines as to the asset classes to include and a range of percents of the investor’s funds to invest in each class. How the investor divides funds into different asset classes is the process of asset allocation. Rather than
provide strict percentages, asset allocation is usually expressed in ranges. This allows the investment manager some freedom, based on his or her reading of capital market trends, to invest toward the upper or lower end of the ranges. For example, suppose a policy statement requires that common stocks be 60 percent to 80 percent of the value of the portfolio and that bonds should be 20 percent to 40 percent of the portfolio’s value. If a manager is particularly bullish about stocks, she will increase the allocation of stocks toward the 80 percent upper end of the equity range and decrease bonds toward the 20 percent lower end of the bond range. Should she be optimistic about bonds or bearish on stocks, that manager may shift the allocation closer to 40 percent invested in bonds with the remainder in equities.

A review of historical data and empirical studies provides strong support for the contention that the asset allocation decision is a critical component of the portfolio management process. In general, there are four decisions involved in constructing an investment strategy:

- What asset classes should be considered for investment?
- What policy weights should be assigned to each eligible asset class?
- What are the allowable allocation ranges based on policy weights?
- What specific securities or funds should be purchased for the portfolio?

The asset allocation decision involves the first three points. How important is the asset allocation decision to an investor? In a word, very. Several studies by Ibbotson and Kaplan (2000); Brinson, Hood, and Beebower (1986); and Brinson, Singer, and Beebower (1991) have examined the effect of the normal policy weights on investment performance, using data from both pension funds and mutual funds, during time periods extending from the early 1970s to the late 1990s. The studies all found similar results: About 90 percent of a fund’s returns over time can be explained by its target asset allocation policy. Exhibit 2.7 shows the relationship between returns on the target or policy portfolio allocation and actual returns on a sample mutual fund.

Rather than looking at just one fund and how the target asset allocation determines its returns, some studies have looked at how much the asset allocation policy affects returns on a variety of funds with different target weights. For example, Ibbotson and Kaplan (2000) found that, across a sample of funds, about 40 percent of the difference in fund returns is explained by differences in asset allocation policy. And what does asset allocation tell us about the level of a particular fund’s returns? The studies by Brinson and colleagues (1986, 1991) and Ibbotson and Kaplan (2000) answered that question as well. They divided the policy return (what the fund return would have been had it been invested in indexes at the policy weights) by the actual fund return (which includes the effects of varying from the policy weights and security selection). Thus, a fund that was passively invested at the target weights would have a ratio value of 1.0, or 100 percent. A fund managed by someone with skill in market timing (for moving in and out of asset classes) and security selection would have a ratio less than 1.0 (or less than 100 percent); the manager’s skill would result in a policy return less than the actual fund return. The studies showed the opposite: The policy-return/actual-return ratio averaged over 1.0, showing that asset allocation explains slightly more than 100 percent of the level of a fund’s returns. Because of market efficiency, fund managers practicing market timing and security selection, on average, have difficulty surpassing passively invested index returns, after taking into account the expenses and fees of investing.

Thus, asset allocation is a very important decision. Across all funds, the asset allocation decision explains an average of 40 percent of the variation in fund returns. For a single fund, asset allocation explains 90 percent of the fund’s variation in returns over time and slightly more than 100 percent of the average fund’s level of return.

Good investment managers may add some value to portfolio performance, but the major source of investment return—and risk—over time is the asset allocation decision (Brown, 2000).
and inflation. Municipal bonds, because of the protection they offer from taxes, earned an average annual real return of almost 4.05 percent during this time.

This historical analysis demonstrates that, for taxable investments, a reasonable way to maintain purchasing power over long time periods when investing in financial assets is to invest in common stocks. Put another way, an asset allocation decision for a taxable portfolio that does not include a substantial commitment to common stocks makes it difficult for the portfolio to maintain real value over time.

Notably, the fourth column, labeled "After inflation (only)," is more encouraging since it refers to results for a tax-free retirement account that is only impacted by inflation. These results should encourage investors to take advantage of tax-free opportunities.

2.6.2 Returns and Risks of Different Asset Classes

By focusing on returns, we have ignored its partner — risk. Assets with higher long-term returns have these returns to compensate for their risk. Exhibit 2.9 illustrates returns (unadjusted for inflation) and exhibits the returns after inflation and taxes. The returns are given for different asset classes, including common stocks (S&P 500), Barclays Capital Government Bond Index, Treasury bills (3 month constant maturity), and Municipal bonds (est.).

2.6.1 Investment Returns after Taxes and Inflation

Exhibit 2.8 provides additional historical perspectives on returns. It indicates how an investment of $1 would have grown over the 1986–2010 period and, using fairly conservative assumptions, examines how investment returns are affected by taxes and inflation.

Focusing first on stocks, funds invested in 1986 in the Standard & Poor’s 500 stocks would have averaged an 11.57 percent annual return through 2010. Unfortunately, this return is unrealistic because if the funds were invested over time, taxes would have to be paid and inflation would erode the real purchasing power of the invested funds.

Except for tax-exempt investors and tax-deferred accounts, annual tax payments reduce investment returns. Incorporating taxes into the analysis lowers the after-tax average annual return of a stock investment to 8.33 percent.

But the major reduction in the value of our investment is caused by inflation. The real after-tax average annual return on a stock over this time frame was only 5.50 percent, which is less than half our initial unadjusted 11.57 percent return!

This example shows the long-run impact of taxes and inflation on the real value of a stock portfolio. For bonds and bills, however, the results in Exhibit 2.8 show something even more surprising. After adjusting for taxes, long-term bonds maintained their purchasing power; T-bills barely provided value in real terms. One dollar invested in long-term government bonds in 1986 gave the investor an annual average after-tax real return of 2.47 percent. An investment in Treasury bills earned an average annual rate of only 0.15 percent after taxes.
inflation, transaction costs and taxes) for several asset classes over time. As expected, the higher returns available from equities (both large cap and small cap) also include higher risk. This is precisely why investors need a policy statement and why the investor and manager must understand the capital markets and have a disciplined approach to investing. Safe Treasury bills will sometimes outperform equities, and, because of their higher risk, common stocks will sometimes lose significant value. These are times when undisciplined and uneducated investors become frustrated, sell their stocks at a loss, and vow never to invest in equities again. In contrast, these are just the times when disciplined investors stick to their investment plan and position their portfolios for the next bull market. By holding on to their stocks and continuing to purchasing more at depressed prices, the equity portion of the portfolio will experience a substantial increase in the future.

The asset allocation decision determines to a great extent both the returns and the volatility of the portfolio. As noted, Exhibit 2.9 indicates that stocks are riskier than bonds or T-bills. Exhibit 2.10 shows that stocks have sometimes experienced returns lower than those of T-bills for extended periods of time. Still, the long-term results in Exhibit 2.9 show that sticking with an investment policy through difficult times provides attractive rates of return over long holding periods.

One popular way to measure risk is to examine the variability of returns over time by computing a standard deviation or variance of annual rates of return for an asset class. This measure, which is used in Exhibit 2.9, indicates that stocks are relatively risky and T-bills are relatively safe. Another intriguing measure of risk is the probability of not meeting your investment return objective. From this perspective, the results in Exhibit 2.10 show that if the investor has a long time horizon (i.e., approaching 20 years), the risk of equities is small and that of T-bills is large because of their differences in long-term expected returns.

capital appreciation, income, or even capital preservation over long time periods should stipulate a sizable allocation to the equity portion in their portfolio. As noted in this section, a strategy’s risk depends on the investor’s goals and time horizon. As demonstrated, investing in T-bills may actually be a riskier strategy than investing in common stocks due to the risk of not meeting long-term investment return goals, especially after considering the impact of inflation and taxes.

### Asset Allocation and Cultural Differences

Thus far, our analysis has focused on U.S. investors. Non-U.S. investors make their asset allocation decisions in much the same manner; but because they face different social, economic, political, and tax environments, their allocation decisions differ from those of U.S. investors. Exhibit 2.11 shows the equity allocations of pension funds in several countries. As shown, the equity allocations vary dramatically from 79 percent in Hong Kong to 37 percent in Japan and only 8 percent in Germany.

National demographic and economic differences can explain much of the divergent portfolio allocations. Of these six nations, the average age of the population is highest in Germany and Japan and lowest in the United States and the United Kingdom, which helps explain the greater use of equities in the United States and United Kingdom. Further, government privatization programs during the 1980s in the United Kingdom encouraged equity ownership among individual and institutional investors. In Germany, regulations prevent insurance firms from having more than 20 percent of their assets in equities. Both Germany and Japan have banking sectors that invest privately in firms and whose officers sit on corporate boards. Since 1980, the cost of living in the United Kingdom has increased at a rate about two times that of

inflation, transaction costs and taxes) for several asset classes over time. As expected, the higher returns available from equities (both large cap and small cap) also include higher risk. This is precisely why investors need a policy statement and why the investor and manager must understand the capital markets and have a disciplined approach to investing. Safe Treasury bills will sometimes outperform equities, and, because of their higher risk, common stocks will sometimes lose significant value. These are times when undisciplined and uneducated investors become frustrated, sell their stocks at a loss, and vow never to invest in equities again. In contrast, these are just the times when disciplined investors stick to their investment plan and position their portfolios for the next bull market. By holding on to their stocks and continuing to purchasing more at depressed prices, the equity portion of the portfolio will experience a substantial increase in the future.

The asset allocation decision determines to a great extent both the returns and the volatility of the portfolio. As noted, Exhibit 2.9 indicates that stocks are riskier than bonds or T-bills. Exhibit 2.10 shows that stocks have sometimes experienced returns lower than those of T-bills for extended periods of time. Still, the long-term results in Exhibit 2.9 show that sticking with an investment policy through difficult times provides attractive rates of return over long holding periods.6

One popular way to measure risk is to examine the variability of returns over time by computing a standard deviation or variance of annual rates of return for an asset class. This measure, which is used in Exhibit 2.9, indicates that stocks are relatively risky and T-bills are relatively safe. Another intriguing measure of risk is the probability of not meeting your investment return objective. From this perspective, the results in Exhibit 2.10 show that if the investor has a long time horizon (i.e., approaching 20 years), the risk of equities is small and that of T-bills is large because of their differences in long-term expected returns.

### 2.6.3 Asset Allocation Summary

A carefully constructed policy statement determines the types of assets that should be included in a portfolio. The asset allocation decision, not the selection of specific stocks and bonds, determines most of the portfolio’s returns over time. Although seemingly risky, investors seeking

6Newton’s law of gravity seems to work two ways in financial markets. What goes up must come down; but it also appears over time that what goes down may come back up. Contrarian investors and some “value” investors use this concept of reversion to the mean to try to outperform the indexes over time.

7The added benefits of diversification—combining different asset classes in the portfolio—may reduce overall portfolio risk without harming potential return. The important topic of diversification is discussed in detail in Chapter 7.
Germany and this inflationary bias in the U.K. economy again favors higher equity allocations. Exhibit 2.12 shows the positive relationship between the level of inflation in a country and its pension fund allocation to equity. These results and many others that could be mentioned indicate that some legislation, the general economic environment, and the demographics of a country have an effect on the asset allocation by the investors in the country.

**SUMMARY**

In this chapter, we saw that investors need to prudently manage risk within the context of their investment goals and preferences. Income, spending, and investing behavior will change over a person’s lifetime. We reviewed the importance of developing an investment policy statement before implementing an investment plan. By forcing investors to examine their needs, risk tolerance, and familiarity with the capital markets, policy statements help investors correctly identify appropriate objectives and constraints. In addition, the policy statement provides a standard by which to evaluate the performance of the portfolio manager.

We also reviewed the importance of the asset allocation decision in determining long-run portfolio investment returns and risks. Because the asset allocation decision follows setting the objectives and constraints, it is clear that the success of the investment program depends on the first step, the construction of the policy statement.

b. Recommend and justify a long-term asset allocation that is consistent with the investment policy statement you created in Part a. Briefly explain the key assumptions you made in generating your allocation.

PROBLEMS

1. Suppose your first job pays you $28,000 annually. What percentage should your cash reserve contain? How much life insurance should you carry if you are unmarried? How much if you are married with two young children?

2. Using Exhibit 2.6, what is the marginal tax rate for a couple, filing jointly, if their taxable income is $20,000? $40,000? $60,000? What is their tax bill for each of these income levels? What is the average tax rate for each of these income levels?

3. What is the marginal tax rate for a single individual if her taxable income is $20,000? $40,000? $60,000? What is her tax bill for each of these income levels? What is her average tax rate for each of these income levels?

4. a. Someone in the 36 percent tax bracket can earn 9 percent annually on her investments in a tax-exempt IRA account. What will be the value of a one-time $10,000 investment in 5 years? 10 years? 20 years?

   b. Suppose the preceding 9 percent return is taxable rather than tax-deferred and the taxes are paid annually. What will be the after-tax value of her $10,000 investment after 5, 10, and 20 years?

5. a. Someone in the 15 percent tax bracket can earn 10 percent on his investments in a tax-exempt IRA account. What will be the value of a $10,000 investment in 5 years? 10 years? 20 years?

   b. Suppose the preceding 10 percent return is taxable rather than tax-deferred. What will be the after-tax value of his $10,000 investment after 5, 10, and 20 years?

6. Assume that the rate of inflation during all these periods was 3 percent a year. Compute the real value of the two tax-deferred portfolios in problems 4a and 5a.

QUESTIONS

1. “Young people with little wealth should not invest money in risky assets such as the stock market, because they can’t afford to lose what little money they have.” Do you agree or disagree with this statement? Why?

2. Your healthy 63-year-old neighbor is about to retire and comes to you for advice. From talking with her, you find out she was planning on taking all the money out of her company’s retirement plan and investing it in bond mutual funds and money market funds. What advice should you give her?

3. Discuss how an individual’s investment strategy may change as he or she goes through the accumulation, consolidation, spending, and gifting phases of life.

4. Why is a policy statement important?

5. Use the questionnaire “How much risk is right for you?” (Exhibit 2.4) to determine your risk tolerance. Use this information to help write a policy statement for yourself.

6. Your 45-year-old uncle is 20 years away from retirement; your 35-year-old older sister is about 30 years away from retirement. How might their investment policy statements differ?

7. What information is necessary before a financial planner can assist a person in constructing an investment policy statement?

8. Use the Internet to find the home pages for some financial-planning firms. What strategies do they emphasize? What do they say about their asset allocation strategy? What are their firms’ emphases—for example, value investing, international diversification, principal preservation, retirement and estate planning?

9. Mr. Franklin is 70 years of age, is in excellent health, pursues a simple but active lifestyle, and has no children. He has interest in a private company for $90 million and has decided that a medical research foundation will receive half the proceeds now and will be the primary beneficiary of his estate upon his death. Mr. Franklin is committed to the foundation’s well-being because he believes strongly that, through it, a cure will be found for the disease that killed his wife. He now realizes that an appropriate investment policy and asset allocations are required if his goals are to be met through investment of his considerable assets. Currently, the following assets are available for use in building an appropriate portfolio for him:

   $45.0 million cash (from sale of the private company interest, net of a $45 million gift to the foundation)
   $10.0 million stocks and bonds ($5 million each)
   $ 9.0 million warehouse property (now fully leased)
   $ 1.0 million value of his residence
   $65.0 million total available assets

   a. Formulate and justify an investment policy statement setting forth the appropriate guidelines within which future investment actions should take place. Your policy statement should encompass all relevant objective and constraint considerations.
b. Recommend and justify a long-term asset allocation that is consistent with the investment policy statement you created in Part a. Briefly explain the key assumptions you made in generating your allocation.

Objectives and Constraints of Institutional Investors

Institutional investors manage large amounts of funds in the course of their business. They include mutual funds, pension funds, insurance firms, endowments, and banks. In this appendix, we review the characteristics of various institutional investors and discuss their typical investment objectives and constraints.

Mutual Funds

A mutual fund pools sums of money from investors, which are then invested in financial assets. Each mutual fund has its own investment objective, such as capital appreciation, high current income, or money market income. A mutual fund will state its investment objective, and investors choose the funds in which to invest. Two basic constraints face mutual funds: those created by law to protect mutual fund investors and those that represent choices made by the mutual fund’s managers. Some of these constraints will be discussed in the mutual fund’s prospectus, which must be given to all prospective investors before they purchase shares in a mutual fund. Mutual funds are discussed in more detail in Chapter 24.

Pension Funds

Pension funds are a major component of retirement planning for individuals. As of 2011, U.S. pension assets were nearly $21 trillion. Basically, a firm’s pension fund receives contributions from the firm, its employees, or both. The funds are invested with the purpose of giving workers either a lump-sum payment or the promise of an income stream after their retirement.

**Defined benefit pension plans** promise to pay retirees a specific income stream after retirement. The size of the benefit is usually based on factors that include the worker’s salary, or time of service, or both. The company contributes a certain amount each year to the pension plan; the size of the contribution depends on assumptions concerning future salary increases and the rate of return to be earned on the plan’s assets. Under a defined benefit plan, the company carries the risk of paying the future pension benefit to retirees; should investment performance be poor, or should the company be unable to make adequate contributions to the plan, the shortfall must be made up in future years. “Poor” investment performance means the actual return on the plan’s assets fell below the assumed actuarial rate of return. The actuarial rate is the discount rate used to find the present value of the plan’s future obligations and thus this rate determines the size of the firm’s annual contribution to the pension plan.

**Defined contribution pension plans** do not promise set benefits but only specified contributions to the plan. As a result, employees’ benefits depend on the size of the contributions made to the pension fund and the returns earned on the fund’s investments. Thus, the plan’s risk related to the rates of return on investments is borne by the employee. Unlike a defined benefit plan, employees’ retirement income is not an obligation of the firm.

A pension plan’s objectives and constraints depend on whether the plan is a defined benefit plan or a defined contribution plan. We review each separately below.

Defined Benefit The plan’s risk tolerance depends on the plan’s funding status and its actuarial rate. For **underfunded plans** (where the present value of the fund’s liabilities to employees exceeds the value of the fund’s assets), a more conservative approach toward risk is taken to ensure that the funding gap is closed over time. This may entail a strategy whereby the firm makes larger plan contributions and assumes a lower actuarial rate. **Overfunded plans** (where the present value of the pension liabilities is less than the plan’s assets) allow a more aggressive investment strategy, which implies a higher actuarial rate. This allows the firm to reduce its contributions and increases the risk exposure of the plan. The return objective is to meet the
Life Insurance Companies

Except for firms dealing only in term life insurance, life insurance firms collect premiums during a person’s lifetime that must be invested until a death benefit is paid to the insurance contract’s beneficiaries. At any time, the insured can turn in her policy and receive its cash surrender value. Discussing investment policy for an insurance firm is also complicated by the insurance industry’s proliferation of insurance and quasi-investment products.

Basically, an insurance company wants to earn a positive “spread,” which is the difference between the rate of return on investment minus the rate of return it credits its various policyholders. This concept is similar to a defined benefit pension fund that tries to earn a rate of return in excess of its actuarial rate. If the spread is positive, the insurance firm’s surplus reserve account rises; if not, the surplus account declines by an amount reflecting the negative spread. A growing surplus is an important competitive tool for life insurance companies. Attractive investment returns allow the company to advertise better policy returns than those of its competitors. A growing surplus also allows the firm to offer new products and expand insurance volume.

Because life insurance companies are quasi-trust funds for savings, fiduciary principles limit the risk tolerance of the invested funds. The National Association of Insurance Commissioners (NAIC) establishes risk categories for bonds and stocks; companies with excessive investments in higher-risk categories must set aside extra funds in a mandatory securities valuation reserve (MSVR) to protect policyholders against losses.

Insurance Companies

The investment objectives and constraints for an insurance company depend on whether it is a life insurance company or a nonlife (such as a property and casualty) insurance firm.
**Life Insurance Companies** Except for firms dealing only in term life insurance, life insurance firms collect premiums during a person’s lifetime that must be invested until a death benefit is paid to the insurance contract’s beneficiaries. At any time, the insured can turn in her policy and receive its cash surrender value. Discussing investment policy for an insurance firm is also complicated by the insurance industry’s proliferation of insurance and quasi-investment products.

Basically, an insurance company wants to earn a positive “spread,” which is the difference between the rate of return on investment minus the rate of return it credits its various policyholders. This concept is similar to a defined benefit pension fund that tries to earn a rate of return in excess of its actuarial rate. If the spread is positive, the insurance firm’s surplus reserve account rises; if not, the surplus account declines by an amount reflecting the negative spread. A growing surplus is an important competitive tool for life insurance companies. Attractive investment returns allow the company to advertise better policy returns than those of its competitors. A growing surplus also allows the firm to offer new products and expand insurance volume.

Because life insurance companies are quasi-trust funds for savings, fiduciary principles limit the risk tolerance of the invested funds. The National Association of Insurance Commissioners (NAIC) establishes risk categories for bonds and stocks; companies with excessive investments in higher-risk categories must set aside extra funds in a mandatory securities valuation reserve (MSVR) to protect policyholders against losses.

Insurance companies’ liquidity needs have increased over the years due to increases in policy surrenders and product-mix changes. A company’s time horizon depends upon its specific product mix. Life insurance policies require longer-term investments, whereas guaranteed insurance contracts (GICs) and shorter-term annuities require shorter investment time horizons.

Tax rules changed considerably for insurance firms in the 1980s. For tax purposes, investment returns are divided into two components: first, the policyholder’s share, which is the return portion covering the actuarially assumed rate of return needed to fund reserves; and second, the balance that is transferred to reserves. Unlike pensions and endowments, life insurance firms pay income and capital gains taxes at the corporate tax rates on the returns transferred to reserves.

Except for the NAIC, most insurance regulation is on the state level. Regulators oversee the eligible asset classes and the reserves (MSVR) necessary for each asset class and enforce the “prudent-expert” investment standard. Audits ensure that various accounting rules and investment regulations are followed.

**Nonlife Insurance Companies** Cash outflows are somewhat predictable for life insurance firms, based on their mortality tables. In contrast, the cash flows required by major accidents, disasters, and lawsuit settlements are not as predictable for nonlife insurance firms.

Due to their fiduciary responsibility to claimants, risk exposures are low to moderate. Depending on the specific company and competitive pressures, premiums may be affected by both the probability of a claim and the investment returns earned by the firm. Typically, casualty insurance firms invest their insurance reserves in relatively safe bonds to provide needed income to pay claims; capital and surplus funds are invested in equities for their growth potential. As with life insurers, property and casualty firms have a stronger competitive position when their surplus accounts are larger than those of their competitors. Many insurers now focus on a total return objective as a means to increase their surplus accounts over time.

Because of uncertain claim patterns, liquidity is a concern for property and casualty insurers who also want liquidity so they can switch between taxable and tax-exempt investments as their underwriting activities generate losses and profits. The time horizon for investments is typically shorter than that of life insurers, although many invest in long-term bonds to earn the higher yields available on these instruments. Investing strategy for the firm’s surplus account focuses on long-term growth.
Regulation of property and casualty firms is more permissive than for life insurers. Similar to life companies, states regulate classes and quality of investments for a certain percentage of the firm’s assets. Beyond this restriction, insurers can invest in many different types and qualities of instruments, although some states limit the proportion that can be invested in real estate assets.

**Banks**

Pension funds, endowments, and insurance firms obtain virtually free funds for investment purposes. Not so with banks. To have funds to lend, they must attract investors in a competitive interest rate environment. They compete against other banks and also against companies that offer other investment vehicles, from bonds to common stocks. A bank’s success relies primarily on its ability to generate returns in excess of its funding costs.

A bank tries to maintain a positive difference between its cost of funds and its returns on assets. If banks anticipate falling interest rates, they will try to invest in longer-term assets to lock in the returns while seeking short-term deposits, whose interest cost is expected to fall over time. When banks expect rising rates, they will try to lock in longer-term deposits with fixed-interest costs, while investing funds short term to capture rising interest rates. The risk of such strategies is that losses may occur should a bank incorrectly forecast the direction of interest rates. The aggressiveness of a bank’s strategy will be related to the size of its capital ratio and the oversight of regulators.

Banks need substantial liquidity to meet withdrawals and loan demand. A bank has two forms of liquidity. *Internal liquidity* is provided by a bank’s investment portfolio that includes highly liquid assets. A bank has *external liquidity* if it can borrow funds in the federal funds markets (where banks lend reserves to other banks), from the Federal Reserve Bank’s discount window, or if it can sell certificates of deposit at attractive rates.

Banks have a short time horizon for several reasons. First, they have a strong need for liquidity. Second, because they want to maintain an adequate interest revenue–interest expense spread, they generally focus on shorter-term investments to avoid interest rate risk and to avoid getting “locked in” to a long-term revenue source. Third, because banks typically offer short-term deposit accounts (demand deposits, NOW accounts, and such) they need to match the maturity of their assets and liabilities to avoid taking undue risks. This desire to match the maturity of assets and liabilities is shared by virtually all financial institutions.

Banks are heavily regulated by numerous state and federal agencies. The Federal Reserve Board, the Comptroller of the Currency, and the Federal Deposit Insurance Corporation all oversee various components of bank operations. The Glass-Steagall Act restricts the equity investments that banks can make. Unique situations that affect each bank’s investment policy depend on their size, market, and management skills in matching asset and liability sensitivity to interest rates. For example, a bank in a small community may have many customers who deposit their money with it for the sake of convenience. A bank in a more populated area will find its deposit flows are more sensitive to interest rates and competition from nearby banks.

**Institutional Investment Summary**

Among the great variety of institutions, each institution has its “typical” investment objectives and constraints. This discussion has indicated the differences that exist among types of institutions and some of the major issues confronting them. Notably, just as with individual investors, “cookie-cutter” policy statements are inappropriate for institutional investors. The specific objectives, constraints, and investment strategies must be determined on a case-by-case basis.
CHAPTER 3
Selecting Investments in a Global Market

After you read this chapter, you should be able to answer the following questions:

1. Why should investors have a global perspective regarding their investments?
2. What has happened to the relative size of U.S. and foreign stock and bond markets?
3. What are the differences in the rates of return on U.S. and foreign securities markets?
4. How can changes in currency exchange rates affect the returns that U.S. investors experience on foreign securities?
5. Is there additional advantage to diversifying in international markets beyond the benefits of domestic diversification?
6. What alternative securities are available? What are their cash flow and risk properties?
7. What are the historical return and risk characteristics of the major investment instruments?
8. What is the relationship among the returns for foreign and domestic investment instruments?
9. What is the implication of these relationships for portfolio diversification?

Individuals are willing to defer current consumption for many reasons. Some save for their children's college tuition or their own; others wish to accumulate down payments for a home, car, or boat; others want to amass adequate retirement funds for the future. Whatever the reasons for an investment program, the techniques we used in Chapter 1 to measure risk and return will help you evaluate alternative investments. But what are those alternative investments? Thus far, we have said little about the investment opportunities available in financial markets. In this chapter, we address this issue by surveying investment alternatives. This is essential background for making the asset allocation decision discussed in Chapter 2 and for later chapters where we analyze several individual investments, such as bonds, common stock, and other securities. It is also important when we consider how to construct and evaluate portfolios of investments.

As an investor in the 21st century, you have an array of investment choices unavailable a few decades ago. As discussed by Miller (1991), a combination of dynamic financial markets, technological advances, and new regulations have resulted in numerous new investment instruments and expanded trading opportunities. Improvements in communications and relaxation of international regulations have made it easier for investors to trade in both domestic and global markets. Telecommunications networks enable U.S. brokers to reach security exchanges in London, Tokyo, and other European and Asian cities as easily as those in New York, Chicago, and other U.S. cities. The competitive environment in the brokerage industry and the deregulation of the banking sector have made it possible for more financial institutions to compete for investor dollars.

All of his has spawned investment vehicles with a variety of maturity, risk-return characteristics, and cash flow patterns. In this chapter, we examine some of these choices. As an investor, you need to understand the differences among investments so you can build a properly diversified portfolio that conforms to your objectives. That is, you should seek to acquire a group of investments with different patterns of returns over time. If chosen carefully, such portfolios minimize risk for a given level of return because low or negative rates of return on some investments during a period of time are offset by above-average returns on others. Your goal should be to build a balanced portfolio of investments with relatively stable overall rates of return. A major goal of this text is to help you understand and evaluate the risk-return characteristics of investment portfolios. An appreciation of alternative security types is the starting point for this analysis.

This chapter is divided into three main sections. Because investors can choose securities from around the world, we initially look at a combination of reasons why investors should include foreign as well as domestic securities in their portfolios. Taken together, these reasons provide a compelling case for global investing. In the second section of this chapter, we discuss securities in domestic and global markets, describing their main features and cash flow patterns. You will see that the varying risk-return characteristics of alternative investments suit the preferences of different investors. The third and final section contains the historical risk and return performance of several investment instruments from around the world and examines the relationship among the returns for many of these securities. These results provide strong empirical support for global investing.

3.1 The Case for Global Investments

Twenty years ago, the bulk of investments available to individual investors consisted of U.S. stocks and bonds. Now, however, a call to your broker gives you access to a wide range of securities sold throughout the world. Currently, you can purchase stock in General Motors or Toyota, U.S. Treasury bonds or Japanese government bonds, a mutual fund that invests in U.S. biotechnology companies, a global growth stock fund, a German or Chinese stock fund, or options on a U.S. stock index.

Several changes have caused this explosion of investment opportunities. For one, the growth and development of numerous foreign financial markets, such as those in Japan, the United Kingdom, and Germany, as well as emerging markets, such as China and India, have made these markets accessible and viable for investors around the world. U.S. investment firms have recognized this opportunity and established facilities in these countries aided by advances in telecommunications technology that allow constant contact with offices and financial markets around the world. In addition to the efforts by U.S. firms, foreign firms and investors undertook counterbalancing initiatives, including significant mergers of firms and security exchanges. As a result, as described by Pardee (1987), investors and investment firms can easily trade securities in markets around the world.

There are three interrelated reasons U.S. investors should think of constructing global investment portfolios:

1. When investors compare the absolute and relative sizes of U.S. and foreign markets for stocks and bonds, they see that ignoring foreign markets reduces their choices to less.

Individuals are willing to defer current consumption for many reasons. Some save for their children’s college tuition or their own; others wish to accumulate down payments for a home, car, or boat; others want to amass adequate retirement funds for the future. Whatever the reasons for an investment program, the techniques we used in Chapter 1 to measure risk and return will help you evaluate alternative investments.

But what are those alternative investments? Thus far, we have said little about the investment opportunities available in financial markets. In this chapter, we address this issue by surveying investment alternatives. This is essential background for making the asset allocation decision discussed in Chapter 2 and for later chapters where we analyze several individual investments, such as bonds, common stock, and other securities. It is also important when we consider how to construct and evaluate portfolios of investments.

As an investor in the 21st century, you have an array of investment choices unavailable a few decades ago. As discussed by Miller (1991), a combination of dynamic financial markets, technological advances, and new regulations have resulted in numerous new investment instruments and expanded trading opportunities. Improvements in communications and relaxation of international regulations have made it easier for investors to trade in both domestic and global markets. Telecommunications networks enable U.S. brokers to reach security exchanges in London, Tokyo, and other European and Asian cities as easily as those in New York, Chicago, and other U.S. cities. The competitive environment in the brokerage industry and the deregulation of the banking sector have made it possible for more financial institutions to compete for investor dollars.

*The authors acknowledge data collection help on this chapter from Edgar Norton of Illinois State University and David J. Wright from the University of Wisconsin–Parkside.
All of this has spawned investment vehicles with a variety of maturities, risk-return characteristics, and cash flow patterns. In this chapter, we examine some of these choices.

As an investor, you need to understand the differences among investments so you can build a properly diversified portfolio that conforms to your objectives. That is, you should seek to acquire a group of investments with different patterns of returns over time. If chosen carefully, such portfolios minimize risk for a given level of return because low or negative rates of return on some investments during a period of time are offset by above-average returns on others. Your goal should be to build a balanced portfolio of investments with relatively stable overall rates of return. A major goal of this text is to help you understand and evaluate the risk-return characteristics of investment portfolios. An appreciation of alternative security types is the starting point for this analysis.

This chapter is divided into three main sections. Because investors can choose securities from around the world, we initially look at a combination of reasons why investors should include foreign as well as domestic securities in their portfolios. Taken together, these reasons provide a compelling case for global investing.

In the second section of this chapter, we discuss securities in domestic and global markets, describing their main features and cash flow patterns. You will see that the varying risk-return characteristics of alternative investments suit the preferences of different investors.

The third and final section contains the historical risk and return performance of several investment instruments from around the world and examines the relationship among the returns for many of these securities. These results provide strong empirical support for global investing.

### 3.1 The Case for Global Investments

Twenty years ago, the bulk of investments available to individual investors consisted of U.S. stocks and bonds. Now, however, a call to your broker gives you access to a wide range of securities sold throughout the world. Currently, you can purchase stock in General Motors or Toyota, U.S. Treasury bonds or Japanese government bonds, a mutual fund that invests in U.S. biotechnology companies, a global growth stock fund, a German or Chinese stock fund, or options on a U.S. stock index.

Several changes have caused this explosion of investment opportunities. For one, the growth and development of numerous foreign financial markets, such as those in Japan, the United Kingdom, and Germany, as well as emerging markets, such as China and India, have made these markets accessible and viable for investors around the world. U.S. investment firms have recognized this opportunity and established facilities in these countries aided by advances in telecommunications technology that allow constant contact with offices and financial markets around the world. In addition to the efforts by U.S. firms, foreign firms and investors undertook counterbalancing initiatives, including significant mergers of firms and security exchanges. As a result, as described by Pardee (1987), investors and investment firms can easily trade securities in markets around the world.

There are three interrelated reasons U.S. investors should think of constructing global investment portfolios:

1. When investors compare the absolute and relative sizes of U.S. and foreign markets for stocks and bonds, they see that ignoring foreign markets reduces their choices to less
than 50 percent of available investment opportunities. Because more opportunities broaden your range of risk-return choices, it makes sense to evaluate foreign securities when selecting investments and building a portfolio.

2. The rates of return available on non-U.S. securities often have substantially exceeded those for U.S.-only securities. The higher returns on non-U.S. equities can be justified by the higher growth rates for the countries where they are issued.

3. A major tenet of investment theory is that investors should diversify their portfolios. Because the relevant factor when diversifying a portfolio is low correlation between asset returns over time, diversification with foreign securities that have very low correlation with U.S. securities can substantially reduce portfolio risk.

In this section, we analyze these reasons to demonstrate the advantages to a growing role of foreign financial markets for U.S. investors and to assess the benefits and risks of trading in these markets. Notably, the reasons that global investing is appropriate for U.S. investors are generally even more compelling for non-U.S. investors.

3.1.1 Relative Size of U.S. Financial Markets

Prior to 1970, the securities traded in the U.S. stock and bond markets comprised about 65 percent of all the securities available in world capital markets. Therefore, a U.S. investor selecting securities strictly from U.S. markets had a fairly complete set of investments available. Under these conditions, most U.S. investors probably believed that it was not worth the time and effort to expand their investment universe to include the limited investments available in foreign markets. That situation has changed dramatically over the past 40 plus years. Currently, investors who ignore foreign stock and bond markets limit their investment choices substantially.

Exhibit 3.1 shows the breakdown of securities available in world capital markets in 1969 and 2010. Not only has the overall value of all securities increased dramatically (from $2.3 trillion to $113.6 trillion), but the composition has also changed. Concentrating on proportions of bond and equity investments, the exhibit shows that in 1969 U.S. dollar bonds and U.S. equity securities made up 53 percent of the total value of all securities versus 28.4 percent for the total of nondollar bonds and equity. By 2010, U.S. bonds and equities accounted for 42.6 percent.
of the total securities market versus 47.2 percent for nondollar bonds and stocks. These data indicate that if you consider only the U.S. proportion of this combined stock and bond market, it has declined from 65 percent of the total in 1969 to about 47 percent in 2010.

The point is, the U.S. security markets now include a substantially smaller proportion of the total world capital market, and this trend will almost certainly continue. The faster economic growth of many other countries compared to the United States will require foreign governments and individual companies to issue debt and equity securities to finance this growth. Therefore, U.S. investors should consider investing in foreign securities because of the growing importance of these foreign securities in world capital markets. Put another way, not investing in foreign stocks and bonds means you are ignoring over 50 percent of the securities that are available to you. This approximate 50–50 breakdown is about the same for bonds alone, while U.S. stocks are only about 42 percent of global stocks.

### 3.1.2 Rates of Return on U.S. and Foreign Securities

An examination of the rates of return on U.S. and foreign securities not only demonstrates that many non-U.S. securities provide superior rates of return but also shows the impact of the exchange rate risk discussed in Chapter 1.

**Global Bond-Market Returns** Exhibit 3.2 reports annual rates of return for several major international bond markets for 1986–2010. The returns have been converted to U.S. dollar returns, so the exhibit shows mean annual returns and standard deviations that a U.S.-based investor would receive. An analysis of the returns in Exhibit 3.2 indicates that the return performance of the U.S. bond market ranked fifth out of the six countries. Part of the reason for the better performance in dollar terms of the non-U.S. markets is that the dollar generally weakened during this time frame, giving U.S. investors a boost to their foreign returns. Put another way, U.S. investors who invested in these foreign bonds received the return on the bonds equal to that of local investors, but also received a return for holding the foreign currency that appreciated relative to the U.S. dollar.

**Global Equity-Market Returns** Exhibit 3.3 shows the annual returns in U.S. dollars for 34 major equity markets yearly from 2007 through 2010. The United States’ average rank in U.S. dollar returns in 2007–2010 was 17.5 out of 34 countries (and it was only in the top 10 once). Its performance was typically behind the returns of numerous stock markets in these years.

These results for equity and bond markets around the world indicate that investors who limit themselves to the U.S. market may well experience rates of return below those in many other countries.

### 3.1.3 Risk of Combined Country Investments

Thus far, we have discussed the risk and return results for individual countries. In Chapter 1, we considered the idea of combining a number of assets into a portfolio and noted that

The way to measure whether two investments will contribute to diversifying a portfolio is to compute the correlation coefficient between their rates of return over time. Correlation coefficients can range from +1.00 to −1.00. A correlation of +1.00 means that the rates of return for these two investments move exactly together. Combining investments that move exactly together in a portfolio would not help diversify the portfolio because they have identical rate-of-return patterns over time. In contrast, a correlation coefficient of −1.00 means that the rates of return for two investments move exactly opposite to each other. When one investment is experiencing above-average rates of return, the other is suffering through similar below-average rates of return. Combining two investments with large negative correlation in a portfolio would be ideal for diversification because it would stabilize the rates of return over time, reducing the standard deviation of the portfolio rates of return and hence the risk of the portfolio. Therefore, if you want to diversify your portfolio and reduce your risk, you want an investment that has either low positive correlation, zero correlation, or, ideally, negative correlation with the other investments in your portfolio. With this in mind, the following discussion considers the correlations of returns among U.S. bonds and stocks with the returns on foreign bonds and stocks.

Global Bond Portfolio Risk

Exhibit 3.4 lists the correlation coefficients between rates of return for bonds in the United States and bonds in major foreign markets in U.S. dollar terms from 1986–2010. For a U.S. investor, these important correlations averaged only 0.58. These relatively low positive correlations among returns in U.S. dollars mean that U.S. investors have substantial opportunities for risk reduction through global diversification of bond portfolios. A U.S. investor who bought bonds in these non-U.S. markets especially Japan would reduce the standard deviation of a well-diversified U.S. bond portfolio.

Why do these correlation coefficients for returns between U.S. bonds and those of various foreign countries differ? That is, why is the U.S.-Canada correlation 0.75, whereas the U.S.-Japan correlation is only 0.34? The answer is because the international trade patterns, economic growth, fiscal policies, and monetary policies of the countries differ. We do not have an integrated world economy but, rather, a collection of economies that are related to one another in different ways. As an example, the U.S. and Canadian economies are closely related because of their geographic proximity, similar domestic economic policies, and the extensive trade between them. Each is the other’s largest trading partner. In contrast, the United States has less trade with Japan and the fiscal and monetary policies of the two countries differ dramatically. For example, the U.S. economy was growing during much of the 1990s while the Japanese economy experienced a prolonged recession.

The point is, macroeconomic differences cause the correlation of bond returns between the United States and each country to likewise differ. These differing correlations make it worthwhile to diversify the portfolio internationally.

We discussed how proper diversification reduces the variability (our measure of risk) of the portfolio because alternative investments have different patterns of returns over time. Specifically, when the rates of return on some investments are negative or below average, potentially other investments in the portfolio will be experiencing above-average rates of return. Therefore, if a portfolio is properly diversified, it should provide a more stable rate of return for the total portfolio (that is, it will have a lower standard deviation and therefore less risk). Although we will discuss and demonstrate portfolio theory in detail in Chapter 7, we need to consider the concept at this point to fully understand the benefits of global investing.
The way to measure whether two investments will contribute to diversifying a portfolio is to compute the correlation coefficient between their rates of return over time. Correlation coefficients can range from +1.00 to −1.00. A correlation of +1.00 means that the rates of return for these two investments move exactly together. Combining investments that move exactly together in a portfolio would not help diversify the portfolio because they have identical rate-of-return patterns over time. In contrast, a correlation coefficient of −1.00 means that the rates of return for two investments move exactly opposite to each other. When one investment is experiencing above-average rates of return, the other is suffering through similar below-average rates of return. Combining two investments with large negative correlation in a portfolio would be ideal for diversification because it would stabilize the rates of return over time, reducing the standard deviation of the portfolio rates of return and hence the risk of the portfolio. Therefore, if you want to diversify your portfolio and reduce your risk, you want an investment that has either low positive correlation, zero correlation, or, ideally, negative correlation with the other investments in your portfolio. With this in mind, the following discussion considers the correlations of returns among U.S. bonds and stocks with the returns on foreign bonds and stocks.

Global Bond Portfolio Risk Exhibit 3.4 lists the correlation coefficients between rates of return for bonds in the United States and bonds in major foreign markets in U.S. dollar terms from 1986–2010. For a U.S. investor, these important correlations averaged only 0.58.

A U.S. investor who bought bonds in these non-U.S. markets especially Japan would reduce the standard deviation of a well-diversified U.S. bond portfolio.

Why do these correlation coefficients for returns between U.S. bonds and those of various foreign countries differ? to diversify with foreign bonds, and the different correlations indicate which countries will provide the greatest reduction in the standard deviation (risk) of bond portfolio returns for a U.S. investor.

Also, the correlation of returns between a single pair of countries changes over time because the factors influencing the correlations, such as international trade, economic growth, fiscal policy, and monetary policy, change over time. A change in any of these variables will produce a change in how the economies are related and a change in the relationship between returns on bonds. For example, the correlation in U.S. dollar returns between U.S. and Japanese bonds was 0.07 in the late 1960s and 1970s; it was 0.35 in the 1980s and 0.25 in the 1990s but only about 0.30 in the 2000–2010 time frame.

Exhibit 3.5 shows what happens to the risk-return trade-off when we combine U.S. and foreign bonds. A comparison of a completely non-U.S. portfolio (100 percent foreign) and a 100 percent U.S. portfolio indicates that the non-U.S. portfolio has both a higher rate of return and a higher standard deviation of returns than the U.S. portfolio. Combining the two portfolios in different proportions provides an interesting set of points.

As we will discuss in Chapter 7, the expected rate of return is a weighted average of the two portfolios. In contrast, the risk (standard deviation) of the combination is not a weighted average but also depends on the correlation between the two portfolios. In this example, the risk levels of the combined portfolios decline below those of the individual portfolios. Therefore, by adding foreign bonds that have low correlation with a portfolio of U.S. bonds, a U.S. investor is able to not only increase the expected rate of return but also reduce the risk compared to a total U.S. bond portfolio.

**Global Equity Portfolio Risk** The correlation of world equity markets resembles that for bonds. Exhibit 3.6 lists the correlation coefficients between monthly equity returns in U.S. dollars.
stocks indicated a consistent pattern of relatively low positive correlations. Therefore, the existence of similar rates of return on foreign securities combined with low correlation coefficients indicates that adding foreign stocks and bonds to a U.S. portfolio will almost certainly reduce the risk of the portfolio and can possibly increase its average return.

Given the several compelling reasons for adding foreign securities to a U.S. portfolio, investors should develop a global investment perspective because this approach is clearly justified, and this trend toward global investing is expected to continue. Implementing this new global investment perspective will not be easy because it requires an understanding of new terms, instruments (such as Eurobonds), and institutions (such as non-U.S. stock and bond markets). Still, the effort is justified because you are developing a set of skills and a way of thinking that will enhance your long-term investing results.

The next section presents an overview of investment alternatives from around the world, beginning with fixed-income investments and progressing through numerous alternatives.

of each country and the U.S. market for the period from 1988 to 2010. Only 4 of the 11 correlations between U.S. dollar returns were over 0.70, and the average correlation was only 0.65.

These relatively small positive correlations between U.S. stocks and foreign stocks have similar implications to those derived for bonds. Investors can reduce the overall risk of their stock portfolios by including foreign stocks.

Exhibit 3.7 demonstrates the impact of international equity diversification. These curves demonstrate that, as you increase the number of randomly selected securities in a portfolio, the standard deviation will decline due to the benefits of diversification within your own country. This is referred to as domestic diversification. After a certain number of securities (40 to 50), the curve will flatten out at a risk level that reflects the basic market risk for the domestic economy (see Campbell, Lettau, Malkiel, and Xu [2001]). The lower curve illustrates the benefits of international diversification. This curve demonstrates that adding foreign securities to a U.S. portfolio to create a global portfolio enables an investor to experience lower overall risk because the non-U.S. securities are not correlated with our economy or our stock market, allowing the investor to eliminate some of the basic market risks of the U.S. economy.

To see how this works, consider, for example, the effect of inflation and interest rates on all U.S. securities. As discussed in Chapter 1, all U.S. securities will be affected by these variables. In contrast, a Japanese stock is mainly affected by what happens in the Japanese economy and will typically not be affected by changes in U.S. variables. Thus, adding Japanese, Australian, and Italian stocks to a U.S. stock portfolio reduces the portfolio risk of the global portfolio to a level that reflects only worldwide systematic factors.

Summary on Global Investing At this point, we have considered the relative size of the market for non-U.S. bonds and stocks and found that it has grown in size and importance, becoming too big to ignore. We have also examined the rates of return for foreign bond and stock investments and determined that, when considering results, their rates of return were often superior to those in the U.S. market. Finally, we discussed constructing a portfolio of investments and the importance of diversification in reducing the variability of returns over time, which reduces the risk of the portfolio. As noted, to have successful diversification, an investor should combine investments with low positive or negative correlations between rates of return. An analysis of the correlation between rates of return on U.S. and foreign bonds and
stocks indicated a consistent pattern of relatively low positive correlations. Therefore, the existence of similar rates of return on foreign securities combined with low correlation coefficients indicates that adding foreign stocks and bonds to a U.S. portfolio will almost certainly reduce the risk of the portfolio and can possibly increase its average return.

Given the several compelling reasons for adding foreign securities to a U.S. portfolio, investors should develop a global investment perspective because this approach is clearly justified, and this trend toward global investing is expected to continue. Implementing this new global investment perspective will not be easy because it requires an understanding of new terms, instruments (such as Eurobonds), and institutions (such as non-U.S. stock and bond markets). Still, the effort is justified because you are developing a set of skills and a way of thinking that will enhance your long-term investing results.

The next section presents an overview of investment alternatives from around the world, beginning with fixed-income investments and progressing through numerous alternatives.

### 3.2 Global Investment Choices

This section provides an important foundation for subsequent chapters in which we describe techniques to value individual investments and combine alternative investments into properly diversified portfolios that conform to your risk-return objectives. In this section, we briefly describe the numerous investment alternatives available. This survey introduces each of these investment alternatives so you can appreciate the full spectrum of opportunities. Most of these assets will be described in greater detail in subsequent chapters.

The investments are divided by asset classes. First, we describe fixed-income investments, including bonds and preferred stocks. In the second subsection, we discuss equity investments,
and the third subsection contains a discussion of special equity instruments, such as warrants and options, which have characteristics of both fixed-income and equity instruments. In subsection four, we consider futures contracts that allow for a wide range of return-risk profiles. The fifth subsection considers investment companies.

All these investments are called financial assets because their payoffs are in money. In contrast, real assets, such as real estate, are discussed in the sixth subsection. We conclude with assets that are considered low liquidity investments because of the relative difficulty in buying and selling them. This includes art, antiques, coins, stamps, and precious gems.

The final section of the chapter presents the historical return and risk patterns for many individual investment alternatives and the correlations among the returns for these investments. This additional background and perspective will help you evaluate individual investments in order to build a properly diversified portfolio of global investments.

3.2.1 Fixed-Income Investments

Fixed-income investments have a contractually mandated payment schedule. Their investment contracts promise specific payments at predetermined times, although the legal force behind the promise varies and this affects their risks and required returns. At one extreme, if the issuing firm does not make its payment at the appointed time, creditors can declare the issuing firm in default. In other cases (for example, income bonds), the issuing firm must make payments only if it earns profits. In yet other instances (for example, preferred stock), the issuing firm does not have to make dividend payments unless its board of directors votes to do so.

Investors who acquire fixed-income securities (except preferred stock) are really lenders to the issuers. Specifically, you lend some amount of money, the principal, to the borrower. In return, the borrower typically promises to make periodic interest payments and to pay back the principal at the maturity of the loan.

Savings Accounts You might not think of savings accounts as fixed-income investments, yet an individual who deposits funds in a savings account at a financial institution is really lending money to the institution and, as a result, earning a fixed payment. These investments are considered to be convenient, liquid, and low risk because almost all are insured. Consequently, their rates of return are generally low compared with other alternatives. Several versions of these accounts have been developed to appeal to investors with differing objectives.

Passbook savings accounts have no minimum balance, and funds may be withdrawn at any time with little loss of interest. Due to their flexibility, the promised interest on passbook accounts is relatively low.

For investors with larger amounts of funds who are willing to give up liquidity, financial institutions developed certificates of deposit (CDs), which require minimum deposits (typically $500) and have fixed durations (usually three months, six months, one year, two years). The promised rates on CDs are higher than those for passbook savings accounts, and the rate increases with the size and the duration of the deposit. An investor who wants to cash in a CD prior to its stated expiration date must pay a heavy penalty in the form of a much lower interest rate.

Investors with large sums of money ($10,000 or more) can invest in Treasury bills (T-bills)—short-term obligations (maturing in 3–12 months) of the U.S. government. To compete against T-bills, banks issue money market certificates, which require minimum investments of $10,000 and have minimum maturities of six months. The promised rate on these certificates fluctuates at some premium over the weekly rate on six-month T-bills. Investors can redeem these certificates only at the bank of issue, and they incur penalties if they withdraw their funds before maturity.

Capital Market Instruments Capital market instruments are fixed-income obligations that trade in the secondary market, which means you can buy and sell them to other individuals or
provisions and sinking funds. Call provisions specify when a firm can issue a call for the bonds prior to their maturity, at which time current bondholders must submit the bonds to the issuing firm, which redeems them (that is, pays back the principal and a small premium). A sinking fund provision specifies payments the issuer must make to redeem a given percentage of the outstanding issue prior to maturity.

Corporate bonds fall into various categories based on their contractual promises to investors. They will be discussed in order of their seniority. Secured bonds are the most senior bonds in a firm’s capital structure and have the lowest risk of distress or default. They include various secured issues that differ based on the assets that are pledged. Mortgage bonds are backed by liens on specific assets, such as land and buildings. In the case of default, the proceeds from the sale of these assets are used to pay off the mortgage bondholders. Collateral trust bonds are a form of mortgage bond except that the assets backing the bonds are financial assets, such as stocks, notes, and other high-quality bonds. Finally, equipment trust certificates are mortgage bonds that are secured by specific pieces of transportation equipment, such as locomotives and boxcars for a railroad and airplanes for an airline.

Debentures are promises to pay interest and principal, but they pledge no specific assets (referred to as collateral) in case the firm does not fulfill its promise. This means that the bondholder depends on the success of the borrower to make the promised payment. Debenture owners usually have first call on the firm’s earnings and any assets that are not already pledged by the firm as backing for senior secured bonds. If the issuer does not make an interest payment, the debenture owners can declare the firm bankrupt and claim any unpledged assets to pay off the bonds.

Subordinated bonds are similar to debentures, but, in the case of default, subordinated bondholders have claim to the assets of the firm only after the firm has satisfied the claims of all senior secured and debenture bondholders. That is, the claims of subordinated issues are secondary to those of other bondholders. Within this general category of subordinated issues, you can find senior subordinated, subordinated, and junior subordinated bonds. Junior subordinated bonds have the weakest claim of all bondholders.

Income bonds stipulate interest payment schedules, but the interest is due and payable only if the issuers earn the income to make the payment by stipulated dates. If the company does not earn the required amount, it does not have to make the interest payment and it cannot be declared in default. Instead, the interest payment is considered in arrears and, if subsequently earned, it must be paid off. Because the issuing firm is not legally bound to make its interest payments except when the firm earns it, an income bond is not considered as safe as a debenture or a mortgage bond, so income bonds offer higher returns to compensate investors for the added risk. There are a limited number of corporate income bonds. In contrast, income bonds are fairly popular with municipalities because municipal revenue bonds discussed previously are basically income bonds.

Convertible bonds have the interest and principal characteristics of other bonds, with the added feature that the bondholder has the option to turn them back to the firm in exchange for its common stock. For example, a firm could issue a $1,000 face-value bond and stipulate that owners of the bond could turn the bond in to the issuing corporation and convert it into 40 shares of the firm’s common stock. These bonds appeal to investors because they combine the features of a fixed-income security with the option of conversion into the common stock of the firm, should the firm prosper.

Because of their desirable conversion option, convertible bonds generally pay lower interest rates than nonconvertible debentures of comparable risk. The difference in the required interest rate increases with the growth potential of the company because this growth potential 74 Part 1: The Investment Background

Institutions. Capital market instruments fall into four categories: (1) U.S. Treasury securities, (2) U.S. government agency securities, (3) municipal bonds, and (4) corporate bonds.

**U.S. Treasury Securities** All government securities issued by the U.S. Treasury are fixed-income instruments. They may be bills, notes, or bonds depending on their initial times to maturity. Specifically, bills mature in one year or less, notes in over one to 10 years, and bonds in more than 10 years from time of issue. U.S. government obligations are essentially free of credit risk because there is little chance of default and they are highly liquid.

**U.S. Government Agency Securities** Agency securities are sold by various agencies of the government to support specific programs, but they are not direct obligations of the Treasury. Examples of agencies that issue these bonds include the Federal National Mortgage Association (FNMA or Fannie Mae), and the Federal Home Loan Mortgage Corporation (Freddie Mac) which sells bonds and uses the proceeds to purchase mortgages from insurance companies or savings and loans; and the Federal Home Loan Bank (FHLB), which sells bonds and loans the money to its 12 banks, which in turn provide credit to savings and loans and other mortgage-granting institutions. Other agencies are the Government National Mortgage Association (GNMA or Ginnie Mae), Banks for Cooperatives, Federal Land Banks (FLBs), and the Federal Housing Administration (FHA).

Although the securities issued by federal agencies (except GNMA) are not direct obligations of the government (they are not officially guaranteed by the Treasury), they have been considered default-free because it was believed that the government would not allow them to default.¹

**Municipal Bonds** Municipal bonds are issued by local government entities as either general obligation or revenue bonds. General obligation bonds (GOs) are backed by the full taxing power of the municipality. In contrast, revenue bonds pay the interest from revenue generated by specific projects (e.g., the revenue to pay the interest on sewer bonds comes from water taxes).

Municipal bonds differ from other fixed-income securities because they are tax-exempt. The interest earned from them is exempt from taxation by the federal government and historically by some states that issued the bond, provided the investor is a resident of that state. For this reason, municipal bonds are popular with investors in high tax brackets. For an investor having a marginal tax rate of 35 percent, a regular bond with an interest rate of 8 percent yields a net return after taxes of only 5.20 percent \((0.08 \times (1 - 0.35))\). Such an investor would prefer a tax-free bond of equal risk with a 6 percent yield. This allows municipal bonds to offer yields that are generally 20 to 30 percent lower than yields on comparable taxable bonds. As will be discussed in Chapter 17, this relationship changed temporarily in 2010 and 2011 for several reasons. We will also discuss taxable municipal bonds.

**Corporate Bonds** Corporate bonds are fixed-income securities issued by industrial corporations, public utility corporations, or railroads to raise funds to invest in plant, equipment, or working capital. They can be broken down by issuer (industrial or utility), in terms of credit quality (measured by the ratings assigned by an agency on the basis of probability of default), in terms of maturity (short term, intermediate term, or long term), or based on some component of the indenture (sinking fund or call feature). Historically, corporate bonds have been substantially less liquid than Treasury or agency bonds, but the difference has declined due to real-time quotes for about 6,000 bonds on the NYSE and improved acquisition alternatives, described by Kim (2007).

All bonds include an indenture, which is the legal agreement that lists the obligations of the issuer to the bondholder, including the payment schedule and features such as call

¹During the market crash of 2006–2009, this belief was tested when Fannie and Freddie were taken over by the federal government. This set of events will be discussed further in Chapter 17.
provisions and sinking funds. Call provisions specify when a firm can issue a call for the bonds prior to their maturity, at which time current bondholders must submit the bonds to the issuing firm, which redeems them (that is, pays back the principal and a small premium). A sinking fund provision specifies payments the issuer must make to redeem a given percentage of the outstanding issue prior to maturity.

Corporate bonds fall into various categories based on their contractual promises to investors. They will be discussed in order of their seniority.

**Secured bonds** are the most senior bonds in a firm’s capital structure and have the lowest risk of distress or default. They include various secured issues that differ based on the assets that are pledged. **Mortgage bonds** are backed by liens on specific assets, such as land and buildings. In the case of default, the proceeds from the sale of these assets are used to pay off the mortgage bondholders. **Collateral trust bonds** are a form of mortgage bond except that the assets backing the bonds are financial assets, such as stocks, notes, and other high-quality bonds. Finally, **equipment trust certificates** are mortgage bonds that are secured by specific pieces of transportation equipment, such as locomotives and boxcars for a railroad and airplanes for an airline.

**Debentures** are promises to pay interest and principal, but they pledge no specific assets (referred to as collateral) in case the firm does not fulfill its promise. This means that the bondholder depends on the success of the borrower to make the promised payment. Debenture owners usually have first call on the firm’s earnings and any assets that are not already pledged by the firm as backing for senior secured bonds. If the issuer does not make an interest payment, the debenture owners can declare the firm bankrupt and claim any unpledged assets to pay off the bonds.

**Subordinated bonds** are similar to debentures, but, in the case of default, subordinated bondholders have claim to the assets of the firm only after the firm has satisfied the claims of all senior secured and debenture bondholders. That is, the claims of subordinated bondholders are secondary to those of other bondholders. Within this general category of subordinated issues, you can find senior subordinated, subordinated, and junior subordinated bonds. Junior subordinated bonds have the weakest claim of all bondholders.

**Income bonds** stipulate interest payment schedules, but the interest is due and payable only if the issuers earn the income to make the payment by stipulated dates. If the company does not earn the required amount, it does not have to make the interest payment and it cannot be declared in default. Instead, the interest payment is considered in arrears and, if subsequently earned, it must be paid off. Because the issuing firm is not legally bound to make its interest payments except when the firm earns it, an income bond is not considered as safe as a debenture or a mortgage bond, so income bonds offer higher returns to compensate investors for the added risk. There are a limited number of corporate income bonds. In contrast, income bonds are fairly popular with municipalities because municipal revenue bonds discussed previously are basically income bonds.

**Convertible bonds** have the interest and principal characteristics of other bonds, with the added feature that the bondholder has the option to turn them back to the firm in exchange for its common stock. For example, a firm could issue a $1,000 face-value bond and stipulate that owners of the bond could turn the bond in to the issuing corporation and convert it into 40 shares of the firm’s common stock. These bonds appeal to investors because they combine the features of a fixed-income security with the option of conversion into the common stock of the firm, should the firm prosper.

Because of their desirable conversion option, convertible bonds generally pay lower interest rates than nonconvertible debentures of comparable risk. The difference in the required interest rate increases with the growth potential of the company because this growth potential
increases the value of the option to convert the bonds into common stock. These bonds are almost always subordinated to the nonconvertible debt of the firm, so they are considered to have higher credit risk and receive a lower credit rating from the bond rating firms.

An alternative to convertible bonds is a debenture with warrants attached. The **warrant** is likewise an option that allows the bondholder to purchase the firm’s common stock from the firm at a specified price for a given time period. The specified purchase price for the stock set in the warrant is typically above the price of the stock at the time the bond issues the bond but below the expected future stock price. The warrant makes the debenture more desirable, which lowers its required yield. The warrant also provides the firm with future common stock capital because when the bond holder exercises the warrant, he/she buys the stock from the firm.

Unlike the typical bond that pays interest every six months and its face value at maturity, a **zero coupon bond** promises no interest payments during the life of the bond but only the payment of the principal at maturity. Therefore, the purchase price of the bond is the present value of the principal payment at the required rate of return. For example, the price of a zero coupon bond that promises to pay $10,000 in five years with a required rate of return of 8 percent is $6,756. To find this, assuming semiannual compounding (which is the norm), use the present value factor for 10 periods at 4 percent, which is 0.6756.

**Preferred Stock** **Preferred stock** is classified as a fixed-income security because its yearly payment is stipulated as either a coupon (for example, 5 percent of the face value) or a stated dollar amount (for example, $5 preferred). Preferred stock differs from bonds because its payment is a dividend and therefore not legally binding. For each period, the firm’s board of directors must vote to pay it, similar to a common stock dividend. Even if the firm earned enough money to pay the preferred stock dividend, the board of directors could theoretically vote to withhold it. Because most preferred stock is cumulative, the unpaid dividends would accumulate to be paid in full at a later time.

Although preferred dividends are not legally binding, as are the interest payments on a bond, they are considered **practically** binding because of the credit implications of a missed dividend. Because corporations can exclude 80 percent of intercompany dividends from taxable income, preferred stocks have become attractive investments for financial corporations. For example, a corporation that owns preferred stock of another firm and receives $100 in dividends can exclude 80 percent of this amount and pay taxes on only 20 percent of it ($20). Assuming a 40 percent tax rate, the tax would only be $8 or 8 percent versus 40 percent on other investment income. Due to this tax benefit to corporations, the yield on high-grade preferred stock is typically lower than that on high-grade bonds.

### 3.2.2 International Bond Investing

As noted earlier, more than half of all fixed-income securities available to U.S. investors are issued by firms in countries outside the United States. Investors identify these securities in different ways: by the country or city of the issuer (for example, United States, United Kingdom, Japan); by the location of the primary trading market (for example, United States, London); by the home country of the major buyers; and by the currency in which the securities are denominated (for example, dollars, yen, euros). We identify foreign bonds by their country of origin and include these other differences in each description.

A **Eurobond** is an international bond denominated in a currency not native to the country where it is issued. Specific kinds of Eurobonds include Eurodollar bonds, Euroyen bonds, and Eurosterling bonds. A Eurodollar bond is denominated in U.S. dollars and sold outside the United States to non-U.S. investors. A specific example would be a U.S. dollar bond issued by General Electric and sold in London. Eurobonds are typically issued in Europe, with the major concentration in London.
Acquiring Foreign Equities

We begin our discussion on foreign equities by considering how you buy and sell these securities because this procedural information has often been a major impediment. Many investors may recognize the desirability of investing in foreign common stock because of the risk and return characteristics discussed earlier, but they may be intimidated by the logistics of the transaction. This section attempts to alleviate this concern by explaining the alternatives available. Currently, there are several ways to acquire foreign common stock:

1. Purchase or sale of American Depository Receipts (ADRs)
2. Purchase or sale of American shares
3. Direct purchase or sale of foreign shares listed on a U.S. or foreign stock exchange
4. Purchase or sale of international or global mutual funds or exchange-traded funds (ETFs)

Purchase or Sale of American Depository Receipts

The easiest way to acquire shares of an individual foreign company directly is through American Depository Receipts (ADRs). These are certificates of ownership issued by a U.S. bank that represent indirect ownership of a certain number of shares of a specific foreign firm on deposit in a bank in the firm’s home country. ADRs are a convenient way to own foreign shares because the investor buys and sells them in U.S. dollars and receives all dividends in U.S. dollars. Therefore, the price and returns reflect both the domestic returns for the stock and the exchange rate effect. Also, the price of an ADR can reflect the fact that it represents multiple shares—for example, an ADR can be for 5 or 10 shares of the foreign stock. ADRs can be issued at the discretion of a bank based on the demand for the stock. The shareholder absorbs the additional handling costs of an ADR through higher transfer expenses, which are deducted from dividend payments.

ADRs are quite popular in the United States because of their diversification benefits, as documented by Wahab and Khandwala (1993). At the end of 2010, 474 foreign companies had stocks listed on the New York Stock Exchange (NYSE) and 361 of these were available through ADRs, including all the stock listed from Japan, the United Kingdom, Australia, Mexico, and the Netherlands.

Purchase or Sale of American Shares

American shares are securities issued in the United States by a transfer agent acting on behalf of a foreign firm. Because of the added effort and expense incurred by the foreign firm, a limited number of American shares are available.

Direct Purchase or Sale of Foreign Shares

The most difficult and complicated foreign equity transaction takes place in the country where the firm is located because it must be carried out in the foreign currency and the shares must then be transferred to the United States. This routine can be cumbersome. A second alternative is a transaction on a foreign stock exchange outside the country where the securities originated. For example, if you acquired shares of a French auto company listed on the London Stock Exchange (LSE), the shares would be denominated in pounds and the transfer would be swift, assuming your broker has a membership on the LSE.

Finally, you could purchase foreign stocks listed on the NYSE or NASDAQ. This is similar to buying a U.S. stock, but only a limited number of foreign firms qualify for—and are willing to accept—the cost of listing. Still, this number is growing. At the end of 2010, more than 110 foreign firms (mostly Canadian) were directly listed on the NYSE, in addition to the firms that were available through ADRs. Also, many foreign firms are traded on the NASDAQ market.

Purchase or Sale of Global Mutual Funds or ETFs

Numerous mutual funds or exchange-traded funds (ETFs) make it possible for investors to indirectly acquire the stocks of firms from outside the United States. The alternatives range from global funds, which invest in both U.S. stocks and foreign stocks, to international funds, which invest almost wholly outside the United States. In turn, international funds can (1) diversify across many countries, (2) gain exposure to specific industries, and (3) provide liquidity. The advantages of investing in international funds include lower taxes, lower fees, and better diversification. However, there are also disadvantages, such as higher transaction costs and currency risk. As shown, this is reflected in relative return volatility.

3.2.3 Equity Instruments

This section describes several equity instruments, which differ from fixed-income securities because their returns are not contractual. As a result, you can receive returns that are much better or much worse than what you would receive on a bond. We begin with common stock, the most popular equity instrument and probably the most popular investment instrument.

Common stock represents ownership of a firm. Owners of the common stock of a firm share in the company’s successes and problems. If—like Walmart, Microsoft, Google, or Apple—the company prospers, the investor receives high rates of return and can become wealthy. In contrast, the investor can lose money if the firm does not do well or even goes bankrupt, as in the case of K-Mart, Enron, W. T. Grant, and several U.S. airlines all did. In these instances, the firm may be forced to liquidate its assets and pay off all its creditors. Notably, the firm’s preferred stockholders and common stock owners receive what is left, which is usually little or nothing. Investing in common stock entails all the advantages and disadvantages of ownership and is a relatively risky investment compared to fixed-income securities. As shown, this is reflected in relative return volatility.

Common Stock Classifications

When considering an investment in common stock, people tend to divide the vast universe of stocks into categories based on general business lines and by industry within these business lines. The division includes broad classifications for industrial firms, utilities, transportation firms, and financial institutions. Within each of these broad classes are specific industries. The industrial group, which is very diverse, includes such industries as automobiles, industrial machinery, chemicals, and beverages. Utilities include electrical power companies, gas suppliers, and the water industry. Transportation includes airlines, trucking firms, and railways. Financial institutions include commercial banks, insurance companies, and investment firms.

An alternative classification scheme might separate domestic (U.S.) and foreign common stocks. We avoid this division because the business-line-industry breakdown is more appropriate and useful when constructing a diversified portfolio of global common stock investments. With a global capital market, the focus of analysis should include all the companies in an industry viewed in a global setting. The point is, it is not relevant whether a major chemical firm is located in the United States or Germany, just as it is not relevant whether a computer firm is located in Michigan or California. Therefore, when considering the automobile industry, it is necessary to go beyond pure U.S. auto firms like General Motors and Ford and consider auto firms from throughout the world, such as Honda Motors, Porsche, Daimler, Nissan, Toyota, and Fiat.

Trade for wheat in September, December, March, and May of the next year. If the investor expected the price of a commodity to rise, he or she could buy a futures contract on one of the commodity exchanges for later sale. If the investor expected the price to fall, he or she could sell a futures contract on an exchange with the expectation of buying similar contracts later when the price had (hopefully) declined to cover the sale.

Several differences exist between investing in an asset through a futures contract and investing in the asset itself. One is the use of a small good-faith deposit, which increases the volatility of returns. Because an investor puts up only a small portion of the total value of the futures contract (10 to 15 percent), when the price of the commodity changes, the change in the total value of the contract (up or down) is large compared to the amount invested. Another unique aspect is the term of the investment: Although stocks can have infinite maturities, futures contracts typically expire in less than a year.

**Financial Futures**

In addition to futures contracts on commodities, there also has been the development of futures contracts on financial instruments, such as T-bills, Treasury bonds, and Eurobonds. For example, it is possible to buy or sell a futures contract that promises future delivery of $100,000 of Treasury bonds at a set price and yield. The major exchanges for financial futures are the Chicago Mercantile Exchange (CME) and the Chicago Board of Trade (CBOT).

These futures contracts allow individual investors, bond portfolio managers, and corporate financial managers to protect themselves against volatile interest rates. Certain currency futures allow individual investors or portfolio managers to speculate on or to protect against changes in currency exchange rates. Finally, there are futures contracts on various stock market series, such as the S&P (Standard & Poor’s) 500, the Value Line Index, and the Nikkei Average on the Tokyo Stock Exchange.

### 3.2.6 Investment Companies

The investment alternatives described so far are individual securities that can be acquired from a government entity, a corporation, or another individual. However, rather than directly buying an individual stock or bond issued by one of these sources, you may choose to acquire these investments indirectly by buying shares in an investment company that owns a portfolio of individual stocks, bonds, or a combination of the two. Specifically, an investment company sells shares in itself and invests the pooled investor dollars in bonds, stocks, or other investment instruments. The main types of investment companies are mutual funds, closed-end funds, and exchange-traded funds.

**Mutual funds** are also referred to as open-ended funds because they issue "redeemable securities" meaning that the fund stands ready to buy or sell the shares at their net asset value with (a load) or without (no-load) a transaction fee. A closed-end fund issues a fixed number of shares that trade intraday on stock exchanges at market-determined prices. Investors in a closed-end fund buy or sell shares through a broker just like any publicly traded company. An **exchange traded fund (ETF)** is an investment company, typically a mutual fund whose shares are traded intraday on stock exchanges at market-determined prices—in contrast to open-ended funds that are priced only once a day at the market closing prices. Investors may buy or sell ETF shares through a broker just as they would the shares of any publicly traded company.

An investor who acquires shares in an investment company is a partial owner of the investment company’s portfolio of stocks or bonds. In the following discussion we will distinguish between investment companies by the types of investment instruments they acquire.

**Money Market Funds**

Money market funds are investment companies that acquire high-quality, short-term investments (referred to as money market instruments), such as T-bills, and other similar securities. These two exchanges merged in early 2008.

### 3.2.4 Special Equity Instruments: Options

In addition to common stock investments, it is also possible to invest in equity-derivative securities, which are securities that have a claim on the common stock of a firm. This would include options—rights to buy or sell common stock at a specified price for a stated period of time. The two kinds of option instruments are: (1) warrants and (2) puts and calls.

**Warrants** As mentioned earlier, a warrant is an option issued by a corporation that gives the holder the right to acquire a firm’s common stock from the company at a specified price within a designated time period. The warrant does not constitute ownership of the stock, only the option to buy the stock.

**Puts and Calls** A call option is similar to a warrant because it is an option to buy the common stock of a company within a certain period at a specified price called the striking price. A call option differs from a warrant because it is not issued by the company but by another investor who is willing to assume the other side of the transaction. Options also are typically valid for a shorter time period than warrants. Call options are generally valid for less than a year, whereas warrants often extend more than five years. The holder of a put option has the right to sell a given stock at a specified price during a designated time period. Puts are useful to investors who expect a stock price to decline during the specified period or to investors who own the stock and want hedge protection from a price decline.

### 3.2.5 Futures Contracts

Another instrument that provides an alternative to the purchase of an investment is a futures contract. This agreement provides for the future exchange of a particular asset at a specified delivery date (usually within nine months) in exchange for a specified payment at the time of delivery. Although the full payment is not made until the delivery date, a good-faith deposit, the margin, is made to protect the seller. This is typically about 10 percent of the value of the contract.

The bulk of trading on the commodity exchanges is in futures contracts. The current price of the futures contract is determined by the participants’ beliefs about the future for the commodity. For example, in July of a given year, a trader could speculate on the Chicago Board of

Exchange-Traded Funds (ETFs)

A problem with open-ended mutual funds in general and index funds in particular is that they are only priced daily at the close of the market and all transactions take place at that price. As a result, if you are aware of changes taking place for the aggregate market due to some economic event during the day and want to buy or sell to take advantage of this, you can put in an order for a mutual fund, but it will not be executed until the end of the day at closing prices. In response to this problem, the AMEX in 1993 created an indexed fund tied to the S&P 500—that is, an exchange-traded fund, ETF—that could be traded continuously because the prices for the 500 stocks are updated continuously so it is possible to buy and sell this ETF like a share of stock, as noted previously. As discussed earlier in the section on buying foreign securities, ETFs have been created for numerous foreign and domestic indexes including the Morgan Stanley Capital International (MSCI) indexes. Bar- clay's Global Investors (BGI) have created "i shares," using the MSCI indexes for numerous individual countries. The performance of these ETFs have been analyzed by Khorana, Nelling, and Trester (1998). As noted earlier, the growth in the number and value of ETFs over the past decade has been substantial.

3.2.7 Real Estate

Like commodities, most investors view real estate as an interesting and profitable investment alternative but believe that it is only available to a small group of experts with a lot of capital to invest. In reality, some feasible real estate investments require no detailed expertise or large capital commitments. We will begin by considering low-capital alternatives.

Real Estate Investment Trusts (REITs)

A real estate investment trust is an investment fund designed to invest in various real estate properties. It is similar to a stock or bond mutual fund, except that the money provided by the investors is invested in property and buildings rather than in stocks and bonds. There are several types of REITs.

**Construction and development trusts** lend the money required by builders during the initial construction of a building.

**Mortgage trusts** provide the long-term financing for properties. Specifically, they acquire long-term mortgages on properties once construction is completed.

**Equity trusts** own various income-producing properties, such as office buildings, shopping centers, or apartment houses. Therefore, an investor who buys shares in an equity real estate investment trust is buying part of a portfolio of income-producing properties.

REITs have experienced periods of great popularity and significant depression in line with changes in the aggregate economy and the money market. Although they are subject to cyclical risks depending on the economic environment, they offer small investors a way to participate in real estate investments, as described by Hardy (1995), Kuhn (1996), and Myer and Webb (1993).

**Direct Real Estate Investment**

The most common type of direct real estate investment is the purchase of a home, which is the largest investment most people ever make. According to the Federal Home Loan Bank, the average cost of a single family house in early 2011 exceeds $155,000. The purchase of a home is considered an investment because the buyer pays a sum of money either all at once or over a number of years through a mortgage. For most people who are unable to pay cash for a house, the financial commitment includes a down payment (typically 10–20 percent of the purchase price) and specific mortgage payments over a 20- to 30-year period that amortize both the loan’s principal and interest due on the outstanding balance. Subsequently, a homeowner hopes to sell the house for its cost plus a gain.

**Raw Land**

Another direct real estate investment is the purchase of raw land with the intention of selling it in the future at a profit. During the time you own the land, you have negative cash flows caused by mortgage payments, property maintenance, and taxes. An obvious risk is

---

4Stock and bond indexes are discussed in Chapter 5.
the possible difficulty of selling it for an uncertain price. Raw land generally has low liquidity compared to most stocks and bonds. An alternative to buying and selling the raw land is the development of the land.

**Land Development**

Land development can involve buying raw land, dividing it into individual lots, and building houses on it. Alternatively, buying land and building a shopping mall would also be considered land development. This is a feasible form of investment but requires a substantial commitment of capital, time, and expertise. Although the risks can be high because of the commitment of time and capital, the rates of return from a successful housing or commercial development can be significant, as shown in studies by Goetzmann and Ibbotson (1990) and Ross and Zisler (1991). Diversification benefits are documented in Hudson-Wilson and Elbaum (1995).

**Rental Property**

Many investors with an interest in real estate investing acquire apartment buildings or houses with low down payments, with the intention of deriving enough income from the rents to pay the expenses of the structure, including the mortgage payments. For the first few years following the purchase, the investor generally has no reported income from the building because of tax-deductible expenses, including the interest component of the mortgage payment and depreciation on the structure. Subsequently, rental property provides a cash flow and an opportunity to profit from the sale of the property, as discussed by Harris (1984).

### 3.2.8 Low-Liquidity Investments

Most of the investment alternatives we have described thus far are traded on securities markets and except for real estate, have good liquidity. In contrast, the investments we discuss in this section have very poor liquidity and financial institutions do not typically acquire them because of the illiquidity and high transaction costs compared to stocks and bonds. Many of these assets are sold at auctions, causing expected prices to vary substantially. In addition, transaction costs are high because there is generally no national market for these investments, so local dealers must be compensated for the added carrying costs and the cost of searching for buyers or sellers. Therefore, many financial theorists view the following low-liquidity investments more as hobbies than investments, even though studies have indicated that some of these assets have experienced substantial rates of return.

**Antiques**

The greatest returns from antiques are earned by dealers who acquire them at estate sales or auctions to refurbish and sell at a profit. If we gauge the value of antiques based on prices established at large public auctions, it appears that many serious collectors enjoy substantial rates of return. In contrast, the average investor who owns a few pieces to decorate his or her home finds such returns elusive. The high transaction costs and illiquidity of antiques may erode any profit that the individual may expect to earn when selling these pieces.

**Art**

The entertainment sections of newspapers or the personal finance sections of magazines often carry stories of the results of major art auctions, such as when Van Gogh’s *Irises* and *Sunflowers* sold for $59 million and $36 million, respectively. Obviously, these examples and others indicate that some paintings have increased significantly in value and thereby have generated large rates of return for their owners. However, investing in art typically requires substantial knowledge of art and the art world, a large amount of capital to acquire the work of well-known artists, patience, and an ability to absorb high transaction costs. For investors who enjoy fine art and have the resources, these can be satisfying investments; but, for most small investors, it is difficult to get returns that compensate for the uncertainty, illiquidity, and high transaction costs.

---

**Exchange-Traded Funds (ETFs)** A problem with open-ended mutual funds in general and index funds in particular is that they are only priced daily at the close of the market and all transactions take place at that price. As a result, if you are aware of changes taking place for the aggregate market due to some economic event during the day and want to buy or sell to take advantage of this, you can put in an order for a mutual fund, but it will not be executed until the end of the day at closing prices. In response to this problem, the AMEX in 1993 created an indexed fund tied to the S&P 500—that is, an exchange-traded fund, ETF—that could be traded continuously because the prices for the 500 stocks are updated continuously so it is possible to buy and sell this ETF like a share of stock, as noted previously. As discussed earlier in the section on buying foreign securities, ETFs have been created for numerous foreign and domestic indexes including the Morgan Stanley Capital International (MSCI) indexes. Barclay’s Global Investors (BGI) have created “i shares,” using the MSCI indexes for numerous individual countries. The performance of these ETFs have been analyzed by Khorana, Nelling, and Trester (1998). As noted earlier, the growth in the number and value of ETFs over the past decade has been substantial.

**3.2.7 Real Estate**

Like commodities, most investors view real estate as an interesting and profitable investment alternative but believe that it is only available to a small group of experts with a lot of capital to invest. In reality, some feasible real estate investments require no detailed expertise or large capital commitments. We will begin by considering low-capital alternatives.

**Real Estate Investment Trusts (REITs)** A real estate investment trust is an investment fund designed to invest in various real estate properties. It is similar to a stock or bond mutual fund, except that the money provided by the investors is invested in property and buildings rather than in stocks and bonds. There are several types of REITs.

*Construction and development trusts* lend the money required by builders during the initial construction of a building. *Mortgage trusts* provide the long-term financing for properties. Specifically, they acquire long-term mortgages on properties once construction is completed. *Equity trusts* own various income-producing properties, such as office buildings, shopping centers, or apartment houses. Therefore, an investor who buys shares in an equity real estate investment trust is buying part of a portfolio of income-producing properties.

**Coins and Stamps** Many individuals enjoy collecting coins or stamps as a hobby and as an investment. The market for coins and stamps is fragmented compared to the stock market, but it is more liquid than the market for art and antiques as indicated by the publication of weekly and monthly price lists. An investor can get a widely recognized grading specification on a coin or stamp, and, once graded, a coin or stamp can usually be sold quickly through a dealer, as described by Henriques (1989) and Bradford (1989). Notably, the percentage difference between the bid price the dealer will pay to buy the stamp or coin and the asking or selling price the investor must pay the dealer is going to be substantially larger than the bid-ask spread on stocks and bonds.

**Diamonds** Diamonds can be and have been good investments during many periods. Still, investors who purchase diamonds must realize that (1) diamonds can be highly illiquid, (2) the grading process that determines their quality is quite subjective, (3) most investment-grade gems require substantial capital, and (4) they generate no positive cash flow during the holding period until the stone is sold. In fact, during the holding period, the investor must cover costs of insurance and storage and there are appraisal costs before selling.

In this section, we have briefly described the most common investment alternatives. Following this brief description, we will discuss many of these investment alternatives in more detail when we consider how you evaluate them for investment purposes.

In our final section, we present data on historical rates of return and risk measures, as well as correlations among several of these investments. This provides insights into future expected returns and risk characteristics (both total and systematic risk) for these investment alternatives.

### 3.3 Historical Risk-Returns on Alternative Investments

How do investors weigh the costs and benefits of owning investments and make decisions to build portfolios that will provide the best risk-return combinations? To help individual or institutional investors answer this question, financial theorists have examined extensive data to provide information on the return and risk characteristics of various investments.

There have been numerous studies of the historical rates of return on common stocks (both large-capitalization stocks in terms of aggregate market value and small-capitalization stocks). In addition, there has been a growing interest in the performance of bonds. Because inflation has been so pervasive, many studies include both nominal and real rates of return on investments. Still other investigators have examined the performance of alternative assets such as real estate, foreign stocks, art, antiques, and commodities. The review of these results should help you to make decisions on building your investment portfolio and on the allocation to the various asset classes.

### 3.3.1 World Portfolio Performance

A study by Reilly and Wright (2004) examined the performance of numerous assets, not only in the United States, but around the world. Specifically, for the period from 1980 to 2001, they

There are several monthly coin magazines, including *Coinage*, published by Miller Magazines, Ventura, CA. Amos Press also publishes several stamp magazines, including *Linn’s Stamp News* and *Scott Stamp Monthly*. These magazines provide current prices for coins and stamps.

5 Small-capitalization stocks were broken out as a separate class of asset because several studies have shown that firms with relatively small capitalization (stock with low market value) have experienced rates of return and risk significantly different from those of stocks in general. Therefore, they were considered a unique asset class. We will discuss these studies in Chapter 6, which deals with the efficient markets hypothesis. The large-company stock returns are based upon the S&P Composite Index of 500 stocks—the S&P 500 (described in Chapter 5).
examined the performance of stocks, bonds, cash (the equivalent of U.S. T-bills), real estate, and commodities from the world, United States, Europe, Pacific Basin, Japan, and the emerging markets. They computed annual returns, risk measures, and correlations among the returns for alternative assets. Exhibit 3.8 contains updated geometric and arithmetic average annual rates of return, the standard deviations of returns, and the systematic risk (beta) for a

**Asset Return and Total Risk** The results in Exhibit 3.8 generally confirm the expected relationship between annual rates of return and the total risk (standard deviation) of these securities. The riskier assets with higher standard deviations experienced higher returns. For example, the U.S. stock indexes had relatively high returns (10 to 17 percent) and large standard deviations (15 to 23 percent). It is not a surprise that the highest-risk asset class (without commodities) was the two emerging market stock indexes with standard deviations of 22.98 and 24.92 percent, whereas risk-free U.S. cash equivalents (30-day T-bills) had low returns (4.96 percent) and the smallest standard deviation (0.90 percent).

**Return and Systematic Risk** As shown in Exhibit 3.8, in addition to total risk (standard deviation), the authors also considered systematic risk, which is the volatility of an asset relative to a market portfolio of risky assets (this was discussed briefly in Chapter 1). One of the conclusions of the Reilly and Wright (2004) study was that the systematic risk measure (beta) did a better job of explaining the returns during the period than the total risk measure (standard deviation). In addition, the systematic risk measure (beta) that used the Brinson Global Security Market Index (GSMI) as a market proxy was somewhat better than the beta that used the S&P 500 Index. Thus, Exhibit 3.9, which contains the scatter plot of geometric mean rate of return and GSMI systematic risk, indicates the expected positive risk-return relationship. The two outliers are the Tokyo Stock Exchange Index on the low side and the Wilshire 5000 equal-weighted index.

The correlation of returns with inflation has implications regarding the ability of an asset class to be an inflation hedge—a good inflation hedge should have a strong positive correlation with inflation. As shown, most assets (including common stocks) have negative correlations with inflation, which implies that they are poor inflation hedges. The exceptions appear to be commodities (0.20) and short-term government bonds (especially 30-day Treasury bills with 0.41 correlation).

### 3.3.2 Art and Antiques

Unlike financial securities, where the results of transactions are reported daily, art and antique markets are fragmented and lack any formal transaction reporting system. This makes it difficult to gather data. The best-known series that attempted to provide information about the changing value of art and antiques were developed by Sotheby’s, a major art auction firm. These value indexes covered 13 areas of art and antiques and a weighted aggregate series that combined the 13 areas. Reilly (1992) examined these series for the period from 1976 to 1991 and computed rates of return, measures of risk, and the correlations among the various art and antique series and compared them to stocks, bonds, and the rate of inflation.

Although there was a wide range of mean returns and risk, a risk-return plot indicated a fairly consistent relationship between risk and return during this 16 year period. Comparing the art and antique results to bond and stock indexes indicated that stocks and bonds experienced results that were very consistent with the art and antique series.

Analysis of the correlations among these assets using annual rates of return revealed several important relationships. First, the correlations among alternative antique and art categories vary substantially from above 0.90 to negative correlations. Second, the correlations between art/antiques and bonds were generally negative. Third, the correlations of art/antiques with stocks were typically small positive values. Finally, the correlation of art and antiques with the rate of inflation indicates that several of the categories were fairly good inflation hedges since they were positively correlated with inflation. Notably, they were clearly superior inflation hedges compared to long-term bonds and common stocks as documented in Fama (1991) and Jaffe and Mandelker (1976). The reader should recall our earlier observation that most art and antiques are quite illiquid and the transaction costs are fairly high compared to financial assets.

### 3.3.3 Real Estate

Somewhat similar to art and antiques, returns on real estate are difficult to derive because of the limited number of transactions and the lack of a national source of data for the transactions that allows one to accurately compute rates of return. In the study by Goetzmann and Ibbotson (1990), the authors gathered data on commercial real estate through REITs and Commingled Real Estate Funds (CREFs) and estimated returns on residential real estate from a series created by Case and Shiller (1987). The summary of the real estate returns compared to various stock, bond, and an inflation series is contained in Exhibit 3.11. As shown, the two commercial real estate series reflected strikingly different results. The CREFs had lower returns and low volatility, while the REIT index had higher returns and risk. Notably, the REIT returns were higher than those of common stocks, but the risk measure for real estate was lower (there was a small difference in the time period). The residential real estate series reflected lower returns and low risk. The longer-term results indicate that all the real estate series experienced lower returns and much lower risk than common stock.

The correlations in Exhibit 3.12 among annual returns for the various asset groups indicate a relatively low positive correlation between commercial real estate and stocks. In contrast, there was negative correlation between stocks and residential and farm real estate. This negative relationship with real estate was also true for 20-year government bonds. Studies by...

As shown, the two commercial real estate series reflected strikingly different results. The CREFs had lower returns and low volatility, while the REIT index had higher returns and risk. Notably, the REIT returns were higher than those of common stocks, but the risk measure for real estate was lower (there was a small difference in the time period). The residential real estate series reflected lower returns and low risk. The longer-term results indicate that all the real estate series experienced lower returns and much lower risk than common stock.

The correlations in Exhibit 3.12 among annual returns for the various asset groups indicate a relatively low positive correlation between commercial real estate and stocks. In contrast, there was negative correlation between stocks and residential and farm real estate. This negative relationship with real estate was also true for 20-year government bonds. Studies by

²Unfortunately, it has not been possible to update these results because Sotheby’s stopped computing and publishing the series in 1992.
Investors who want the broadest range of choices in investments must consider foreign stocks and bonds in addition to domestic financial assets. Many foreign securities offer investors higher risk-adjusted returns than do domestic securities. In addition, the low positive or negative correlations between foreign and U.S. securities make them ideal for building a diversified portfolio.

Exhibit 3.13 summarizes the risk and return characteristics of the investment alternatives described in this chapter. Some of the differences are due to unique factors that we discussed. Foreign stocks and bonds are considered riskier than domestic stocks and bonds because of the unavoidable uncertainty due to exchange rate risk and country risk. Such investments as art, antiques, coins, and stamps require heavy liquidity risk premiums. You should divide consideration of real estate investments between your personal home, on which you do not expect as high a return because of non-monetary factors, and commercial real estate, which requires a much higher rate of return due to cash flow uncertainty and illiquidity.

Studies on the historical rates of return for investment alternatives, as presented by Ibbotson and Brinson (1993) (including bonds, commodities, real estate, foreign securities, and art and antiques), point toward two generalizations:

1. A positive relationship typically holds between the rate of return earned on an asset and the variability of its historical rate of return or its systematic risk (beta). This is expected in a world of risk-averse investors who require higher rates of return to compensate for more uncertainty.

2. The correlation among rates of return for selected alternative investments can be quite low, especially for U.S. and foreign stocks and bonds and between these financial assets and real assets, such as art, antiques, and real estate. These correlations confirm the advantage of diversification among different global asset classes.

In addition to describing many direct investments, such as stocks and bonds, we also discussed investment companies that allow investors to buy investments indirectly. These can be important to investors who want to take advantage of professional management but also want instant diversification with a limited amount of funds. With $10,000, you may not be able to buy many individual stocks or bonds, but you could acquire

Note: Correlation coefficient for each pair of asset classes uses the maximum number of observations, that is, the minimum length of the two series in the pair.

Eichholz (1996), Mull and Socnen (1997), and Quan and Titman (1997) that considered international commercial real estate and REITs indicated that the returns were correlated with stock prices but they still provided significant diversification benefits.

These results imply that returns on real estate are equal to or slightly lower than returns on common stocks, but real estate possesses favorable risk and diversification results. Specifically individual real estate assets had much lower standard deviations and either low positive or negative correlations with other asset classes in a portfolio context. Finally, all the real estate series had significant positive correlation with inflation, which implies strong potential as an inflation hedge.
Investors who want the broadest range of choices in investments must consider foreign stocks and bonds in addition to domestic financial assets. Many foreign securities offer investors higher risk-adjusted returns than do domestic securities. In addition, the low positive or negative correlations between foreign and U.S. securities make them ideal for building a diversified portfolio.

shares in a mutual fund or an ETF, which would give you a share of a diversified portfolio that might contain 100 to 150 different U.S. and international stocks or bonds.

- Now that we know the range of domestic and foreign investment alternatives, our next task is to learn about the markets in which they are bought and sold. That is the objective of the following chapter.

### SUGGESTED READINGS

### QUESTIONS

1. What are the advantages of investing in the common stock rather than the corporate bonds of a company? Compare the certainty of returns for a bond with those for a common stock. Draw a line graph to demonstrate the pattern of returns you would envision for each of these assets over time.

2. Discuss three factors that cause U.S. investors to consider including various global securities in their portfolios.

3. Discuss why international diversification reduces portfolio risk. Specifically, why would you expect low correlation in the rates of return for domestic and foreign securities?

4. Discuss why you would expect a difference in the correlation of returns between securities from the United States and from alternative countries (for example, Japan, Canada, South Africa).

5. Discuss whether you would expect any change in the correlations between U.S. stocks and the stocks for different countries. For example, discuss whether you would expect the correlation between U.S. and Japanese stock returns to change over time. If so, why?

6. When you invest in Japanese or German bonds, what major additional risks must you consider besides yield changes within the country?

7. Some investors believe that international investing introduces additional risks. Discuss these risks and how they can affect your return. Give an example.

8. What alternatives to direct investment in foreign stocks are available to investors?

9. You are a wealthy individual in a high tax bracket. Why might you consider investing in a municipal bond rather than a straight corporate bond, even though the promised yield on the municipal bond is lower?

10. You can acquire convertible bonds from a rapidly growing company or from a utility. Speculate on which convertible bond would have the lower yield and discuss the reason for this difference.

11. Compare the liquidity of an investment in raw land with that of an investment in common stock. Be specific as to why and how the liquidity differs. (Hint: Begin by defining liquidity.)

12. What are stock warrants and call options? How do they differ?

13. Discuss why financial analysts consider antiques and art to be illiquid investments. Why do they consider coins and stamps to be more liquid than antiques and art? What must an investor typically do to sell a collection of art and antiques? Briefly contrast this procedure to the sale of a portfolio of stocks listed on a national or international exchange.

14. You have a fairly large portfolio of U.S. stocks and bonds. You meet a financial planner at a social gathering who suggests that you diversify your portfolio by investing in emerging market stocks. Discuss whether the correlation results in Exhibit 3.10 support this suggestion.

15. The pension plan for the Cara Corporation has historically invested in the stocks of only U.S.-domiciled companies. Recently, the fund has decided to add international exposure to the plan portfolio.

Identify and briefly discuss three potential problems that the plan may confront in selecting international stocks that it did not face in choosing U.S. stocks.

16. Alessandra Capital has been experiencing increasing demand from its institutional clients for information and assistance related to international investment management. Recognizing that this is an area of growing importance, the firm has hired an experienced analyst/portfolio manager specializing in international equities and market strategy. His first assignment is to represent Alessandra Capital before a client company’s investment committee to discuss the possibility of changing their present “U.S. securities only” investment approach to one including international investments. He is told that the committee wants a presentation that fully and objectively examines the basic, substantive considerations on which the committee should focus its attention, including both theory and evidence. The company’s pension plan has no legal or other barriers to adoption of an international approach; no non-U.S. pension liabilities currently exist.

Identify and briefly discuss three reasons for adding international securities to the pension portfolio and three problems associated with such an approach.

## PROBLEMS

1. Using a source of international statistics, compare the percentage change in the following economic data for Japan, Germany, Canada, and the United States for a recent year. What were the differences, and which country or countries differed most from the United States?
   a. Aggregate output (GDP)
   b. Consumer Price Index
   c. Money supply growth

2. Using a recent edition of *Barron’s*, examine the weekly percentage change in the stock price indexes for Japan, Germany, United Kingdom, and the United States. For each of three weeks, which foreign series moved most closely with the U.S. series? Which series diverged most from the U.S. series? Discuss these results as they relate to international diversification.

3. Using published sources (for example, *The Wall Street Journal*, *Barron’s*, *Federal Reserve Bulletin*), look up the exchange rate for U.S. dollars with Japanese yen for each of the past 10 years (you can use an average for the year or a specific time period each year). Based on these exchange rates, compute and discuss the yearly exchange rate effect on an investment in Japanese stocks by a U.S. investor. Discuss the impact of this exchange rate effect on the risk of Japanese stocks for a U.S. investor.

4. The following information is available concerning the historical risk and return relationships in the U.S. capital markets:
Covariance

Because most students have been exposed to the concepts of covariance and correlation, the following discussion is set forth in intuitive terms with examples. A detailed, rigorous treatment is contained in DeFusco, McLeavey, Pinto, and Runkle (2004).

Covariance is an absolute measure of the extent to which two sets of numbers move together over time, that is, how often they move up or down together. In this regard, move together means they are generally above their means or below their means at the same time. Covariance between \( i \) and \( j \) is defined as:

\[
\text{COV}_{ij} = \frac{\sum (X_i - \overline{X}_i)(X_j - \overline{X}_j)}{n}
\]

If we define \((X_i - \overline{X}_i)\) as \(X_i^0\) and \((X_j - \overline{X}_j)\) as \(X_j^0\), then

\[
\text{COV}_{ij} = \frac{\sum X_i^0 X_j^0}{n}
\]

Obviously, if both numbers are consistently above or below their individual means at the same time, their products will be positive, and the average will be a large positive value. In contrast, if the \( i \) value is below its mean when the \( j \) value is above its mean consistently or vice versa, their products will be large negative values, giving negative covariance. Exhibit 3A.1 should make this clear. In this example, the two series generally moved together, so they showed positive covariance. As noted, this is an absolute measure of their relationship and, therefore, can range from \(+\infty\) to \(-\infty\). Note that the covariance of a variable with itself is its variance.

Correlation

To obtain a relative measure of a given relationship, we use the correlation coefficient \( r_{ij} \), which is a measure of the relationship:

\[
r_{ij} = \frac{\text{COV}_{ij}}{\sigma_i \sigma_j}
\]

You will recall from your introductory statistics course that

\[
\sigma_i = \sqrt{\frac{\sum (X_i - \overline{X}_i)^2}{N}}
\]

- U.S. Government T-bills 3.50%
- Large-cap common stock 11.75
- Long-term corporate bonds 5.50
- Long-term government bonds 4.90
- Small-capitalization common stock 13.10

The annual rate of inflation during this period was 3 percent. Compute the real rate of return on these investment alternatives.

THOMSON REUTERS

Use the Thomson One—Business School Edition Online Database to answer the following questions.

1. Compare the performance of several country markets. Using the “index” tab, do a search on FTSE. You will obtain a list of many FTSE indexes. Select at least three from different countries or regions (such as Eurobloc, Americas, and Japan). How have their stock markets been performing of late?

2. Some indexes are presented in both U.S. dollar terms and in terms of other currencies. Compare the performance of the DJ Euro STOXX index in terms of euros and the U.S. dollar. Find one other index that will allow a comparison between two different currencies and discuss their relative performance.

3. Using daily stock prices for indexes from the United States, Japan, Canada, and a composite of emerging markets (or China, India, and Indonesia), compute daily percent changes for 25 trading days. Compute the correlations among these indexes. Rank the correlations from high to low.
Covariance

Because most students have been exposed to the concepts of covariance and correlation, the following discussion is set forth in intuitive terms with examples. A detailed, rigorous treatment is contained in DeFusco, McLeavey, Pinto, and Runkle (2004).

**Covariance** is an absolute measure of the extent to which two sets of numbers move together over time, that is, how often they move up or down together. In this regard, move together means they are generally above their means or below their means at the same time. Covariance between \( i \) and \( j \) is defined as

\[
\text{COV}_{ij} = \frac{\sum (i - \bar{i})(j - \bar{j})}{n}
\]

If we define \((i - \bar{i})\) as \(i'\) and \((j - \bar{j})\) as \(j'\), then

\[
\text{COV}_{ij} = \frac{\sum i'j'}{n}
\]

Obviously, if both numbers are consistently above or below their individual means at the same time, their products will be positive, and the average will be a large positive value. In contrast, if the \(i\) value is below its mean when the \(j\) value is above its mean consistently or vice versa, their products will be large negative values, giving negative covariance.

Exhibit 3A.1 should make this clear. In this example, the two series generally moved together, so they showed positive covariance. As noted, this is an absolute measure of their relationship and, therefore, can range from \(+\infty\) to \(\infty\). Note that the covariance of a variable with itself is its variance.

**Correlation**

To obtain a relative measure of a given relationship, we use the correlation coefficient \(r_{ij}\), which is a measure of the relationship:

\[
r_{ij} = \frac{\text{COV}_{ij}}{\sigma_i \sigma_j}
\]

You will recall from your introductory statistics course that

\[
\sigma_i = \sqrt{\frac{\sum (i - \bar{i})^2}{N}}
\]

CHAPTER 4
Organization and Functioning of Securities Markets*

After you read this chapter, you should be able to answer the following questions:

1. What is the purpose and function of a market?
2. What characteristics determine the quality of a market?
3. What is the difference between a primary and secondary capital market, and how do these two markets support each other?
4. What are Rules 415 and 144A and how do they affect corporate security underwriting?
5. For secondary equity markets, what are the two basic trading systems?
6. How are call markets typically used in U.S. markets?
7. How are national exchanges around the world linked, and what is meant by “passing the book”?
8. What are Electronic Communication Networks (ECNs) and alternative trading systems (ATSs) and how do they differ from the primary listing markets?
9. What are the major types of orders available to investors and market makers?
10. What new trading systems on the NYSE and on NASDAQ have made it possible to handle the growth in U.S. trading volume?
11. What are the three recent innovations that contribute to competition within the U.S. equity market?
12. What are the factors causing a global consolidation of stock, bond, and derivative exchanges? What will this global marketplace look like?

The stock market, the Dow Jones Industrials, and the bond market are part of our everyday experience. Each evening on television news broadcasts we find out how stocks and bonds fared; each morning we read in our daily newspapers about expectations for a market rally or decline. Yet most people have an imperfect understanding of how domestic and world capital markets actually function. To be a successful investor in a global environment, you must know what financial markets are available around the world and how they operate.

In this chapter, we take a broad view of securities markets and provide a detailed discussion of how major stock markets function. We also consider how global securities markets have been changing during recent years and discuss how they will probably change in the future.

We begin with a discussion of securities markets and the characteristics of a good market. We describe two components of the capital markets: primary and secondary. Our main emphasis is on the secondary stock market including the national stock exchanges around the world and how these markets, separated by geography and by other factors, function.

\[
\sigma_i^2 = \frac{42}{6} = 7.00 \\
\sigma_j^2 = \frac{34}{6} = 5.67 \\
\sigma_i = \sqrt{7.00} = 2.65 \\
\sigma_j = \sqrt{5.67} = 2.38 \\
\rho = \frac{COV_{ij}}{\sigma_i \sigma_j} = \frac{5.67}{\frac{2.65 \times 2.38}{6.31}} = 0.898
\]

If the two series move completely together, then the covariance would equal \(\sigma_i \sigma_j\) and

\[
\frac{COV_{ij}}{\sigma_i \sigma_j} = 1.0
\]

The correlation coefficient would equal unity in this case, and we would say the two series are perfectly correlated. Because we know that

\[
\rho = \frac{COV_{ij}}{\sigma_i \sigma_j}
\]

we also know that \(COV_{ij} = \rho \sigma_i \sigma_j\). This relationship may be useful when computing the standard deviation of a portfolio, because in many instances the relationship between two securities is stated in terms of the correlation coefficient rather than the covariance.

Continuing the example given in Exhibit 3A.1, the standard deviations are computed in Exhibit 3A.2, as is the correlation between \(i\) and \(j\). As shown, the two standard deviations are rather large and similar but not exactly the same. Finally, when the positive covariance is normalized by the product of the two standard deviations, the results indicate a correlation coefficient of 0.898, which is obviously quite large and close to 1.00. This implies that these two series are highly related.

Time zones are becoming linked into a 24-hour market. We also consider a detailed analysis of how alternative exchange markets operate, including the Electronic Communication Networks (ECNs). In the final section, we consider numerous recent changes in financial markets, including significant mergers, and future changes expected. These numerous changes in our securities markets will have a profound effect on what investments are available from around the world, how we buy and sell them, and at what cost.

4.1 What is a Market?

A market is the means through which buyers and sellers are brought together to aid in the transfer of goods and/or services. Several aspects of this general definition seem worthy of emphasis. First, a market need not have a physical location. It is only necessary that the buyers and sellers can communicate regarding the relevant aspects of the transaction. Second, the market does not necessarily own the goods or services involved. The important criterion for a good market is the smooth, cheap transfer of goods and services. Those who establish and administer the market do not own the assets but simply provide a system that allows potential buyers and sellers to interact. They help the market function by providing information and facilities to aid in the transfer of ownership. Finally, a market can deal in any variety of goods and services. For any commodity or service with a diverse clientele, a market should evolve to aid in the transfer of that commodity or service. Both buyers and sellers benefit from the existence of a market.

4.1.1 Characteristics of a Good Market

Throughout this book, we will discuss markets for different investments such as stocks, bonds, options, and futures in the United States and throughout the world. We will refer to these markets using various terms of quality such as strong, active, liquid, or illiquid. There are many financial markets, but they are not all equal—some are active and liquid, others are relatively illiquid and inefficient in their operations. To appreciate these discussions, you should be aware of the following characteristics that investors look for when evaluating the quality of a market.

One enters a market to buy or sell a good or service quickly at a price justified by the prevailing supply and demand. To determine the appropriate price, participants must have timely and accurate information on the volume and prices of past transactions and all currently outstanding bids and offers. Therefore, one attribute of a good market is timely and accurate information on past transactions and prevailing buy and sell orders.

Another prime requirement is liquidity, the ability to buy or sell an asset quickly and at a known price—that is, a price not substantially different from the prices for prior transactions, assuming no new information is available. An asset’s likelihood of being sold quickly, sometimes referred to as its marketability, is a necessary, but not a sufficient, condition for liquidity. The expected price should also be fairly certain, based on the recent history of transaction prices and current bid-ask quotes. For a formal discussion of liquidity, see Handa and Schwartz (1996) and AIMR’s articles on Best Execution and Portfolio Performance (Jost, 2001).

A component of liquidity is price continuity, which means that prices do not change much from one transaction to the next unless substantial new information becomes available. Suppose no new information is forthcoming, and the last transaction was at a price of $20; if the next trade were at between $19.95 and $20.05, the market would be considered reasonably liquid. The stock market, the Dow Jones Industrials, and the bond market are part of our everyday experience. Each evening on television news broadcasts we find out how stocks and bonds fared; each morning we read in our daily newspapers about expectations for a market rally or decline. Yet most people have an imperfect understanding of how domestic and world capital markets actually function. To be a successful investor in a global environment, you must know what financial markets are available around the world and how they operate.

In this chapter, we take a broad view of securities markets and provide a detailed discussion of how major stock markets function. We also consider how global securities markets have been changing during recent years and discuss how they will probably change in the future.

We begin with a discussion of securities markets and the characteristics of a good market. We describe two components of the capital markets: primary and secondary. Our main emphasis is on the secondary stock market including the national stock exchanges around the world and how these markets, separated by geography and by

A continuous market without large price changes between trades is a characteristic of a liquid market. A market with price continuity requires depth, which means that there are numerous potential buyers and sellers willing to trade at prices above and below the current market price. These buyers and sellers enter the market in response to changes in supply, demand, or both, and thereby prevent drastic price changes. In summary, liquidity requires marketability and price continuity, which, in turn, requires depth.

Another factor contributing to a good market is the transaction cost. Lower costs (as a percent of the value of the trade) make for a more efficient market. An individual comparing the cost of a transaction between markets would choose a market that charges 2 percent of the value of the trade compared with one that charges 5 percent. Most microeconomic textbooks define an efficient market as one in which the cost of the transaction is minimal. This attribute is referred to as internal efficiency.

Finally, a buyer or seller wants the prevailing market price to adequately reflect all the information available regarding supply and demand factors in the market. If such conditions change as a result of new information, the price should change accordingly. Therefore, participants want prices to adjust quickly to new information regarding supply or demand, which means that prevailing market prices reflect all available information about the asset. This attribute is referred to as external, or informational, efficiency. We discuss this attribute extensively in Chapter 6.

In summary, a good market for goods and services has the following characteristics:

1. Timely and accurate information on the price and volume of past transactions.
2. Liquidity, meaning an asset can be bought or sold quickly at a price close to the prices for previous transactions (has price continuity), assuming no new information has been received. In turn, price continuity requires depth.
3. Low transaction costs, including the cost of reaching the market, the actual brokerage costs, and the cost of transferring the asset.
4. Prices that rapidly adjust to new information, so the prevailing price is fair since it reflects all available information regarding the asset.

Decimalization has reduced spread size and transaction costs, which has led to a decline in transaction size and an increase in the number of transactions. For example, the number of transactions on the NYSE went from a daily average of 877,000 in 2000 to over 10 million during 2010, while the average trade size went from 1,187 shares in 2000 to about 300 shares in 2010.

4.1.3 Organization of the Securities Market

Before we discuss the specific operation of the securities market, we need to understand its overall organization. The principal distinction is between primary markets, where new securities are sold, and secondary markets, where outstanding securities are bought and sold. Each of these markets is further divided based on the economic unit that issued the security. We will consider each of these major segments of the securities market, with an emphasis on the individuals involved and the functions they perform.

4.2 PRIMARY CAPITAL MARKETS

The primary market is where new issues of bonds, preferred stock, or common stock are sold by government units, municipalities, or companies who want to acquire new capital. For a review of studies on the primary market, see Jensen and Smith (1986).

4.2.1 Government Bond Issues

U.S. government bond issues are subdivided into three segments based on their original maturities. Treasury bills are negotiable, non-interest-bearing securities with original maturities of one year or less. Treasury notes have original maturities of 2 to 10 years. Finally, Treasury bonds have original maturities of more than 10 years.

To sell bills, notes, and bonds, the Treasury relies on Federal Reserve System auctions. (The bidding process and pricing are discussed in Chapter 17.)

4.2.2 Municipal Bond Issues

New municipal bond issues are sold by one of three methods: competitive bid, negotiation, or private placement. Competitive bid sales typically involve sealed bids. The bond issue is sold to the bidding syndicate of underwriters that submits the bid with the lowest interest cost in accordance with the stipulations set forth by the issuer. Negotiated sales involve contractual arrangements between underwriters and issuers wherein the underwriter helps the issuer prepare the bond issue and set the price and has the exclusive right to sell the issue. Private placements involve the sale of a bond issue by the issuer directly to an investor or a small group of investors (usually institutions).

Note that two of the three methods require an underwriting function. Specifically, in a competitive bid or a negotiated transaction, the investment banker typically underwrites the issue, which means the investment firm purchases the entire issue at a specified price, relieving the issuer from the risk and responsibility of selling and distributing the bonds. Subsequently, the underwriter sells the issue to the investing public. For municipal bonds, this underwriting function is performed by both investment banking firms and commercial banks.

The underwriting function can involve three services: origination, risk-bearing, and distribution. Origination involves the design of the bond issue and initial planning. To fulfill the risk-bearing function, the underwriter acquires the total issue at a price dictated by the competitive bid or through negotiation and accepts the responsibility and risk of reselling it for more than the purchase price. Distribution means selling it to investors, typically with the help of a selling syndicate that includes other investment banking firms and/or commercial banks.

In summary, a good market for goods and services has the following characteristics:

1. Timely and accurate information on the price and volume of past transactions.
2. Liquidity, meaning an asset can be bought or sold quickly at a price close to the prices for previous transactions (has price continuity), assuming no new information has been received. In turn, price continuity requires depth.
3. Low transaction costs, including the cost of reaching the market, the actual brokerage costs, and the cost of transferring the asset.
4. Prices that rapidly adjust to new information, so the prevailing price is fair since it reflects all available information regarding the asset.

4.1.2 Decimal Pricing

Prior to the initiation of changes in late 2000 that were completed in early 2001, common stocks in the United States were always quoted in fractions. Specifically, prior to 1997 they were quoted in eighths (e.g., $\frac{1}{8}$, $\frac{2}{8}$, $\ldots$), with each eighth equal to $0.125$. This was modified in 1997 when the fractions for most stocks went to sixteenths (e.g., $\frac{1}{16}$, $\frac{2}{16}$, $\ldots$, $\frac{15}{16}$) equal to $0.0625$. Now U.S. equities are priced in decimals (cents), so the minimum spread can be in cents (e.g., $30.10$–$30.12$).

The espoused reasons for the change to decimal pricing are threefold. First, is the ease with which investors can understand and compare prices. Second, decimal pricing reduces the size of the bid-ask spread from a minimum of 6.25 cents (when prices are quoted in sixteenths) to 1 cent (when prices are in decimals). Many brokers and investment firms were against the change since the spread is the price of liquidity for the investor and the compensation to the dealer. Third, the change made U.S. markets more competitive on a global basis since other countries were pricing on a comparable basis.

---

1 You should be aware that common stocks are currently sold in decimals (dollars and cents), which is a change from the pre-2000 period when stocks were priced in eighths and sixteenths. This change to decimals is discussed in the following subsection.

2 A subsequent discussion in this chapter on new innovations will make it clear that new technology and competition has resulted in a very internally efficient global equity market.
Decimalization has reduced spread size and transaction costs, which has led to a decline in transaction size and an increase in the number of transactions. For example, the number of transactions on the NYSE went from a daily average of 877,000 in 2000 to over 10 million during 2010, while the average trade size went from 1,187 shares in 2000 to about 300 shares in 2010.

Distribution means selling it to investors, typically with the help of a selling syndicate that includes other investment banking firms and/or commercial banks.
In a negotiated bid, the underwriter will carry out all three services. In a competitive bid, the issuer specifies the amount, maturities, coupons, and call features of the issue and the competing syndicates submit a bid for the entire issue that reflects the yields they estimate for the bonds. The issuer may have received advice from an investment firm on the desirable characteristics for a forthcoming issue, but this advice would have been on a fee basis and would not necessarily involve the ultimate underwriter who is responsible for risk-bearing and distribution. Finally, a private placement involves no risk-bearing, but an investment banker would typically assist in designing the characteristics of the issue and locating potential buyers.

### 4.2.3 Corporate Bond Issues

Corporate bond issues are almost always sold through a negotiated arrangement with an investment banking firm that maintains a relationship with the issuing firm. In a global capital market there has been an explosion of new instruments, which means that the origination function, which involves designing the characteristics and currency for the security, is becoming more important because the corporate chief financial officer (CFO) may not be completely familiar with the availability and issuing requirements of many new instruments and the alternative capital markets around the world. Investment banking firms compete for underwriting business by creating new instruments that appeal to existing investors and by advising issuers regarding desirable countries and currencies. As a result, the expertise of the investment banker can help reduce the issuer’s cost of new capital.

Once a stock or bond issue is specified, the underwriter will put together an underwriting syndicate of other major underwriters and a selling group of smaller firms for its distribution, as shown in Exhibit 4.1.

### 4.2.4 Corporate Stock Issues

In addition to issuing fixed-income securities, corporations can also issue equity securities—generally common stock. For corporations, new stock issues are typically divided into two groups: (1) seasoned equity issues, and (2) initial public offerings (IPOs).
4.2.5 Private Placements and Rule 144A

Rather than a public sale using one of these arrangements, primary offerings can be sold privately. In such an arrangement, referred to as a private placement, the firm designs an issue with the assistance of an investment banker and sells it to a small group of institutions. The firm enjoys lower issuing costs because it does not need to prepare the extensive registration statement required for a public offering. Institutions buying the issue typically benefit because the issuing firm passes some of the cost savings on to the investor as a higher return. In fact, pre-Rule 144A an institution required a higher return because of the absence of any secondary market for these securities, which implied higher liquidity risk.

The private placement market changed dramatically when Rule 144A was introduced by the SEC. This rule allows corporations—including non-U.S. firms—to place securities privately with large, sophisticated institutional investors without extensive registration documents. A major innovation is that these securities can subsequently be traded among these large sophisticated investors (those with assets in excess of $100 million). The SEC introduced this innovation to provide more financing alternatives for U.S. and non-U.S. firms and possibly increase the number, size, and liquidity of private placements, as discussed by Milligan (1990) and Hanks (1990). Presently, more than 85 percent of high-yield bonds are 144A issues.

4.3 SECONDARY FINANCIAL MARKETS

In this section, we consider the importance of secondary markets and provide an overview of the secondary markets for bonds, financial futures, and stocks. Next, we consider national stock markets around the world. Finally, we discuss other primary listing markets, regional exchanges, third markets, and the rapidly growing electronic communication networks (ECNs) and alternative trading systems (ATSs) and provide a detailed presentation on the functioning of stock exchanges.

Secondary markets permit trading in outstanding issues; that is, stocks or bonds already sold to the public are traded between current and potential owners. The proceeds from a sale in the secondary market do not go to the issuing unit (the government, municipality, or company), but rather to the current owner of the security.

4.3.1 Why Secondary Markets Are Important

Because the secondary market involves the trading of securities initially sold in the primary market, it provides liquidity to the individuals who acquired these securities. The point is, after acquiring securities in the primary market, investors may want to sell them again to acquire other securities, buy a house, or go on a vacation. The primary market benefits from this liquidity because investors would hesitate to acquire securities in the primary market if they thought they could not subsequently sell them in the secondary market. That is, without an active secondary market, potential issuers of stocks or bonds in the primary market would have to provide a much higher rate of return to compensate investors for the substantial liquidity risk.

Secondary markets are also important to those selling seasoned securities because the prevailing market price of the securities (price discovery) is determined by transactions in the secondary market. New issues of outstanding stocks or bonds to be sold in the primary market are based on prices and yields in the secondary market. Notably, the secondary market also affects market efficiency and price volatility, as discussed by Foster and Viswanathan (1993) and Jones, Kaul, and Lipson (1994). Even forthcoming IPOs are priced based on the prices and values of comparable stocks or bonds in the public secondary market.

Seasoned equity issues are new shares offered by firms that already have stock outstanding. An example would be General Electric, which is a large, well-regarded firm that has had public stock trading on the NYSE for longer than 50 years. If General Electric needed additional capital, it could sell additional shares of its common stock to the public at a price very close to the current market price of the firm’s stock.

Initial public offerings (IPOs) involve a firm selling its common stock to the public for the first time. At the time of an IPO, there is no existing public market for the stock; that is, the company has been closely held. An example was an IPO by Polo Ralph Lauren, a leading manufacturer and distributor of men’s clothing. The purpose of the offering was to get additional capital to expand its operations and to create a public market for future seasonal offerings.

New issues (seasoned or IPOs) are typically underwritten by investment bankers, who acquire the total issue from the company and sell the securities to interested investors. The lead underwriter gives advice to the corporation on the general characteristics of the issue, its pricing, the timing of the offering, and participates in a “road show” visiting potential institutional investors. The underwriter also accepts the risk of selling the new issue after acquiring it from the corporation. For further discussion, see Brealey and Myers (2010, Chapter 15).

Relationships with Investment Bankers The underwriting of corporate issues typically takes one of three forms: negotiated, competitive bids, or best-efforts arrangements. As noted, negotiated underwritings are the most common, and the procedure is the same as for municipal issues.

A corporation may also specify the type of securities to be offered (common stock, preferred stock, or bonds) and then solicit competitive bids from investment banking firms. This is rare for industrial firms but is typical for utilities, which may be required by law to sell the issue via a competitive bid. Although a competitive bid typically reduces the cost of an issue, it also means that the investment banker gives less advice but still accepts the risk-bearing function by underwriting the issue and fulfills the distribution function.

Alternatively, an investment banker can agree to sell an issue on a best-efforts basis. This is usually done with speculative new issues. In this arrangement, the investment banker does not underwrite the issue because it does not buy any securities. The stock is owned by the company, and the investment banker acts as a broker to sell whatever it can at a stipulated price. Because it bears no risk, the investment banker earns a lower commission on such an issue than on an underwritten issue.

Introduction of Rule 415 The typical practice of negotiated arrangements involving numerous investment banking firms in syndicates and selling groups has changed with the introduction of Rule 415, which allows large firms to register security issues and sell them piecemeal during the following two years. These issues are referred to as shelf registrations because, after they are registered, the issues lie on the shelf and can be taken down and sold on short notice whenever it suits the issuing firm. As an example, Apple Computer could register an issue of 5 million shares of common stock during 2012 and sell a million shares in early 2012, another million shares in late 2012, 2 million shares in early 2013, and the rest in late 2013.

Each offering can be made with little notice or paperwork by one underwriter or several. In fact, because relatively few shares may be involved, the lead underwriter often handles the whole deal without a syndicate or uses only one or two other firms. This arrangement has benefited large corporations because it provides great flexibility, reduces registration fees and expenses, and allows issuing firms to request competitive bids from several investment banking firms.

On the other hand, some observers fear that shelf registrations do not allow investors enough time to examine the current status of the firm issuing the securities. Also, the follow-up offerings reduce the participation of small underwriters. Shelf registrations have typically been used for the sale of straight debentures rather than common stock or convertible issues. For further discussion of Rule 415, see Rogowski and Sorensen (1985).
4.3.2 Secondary Bond Markets

The secondary market for bonds distinguishes among those issued by the federal government, municipalities, or corporations.

Secondary Markets for U.S. Government and Municipal Bonds

U.S. government bonds are traded by bond dealers that specialize in either Treasury bonds or agency bonds. Treasury issues are bought or sold through a set of 35 primary dealers, including large banks in New York and Chicago and some large investment banking firms like Goldman Sachs and Morgan Stanley. These institutions and other firms also make markets for government agency issues, but there is no formal set of dealers for agency securities.

The major market makers in the secondary municipal bond market are banks and investment firms. Banks are active in municipal bond trading and underwriting of general obligation issues since they invest heavily in these securities. Also, many large investment firms have municipal bond departments that underwrite and trade these issues.

Secondary Corporate Bond Markets

Currently, all corporate bonds are traded over the counter by dealers who buy and sell for their own accounts. The major bond dealers are the large investment banking firms that underwrite the issues: firms such as Goldman Sachs, J.P. Morgan, Barclay Capital, and Morgan Stanley. Because of the limited trading in corporate bonds compared to the fairly active trading in government bonds, corporate bond dealers do not carry extensive inventories of specific issues. Instead, they hold a limited number of bonds desired by their clients, and when someone wants to do a trade, they work more like brokers than dealers.

Notably, there is a movement toward a widespread transaction-reporting service as with stocks, especially for large, actively traded bond issues. As discussed in Chapter 17, starting in 2005, dealers have been required to report trades within 15 minutes for transactions on 17,000 corporate bonds. Exhibit 4.2 is a daily table from The Wall Street Journal that provides data for a large set of secondary bond indexes that are similar to various stock indexes.

4.3.3 Financial Futures

In addition to the market for the bonds, a market has developed for futures contracts related to these bonds. These contracts allow the holder to buy or sell a specified amount of a given bond issue at a stipulated price. The two major futures exchanges are the Chicago Board of Trade (CBOT) and the Chicago Mercantile Exchange (CME) that merged during 2007. We discuss these futures contracts and the futures market in Chapter 19.

4.3.4 Secondary Equity Markets

Before 2000, the secondary equity markets in the United States and around the world were divided into three segments: national stock exchanges, regional exchanges, third markets, and the rapidly growing electronic communication networks (ECNs) and alternative trading systems (ATSs) and provide a detailed presentation on the functioning of stock exchanges.

Secondary markets permit trading in outstanding issues; that is, stocks or bonds already sold to the public are traded between current and potential owners. The proceeds from a sale in the secondary market do not go to the issuing unit (the government, municipality, or company), but rather to the current owner of the security.

4.2.5 Private Placements and Rule 144A

Rather than a public sale using one of these arrangements, primary offerings can be sold privately. In such an arrangement, referred to as a private placement, the firm designs an issue with the assistance of an investment banker and sells it to a small group of institutions. The firm enjoys lower issuing costs because it does not need to prepare the extensive registration statement required for a public offering. Institutions buying the issue typically benefit because the issuing firm passes some of the cost savings on to the investor as a higher return. In fact, pre-Rule 144A an institution required a higher return because of the absence of any secondary market for these securities, which implied higher liquidity risk.

The private placement market changed dramatically when Rule 144A was introduced by the SEC. This rule allows corporations—including non-U.S. firms—to place securities privately with large, sophisticated institutional investors without extensive registration documents. A major innovation is that these securities can subsequently be traded among these large sophisticated investors (those with assets in excess of $100 million). The SEC introduced this innovation to provide more financing alternatives for U.S. and non-U.S. firms and possibly increase the number, size, and liquidity of private placements, as discussed by Milligan (1990) and Hanks (1990). Presently, more than 85 percent of high-yield bonds are 144A issues.

4.3 SECONDARY FINANCIAL MARKETS

In this section, we consider the importance of secondary markets and provide an overview of the secondary markets for bonds, financial futures, and stocks. Next, we consider national stock markets around the world. Finally, we discuss other primary listing markets, regional exchanges, third markets, and the rapidly growing electronic communication networks (ECNs) and alternative trading systems (ATSs) and provide a detailed presentation on the functioning of stock exchanges.

Secondary markets permit trading in outstanding issues; that is, stocks or bonds already sold to the public are traded between current and potential owners. The proceeds from a sale in the secondary market do not go to the issuing unit (the government, municipality, or company), but rather to the current owner of the security.

4.3.1 Why Secondary Markets Are Important

Because the secondary market involves the trading of securities initially sold in the primary market, it provides liquidity to the individuals who acquired these securities. The point is, after acquiring securities in the primary market, investors may want to sell them again to acquire other securities, buy a house, or go on a vacation. The primary market benefits from this liquidity because investors would hesitate to acquire securities in the primary market if they thought they could not subsequently sell them in the secondary market. That is, without an active secondary market, potential issuers of stocks or bonds in the primary market would have to provide a much higher rate of return to compensate investors for the substantial liquidity risk.

Secondary markets are also important to those selling seasoned securities because the prevailing market price of the securities (price discovery) is determined by transactions in the secondary market. New issues of outstanding stocks or bonds to be sold in the primary market are based on prices and yields in the secondary market. Notably, the secondary market also affects market efficiency and price volatility, as discussed by Foster and Viswanathan (1993) and Jones, Kaul, and Lipson (1994). Even forthcoming IPOs are priced based on the prices and values of comparable stocks or bonds in the public secondary market.
4.3.2 Secondary Bond Markets

The secondary market for bonds distinguishes among those issued by the federal government, municipalities, or corporations.

**Secondary Markets for U.S. Government and Municipal Bonds** U.S. government bonds are traded by bond dealers that specialize in either Treasury bonds or agency bonds. Treasury issues are bought or sold through a set of 35 primary dealers, including large banks in New York and Chicago and some large investment banking firms like Goldman Sachs and Morgan Stanley. These institutions and other firms also make markets for government agency issues, but there is no formal set of dealers for agency securities.

The major market makers in the secondary municipal bond market are banks and investment firms. Banks are active in municipal bond trading and underwriting of general obligation issues since they invest heavily in these securities. Also, many large investment firms have municipal bond departments that underwrite and trade these issues.

**Secondary Corporate Bond Markets** Currently, all corporate bonds are traded over the counter by dealers who buy and sell for their own accounts. The major bond dealers are the large investment banking firms that underwrite the issues: firms such as Goldman Sachs, J.P. Morgan, Barclay Capital, and Morgan Stanley. Because of the limited trading in corporate bonds compared to the fairly active trading in government bonds, corporate bond dealers do not carry extensive inventories of specific issues. Instead, they hold a limited number of bonds desired by their clients, and when someone wants to do a trade, they work more like brokers than dealers.

Notably, there is a movement toward a widespread transaction-reporting service as with stocks, especially for large, actively traded bond issues. As discussed in Chapter 17, starting in 2005, dealers have been required to report trades within 15 minutes for transactions on 17,000 corporate bonds. Exhibit 4.2 is a daily table from *The Wall Street Journal* that provides data for a large set of secondary bond indexes that are similar to various stock indexes.

4.3.3 Financial Futures

In addition to the market for the bonds, a market has developed for futures contracts related to these bonds. These contracts allow the holder to buy or sell a specified amount of a given bond issue at a stipulated price. The two major futures exchanges are the Chicago Board of Trade (CBOT) and the Chicago Mercantile Exchange (CME) that merged during 2007. We discuss these futures contracts and the futures market in Chapter 19.

4.3.4 Secondary Equity Markets

Before 2000, the secondary equity markets in the United States and around the world were divided into three segments: national stock exchanges, regional stock exchanges, and over-the-counter (OTC) markets for stocks not on an exchange. Because of numerous changes over the past decade, a better classification has been suggested by O’Hara and Ye (2011), as presented in Exhibit 4.3. Following our background discussions on alternative trading systems and call versus continuous markets, we will describe the market types listed in Exhibit 4.3 and discuss how they complement and compete against each other to provide price discovery and liquidity to individual and institutional investors.3

---

3For a collection of essays by financial industry experts that detail the history of these changes and discuss some ideas related to the future of equity markets, see Knight Capital Group, Inc. (2010).
The other major trading system is a dealer market (also referred to as a quote-driven market) where individual dealers provide liquidity for investors by buying and selling the shares of stock for themselves. Ideally, with this system there will be numerous dealers who will compete against each other to provide the highest bid prices when you are selling and the lowest asking price when you are buying stock. Clearly, this is a very decentralized system that derives its benefit from the competition among the dealers who are connected by technology to provide the best price for the buyer and seller. When we discuss the various equity markets, we will indicate the trading system used.

Call versus Continuous Markets

Beyond the different trading systems for equities (brokers vs. dealers), the operation of exchanges can differ in terms of when and how the stocks are traded. In call markets, the intent is to gather all the bids and asks for a stock at a point in time and attempt to arrive at a single price where the quantity demanded is as close as possible to the quantity supplied. Call markets are generally used during the early stages of development of an exchange when there are few stocks listed or a small number of active investors-traders. For an exchange that is strictly a call market with a few listed stocks and traders, a designated market maker would call the roll of stocks and ask for interest in one stock at a time. After determining the available buy and sell orders, exchange officials specify a single price that will satisfy most of the orders, and all orders are transacted at this price. Notably, call markets also are used at the opening for stocks on a large exchange if there is an overnight buildup of buy and/or sell orders, in which case the opening price can differ from the prior day’s closing price. Also, a call market process is used if trading is suspended during the day because of some significant new information. In either case, the specialist or market maker would attempt to derive a new equilibrium price using a call-market approach that would reflect the imbalance and take care of most of the orders. For example, assume a stock has been trading at about $42 per share and some significant, new, positive information was released overnight or during the day. If it happened overnight it would affect the opening price; if it happened during the day, trading would be temporarily suspended and a call-market process would be used to determine a new price that reflects the new information.

Basic Trading Systems: Although stock exchanges are similar because only qualified stocks can be traded by individuals who are members of the exchange, they can differ in their trading systems. There are two major trading systems, and an exchange can use one or a combination of them. One is a pure auction market (also referred to as an order-driven market), in which interested buyers and sellers submit bid-and-ask prices (buy and sell orders) for a given stock to a central location where the orders are matched by a broker who does not own the stock but acts as a facilitating agent. Participants also refer to this system as price-driven because shares of stock are sold to the investor with the highest bid price and bought from the seller with the lowest offering price. Advocates of an auction market argue at the extreme for a very centralized market that ideally will include all the buyers and sellers of the stock.
determine a new equilibrium price that reflects the supply and demand due to the new information. If the buy orders were three or four times as numerous as the sell orders, the new price based on the call market might be $44. For an analysis of price movements surrounding trading halts, see Hopewell and Schwartz (1978) and Fabozzi and Ma (1988). Several studies have shown that using the call-market mechanism contributes to a more orderly market and less volatility at openings and following trading halts.

In a continuous market, trades occur at any time the market is open wherein stocks are priced either by auction or by dealers. In a dealer market, dealers make a market in the stock, which means that they are willing to buy or sell for their own account at a specified bid-and-ask price. In an auction market, enough buyers and sellers are trading to allow the market to be continuous; that is, when one investor comes to buy stock, there is another investor available and willing to sell stock. A compromise between a pure dealer market and a pure auction market is a combination structure wherein the market trading system is basically an auction market, but there exists an intermediary who is willing to act as a dealer if the pure auction market does not have enough activity. These intermediaries who act as both brokers and dealers provide temporary liquidity to ensure the market will be liquid and continuous.

Notably, many continuous auction market exchanges also employ a call-market mechanism on specific occasions at the open and during trading suspensions. The NYSE is such a market.

4.4 CONTRACT CLASSIFICATION OF U.S. SECONDARY EQUITY MARKETS

In this section we consider the different secondary equity markets that currently exist in the United States, as listed in Exhibit 4.3.

4.4.1 Primary Listing Markets

Primary listing markets are formal exchanges or markets where a corporate stock is primarily or formally listed. This category includes the two traditional national exchanges (New York Stock Exchange and American Stock Exchange) and the NASDAQ markets that previously were considered over-the-counter markets but are now recognized as equity markets that simply differ in how they trade securities (as will be discussed).

New York Stock Exchange (NYSE)
The New York Stock Exchange (NYSE), the largest organized securities market in the United States, was established in 1817 as the New York Stock and Exchange Board. The Exchange dates its founding to when the famous Buttonwood Agreement was signed in May 1792 by 24 brokers. The name was changed to the New York Stock Exchange in 1863.

At the end of 2010, approximately 2,850 companies had their stock listed on the NYSE, for a total of about 3,000 stock issues (common and preferred) with a total market value of more than $14 trillion.

The average number of shares traded daily on the NYSE has increased steadily and substantially. Prior to the 1960s, the daily share trading volume averaged less than 3 million shares, compared with the 2010 average daily volume of about 3.5 billion shares.

The NYSE has historically dominated the other exchanges in the United States in trading volume. Given its stringent listing requirements and its prestige, most of the largest and best-known U.S. companies are listed on the NYSE. Historically, about 55 percent of the trading volume for these stocks takes place on the NYSE, but this has changed dramatically beginning in 2004 when alternative trading venues were created as will be discussed in subsequent sections.

American Stock Exchange (AMEX)
The American Stock Exchange (AMEX) was begun by a group who traded unlisted shares at the corner of Wall and Hanover Streets in New York. It was established in 1863.

The other major trading system is a dealer market (also referred to as a quote-driven market) where individual dealers provide liquidity for investors by buying and selling the shares of stock for themselves. Ideally, with this system there will be numerous dealers who will compete against each other to provide the highest bid prices when you are selling and the lowest asking price when you are buying stock. Clearly, this is a very decentralized system that derives its benefit from the competition among the dealers who are connected by technology to provide the best price for the buyer and seller. was originally called the Outdoor Curb Market. In 1910, it established formal trading rules and changed its name to the New York Curb Market Association. The members moved inside a building in 1921 and continued to trade mainly in unlisted stocks (stocks not listed on one of the registered exchanges) until 1946, when its volume in listed stocks finally outnumbered that in unlisted stocks. The current name was adopted in 1953.

The AMEX became a major stock options exchange in January 1975 and subsequently added options on interest rates and stock indexes. In addition, a number of exchange-traded funds (ETFs) that have grown in popularity (as discussed in Chapter 3) are listed on the AMEX. The AMEX and the NASDAQ merged in 1998, but in 2005 NASDAQ sold the AMEX back to its members (see Horowitz and Kelly, 2005). The AMEX was acquired by the NYSE in 2007 and is currently referred to as the NYSE AMEX.

Global Stock Exchanges

The equity-market environment outside the United States is similar in that each country typically will have one relatively large exchange that dominates the market. Examples include the Tokyo Stock Exchange, the London Stock Exchange, the Frankfurt Stock Exchange, and the Paris Bourse.

Notably, even in emerging economies, stock exchanges have been created because of the liquidity that secondary equity markets provide. Three points about these international exchanges: first, there has been a trend toward consolidations or affiliations that will provide more liquidity and greater economies of scale to support the technology required by investors. This trend toward consolidation will be discussed in a subsequent section. Second, many of the larger companies in these countries that can qualify for listing on a U.S. exchange become dual-listed. About 20 percent of the stocks listed on the NYSE are non-U.S. firms. Third, the existence of these strong international exchanges has made possible a global equity market wherein stocks that have a global constituency can be traded around the world continuously, as discussed in the following section. There is intense competition between the various exchanges, as discussed by Ewing and Ascarelli (2000) and Cherney and Beal (2000).

The Global 24-Hour Market

The markets in New York, London, and Tokyo, because of their relative size and importance, can be envisioned to represent the major segments of a worldwide 24-hour stock market wherein investment firms "pass the book" around the world. This means the major active market in securities moves around the globe as trading hours for these three markets (and other exchanges) begin and end.

As an example, consider the individual trading hours for each of the three exchanges, translated into a 24-hour eastern standard time (EST) clock:

Imagine trading starting in New York at 0930 and going until 1600 in the afternoon, being picked up by Tokyo late in the evening and going until 0500 in the morning, and continuing in London (with some overlap) until it begins in New York again (with some overlap) at 0930. Given this scenario, the U.S. trader asks, "What happened in Tokyo and what is happening in London?" The trader in Tokyo is concerned with what happened in New York, and subsequently the London traders are aware of what happened in New York and want to know what is happening in Tokyo. The point is, the markets operate almost continuously and are related in their response to economic events. Therefore, investors are not dealing with three or more separate and distinct exchanges, but with one interrelated world market because of the availability of sophisticated telecommunications. Paraphrasing a statement by O’Hara and
Ye (2011), it is a single virtual market with multiple points of entry. Participants in this global market are the stocks of companies that have global markets for their products like General Electric, Coca Cola, Johnson & Johnson, McDonald’s, and similar international firms.

**The NASDAQ Market** This market system was historically known as the over-the-counter (OTC) market, which included stocks not formally listed on the two major exchanges (NYSE and AMEX). This description has changed since it was recognized that this is an equity market similar to the major exchanges with several minor differences. The first difference is that it is a dealer market, in contrast to a broker/dealer (specialists) market as is the NYSE. Second, trading by dealers on NASDAQ takes place via computer communication rather than on a trading floor as in the other exchanges. Notably, as will be discussed, this is no longer a difference since the NYSE has adopted electronic trading which is growing rapidly. What the NASDAQ also has in common with the other exchanges is a set of requirements for a stock to be traded on the NASDAQ National Market System (NMS). Also while NASDAQ dealers do not have to pay for a seat (membership) on the exchange, they are required to be members of the National Association of Security Dealers (NASD) and abide by its rules.

The NASDAQ market is the largest U.S. secondary market in terms of the number of issues traded. As noted earlier, there are about 3,000 issues traded on the NYSE. In contrast, more than 2,800 issues are actively traded on the NASDAQ NMS and almost 700 on the NASDAQ Small-Cap Market (SCM). The NASDAQ market is also the most diverse secondary market component in terms of quality because it has multiple minimum requirements. Stocks that trade on the NASDAQ market (NMS and SCM) range from those of small, unprofitable companies to large, extremely profitable firms such as Microsoft, Intel, and Apple.

In early 2011, an estimated 650 issues of NASDAQ were either foreign stocks or American Depository Receipts (ADRs). About 300 of these issues trade on both NASDAQ and a foreign exchange such as Toronto. NASDAQ has developed a link with the Singapore Stock Exchange that allows 24-hour trading from NASDAQ in New York to Singapore to a NASDAQ/London link and back to New York.

Although the NASDAQ market has the greatest number of issues, the NYSE has a larger total value of trading. In 2010 the approximate value of average daily equity trading on the NYSE was about $58 billion and on NASDAQ was about $35 billion.

**Operation of the NASDAQ Market** As noted, stocks can be traded on the NASDAQ market as long as there are dealers willing to make a market by buying or selling for their own account.

**Listing Requirements for NASDAQ** Quotes and trading volume for the NASDAQ market are reported in two lists: a National Market System (NMS) list and a regular NASDAQ list. There are alternative standards for initial listing and continued listing on the NASDAQ NMS. A company must meet all of the requirements under at least one of the three listing standards for initial listing and then meet at least one continued listing standard to maintain its listing on the NMS. The standards for the NMS listing are significant but not quite as onerous as for the NYSE. For stocks on this system, reports include up-to-the-minute volume and last-sale information for the competing market makers as well as end-of-the-day information on total volume and high, low, and closing prices.

**A Sample Trade** Assume you are considering the purchase of 100 shares of Intel. Although Intel is large enough and profitable enough to be listed on the NYSE, the company has never applied for listing because it enjoys a very active market on NASDAQ. (It is one of the volume leaders, with daily volume typically above 25 million shares and often in excess of 50 million shares.)

**NASDAQ** is an acronym for National Association of Securities Dealers Automated Quotations. The system is discussed in detail in a later section. To be traded on the NMS, a firm must have a certain size and trading activity and at least four market makers. A specification of requirements for various components of the NASDAQ system is contained in Exhibit 4.7.

**Dealer and market maker** are synonymous.
shares.) When you contact your broker, she will consult the NASDAQ quotation machine to
determine the current dealer quotations for INTC, the trading symbol for Intel.\(^7\) The quote
machine will show that about 35 dealers are making a market in INTC. An example of differ-
ing quotations might be as follows:

<table>
<thead>
<tr>
<th>Dealer</th>
<th>Bid</th>
<th>Ask</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>30.60</td>
<td>30.75</td>
</tr>
<tr>
<td>2</td>
<td>30.55</td>
<td>30.65</td>
</tr>
<tr>
<td>3</td>
<td>30.50</td>
<td>30.65</td>
</tr>
<tr>
<td>4</td>
<td>30.55</td>
<td>30.70</td>
</tr>
</tbody>
</table>

Assuming these are the best markets available from the total group, your broker would call
either Dealer 2 or Dealer 3 because they have the lowest offering prices. After verifying the
quote, your broker would give one of these dealers an order to buy 100 shares of INTC at
$30.65 a share. Because your firm was not a market maker in the stock, the firm would act
as a broker and charge you $3,065 plus a commission for the trade. If your firm had been a
market maker in INTC, with an asking price of $30.65 the firm would have sold the stock to
you at $30.65 net (without commission). If you had been interested in selling 100 shares of
Intel instead of buying, the broker would have contacted Dealer 1, who had the highest bid
($30.60).

**Changing Dealer Inventory** Let’s consider the price quotations by a NASDAQ dealer who
wants to change his inventory on a given stock. For example, assume Dealer 4, with a current
quote of 30.55 bid–30.70 ask, decides to increase his holdings of INTC. The NASDAQ quotes
indicate that the highest bid is currently 30.60. Increasing the bid to 30.60 would bring some
of the business currently going to dealer 1. Taking a more aggressive action, Dealer 4 might
raise the bid to 30.63 and buy all the stock offered, because he has the highest bid. In this ex-
ample, the dealer raises the bid price but does not change the ask price, which was above those
of Dealers 2 and 3. This dealer will buy stock but probably will not sell any. A dealer who had
excess stock would keep the bid below the market (lower than 30.60) and reduce the ask price
to 30.65 or less. Dealers constantly change their bid-and-ask prices, depending on their current
inventories or changes in the outlook based on new information for the stock.

**Other NASDAQ Market Segments** Now that we are familiar with the NASDAQ system
and its operation, we can easily describe the other segments of this market since the major
differences relate to the size and liquidity of the stocks involved.

- The **NASDAQ Small-Cap Market (SCM)** has initial listing requirements that consider
  the same factors as the NMS but are generally about one-half to one-third of the values re-
  quired for the NMS. As of early 2011, there were about 700 stocks listed in the NASDAQ
  small-cap segment. As noted earlier, the NASDAQ NMS contained about 3,000 issues as of
  early 2011. Therefore, the total NASDAQ market includes approximately 3,700 issues (3,000
  NMS and about 700 issues on the SCM).

- The **NASDAQ OTC Electronic Bulletin Board (OTCBB)** reports “indications” for small
  stocks sponsored by NASD dealers. Indications are approximate values—if an investor
  wants to buy or sell the stock it would be necessary to contact a dealer in the stock for a
  tradable quote. As of early 2011, there were about 3,400 stocks included on the OTCBB.

- The **National Quotation Bureau (NQB) Pink Sheets** report order indications for the
  smallest publicly traded stocks in the United States. Pre-1970, these pink sheets (actually

that linked the national and regional exchanges and the CBOE. The ITS allowed trades to go to the best quotes, but unfortunately it was not required or automatic. The transition story is best described by the timeline of events and legislation that started in 1994.

**The Initial Setting**

The equity markets in the early 1990s were best described as relatively busy, but also controlled, with the NYSE and its members dominating the listed stock market and being very prosperous—a "seat" (membership) on the NYSE consistently sold for over $2 million in the early 2000s and had a peak price of $3.25 million in 2005. The NYSE had virtually only one competitor—the NASDAQ market that was concentrated in the over-the-counter (OTC) market that was basically an electronic dealer market.

**The Transition Begins**

The U.S. equity market began to change in 1994 with the publication of a study by Christie and Schultz (1994) that documented the strong tendency for market quotes to be concentrated in quarters (0,$\frac{1}{4}$; $\frac{1}{2}$; $\frac{3}{4}$) even though price quotes could be in eighths ($\frac{1}{8}$; $\frac{3}{8}$; $\frac{5}{8}$; $\frac{7}{8}$). It was documented by Christie and Schultz that the dealers apparently were colluding to maintain wide bid-ask spreads to ensure high profits. The reaction by the Justice Department and the SEC to these empirical findings was fairly fast and dramatic.

In 1996 there were convictions for "anticompetitive behavior," and in early 1997 new order-handling rules were specified that designated computerized trading platforms such as Instinet as electronic communications networks (ECNs) and required that ECNs make their quotes available to the public markets. As a result, previously private quotes were made available to the total market including several small electronic trading markets that were just beginning. This legislation allowed these ECNs to compete with the major exchanges and gain significant market share. It also encouraged the creation of additional ECNs. As a result, significant competition developed among the ECNs on the basis of speed, price, and reliability. This proliferation of ECNs led to a battle for trading volume wherein ECNs began paying for order flow that involved rebates of commissions for limit orders. These rebate fees were revenue for traders and led to a significant increase in trading volume.

**The Move to Decimal Pricing**

The next big change followed shortly in June 1997 when the first change in pricing increments occurred. Specifically, prices went from being quoted in one-eighths (that had been used since the 1800s) to one-sixteenths. While this change clearly was significant and caused a decline in spreads, there were still potential problems with a spread of six cents that led to civil violations by traders and even specialists on the NYSE.

In 2000 the SEC eliminated this problem by ordering the markets to go to decimal pricing (pennies) by April 2001. In response to this mandate, all the markets went to one cent increments in early 2001. The immediate impact was significantly smaller spreads—from six cents to possibly a penny—which caused many NASDAQ traders to leave the business. In response to the decimalization, the NYSE created a new trading order entitled "Direct+" that allowed member firms to electronically trade up to 1,099 shares every 30 seconds without allowing an order to get in front of the order submitted. This innovation, combined with the DOT system that was an electronic order routing system that allowed market and limit orders to go directly to the NYSE trading posts, transformed how large orders were executed. Specifically, rather than "block trades" of 10,000 shares or more, this combination of DIRECT+ and DOT made it possible to do large trades by the use of multiple small orders that could be executed without the information impounded in large trades. Almost immediately (mid-2001) firms developed computer programs (algorithms) to divide the large orders into small orders—these programs were really the initiation of algorithmic trading. A follow-on to the creation of numerous

**4.4.2 Regional Stock Exchanges**

Regional exchanges typically have the same operating procedures as national exchanges in the same countries, but their listing requirements are less stringent than for national exchanges. Regional stock exchanges exist for two main reasons: First, they provide trading facilities for local companies not large enough to qualify for listing on a national exchange.

Second, regional exchanges can list firms that also list on one of the national exchanges to give local brokers access to these securities. As an example, Walmart and General Motors are listed on both the NYSE and several regional exchanges. This dual listing allows a firm that is not a member of the NYSE to buy and sell shares of the dual-listed stock without going through the NYSE. In addition, regional exchanges can trade some stocks on the NASDAQ market under unlisted trading privileges (UTP) granted by the SEC. The majority of trading on regional exchanges is due to dual-listed and UTP stocks.

The regional exchanges in the United States as of 2010 are shown in Exhibit 4.3. The Chicago, Philadelphia, and Boston exchanges accounted for about 90 percent of the volume on all U.S. regional exchanges. A discussion at the end of the chapter will consider regional exchange mergers.

**4.4.3 The Third Market**

Historically, the third category was the third market. The term third market involves dealers and brokers who trade shares that are listed on an exchange away from the exchange. Although most transactions in listed stocks have historically taken place on an exchange, this has been changing, as will be discussed in the following section. The point is, an investment firm that is not a member of one of the major exchanges can make a market in a listed stock away from the exchange. Most third market trading is in well-known stocks such as General Electric, Coca-Cola, and Johnson & Johnson. As will be discussed, the success or failure of the third market depends on whether the alternative market in these stocks is as good as the exchange market and whether the relative cost of the transaction compares favorably with the cost on the exchange. This market was critical during the relatively few periods when trading is not available on the NYSE either because trading is suspended or the exchange is closed. This market has also grown because of the quality and cost factors mentioned. Third market dealers typically displayed their quotes on the NASDAQ InterMarket system. For articles that discuss the impact of third market trading and the practice of purchasing order flow, see Battalio (1997); Battalio, Greene, and Jennings (1997); and Easley, Kiefer, and O’Hara (1996).

**4.4.4 The Significant Transition of the U.S. Equity Markets**

The prior discussion of the U.S. equity market is correct and relevant but it does not reflect the rapid and very dramatic changes that have transpired over the past 17 years to financial institutions that have existed for almost 220 years (recall that the Buttonwood Agreement for the NYSE was signed in 1792). Prior to the significant transition that started in 1994, there were some initial changes introduced by the SEC to bring about a national competitive securities market. The SEC mandated a consolidated tape in the mid-1970s that reported centralized transactions from the national and regional exchanges and NASDAQ. This was followed by consolidated quotations and then the introduction of the Intermarket Trading System (ITS)
that linked the national and regional exchanges and the CBOE. The ITS “allowed” trades to go
to the best quotes, but unfortunately it was not required or automatic. The transition story is
best described by the time line of events and legislation that started in 1994.

**The Initial Setting** The equity markets in the early 1990s were best described as relatively
busy, but also controlled, with the NYSE and its members dominating the listed stock market
and being very prosperous—a “seat” (membership) on the NYSE consistently sold for over $2
million in the early 2000s and had a peak price of $3.25 million in 2005. The NYSE had virtu-
ally only one competitor—the NASDAQ market that was concentrated in the over-the-counter
(OTC) market that was basically an electronic dealer market.

**The Transition Begins** The U.S. equity market began to change in 1994 with the publication
of a study by Christie and Schultz (1994) that documented the strong tendency for market
quotes to be concentrated in quarters (0, ¼, ½) even though price quotes could be in eighths
(¼, ½, ¾). It was documented by Christie and Schultz that the dealers apparently were colluding
to maintain wide bid-ask spreads to ensure high profits. The reaction by the Justice Depart-
ment and the SEC to these empirical findings was fairly fast and dramatic.

In 1996 there were convictions for “anticompetitive behavior,” and in early 1997 new order-
handling rules were specified that designated computerized trading platforms such as Instinet
as electronic communications networks (ECNs) and required that ECNs make their quotes
available to the public markets. As a result, previously private quotes were made available to
the total market including several small electronic trading markets that were just beginning.
This legislation allowed these ECNs to compete with the major exchanges and gain significant
market share. It also encouraged the creation of additional ECNs. As a result, significant com-
petition developed among the ECNs on the basis of speed, price, and reliability. This prolif-
eration of ECNs led to a battle for trading volume wherein ECNs began paying for order flow
that involved rebates of commissions for limit orders. These rebate fees were revenue for trau-
der and led to a significant increase in trading volume.

**The Move to Decimal Pricing** The next big change followed shortly in June 1997 when
the first change in pricing increments occurred. Specifically, prices went from being quoted
in one-eighths (that had been used since the 1800s) to one-sixteenths. While this change

NYSE.9

In 2000 the SEC eliminated this problem by ordering the markets to go to decimal pricing
(pennies) by April 2001. In response to this mandate, all the markets went to one cent incre-
ments in early 2001. The immediate impact was significantly smaller spreads—from six cents
to possibly a penny—which caused many NASDAQ traders to leave the business. In response

the information impounded in large trades. Almost immediately (mid-2001) firms developed
computer programs (algorithms) to divide the large orders into small orders—these programs
were really the initiation of **algorithmic trading**. A follow-on to the creation of numerous

small orders along with the availability of many competing ECNs were “smart order routing” algorithms that selected where to send orders to minimize transaction costs and impact. An obvious result of these changes is that the average size of trades declined dramatically from about 800 shares per trade in 2002 to about 200 shares in 2010, while the number of transactions exploded from 545 million in 2002 to more than 2 trillion in 2008. It is not a surprise that block trades (of 10,000 or more shares) that had accounted for almost 52 percent of the NYSE volume in 2000 declined to barely 10 percent in 2008.

The effects of the order handling rules that affected the ECNs and the decimalization that affected trading practices can be summarized as:

- Numerous small orders
- Very tight spreads
- Significant impacts from trading algorithms
- Trend toward electronic trading

**The National Market System (NMS)** The trend toward electronic trading accelerated in 2005 when the SEC passed Regulation NMS (National Market System) that was to be implemented by August 2007. This mandated the electronic linkage of the various exchanges into one electronic market. Further, this required all markets to immediately respond to electronic orders or be branded a “slow market.” To meet this requirement, the NYSE created a “hybrid” market that was electronic, but also included a manual component if needed. Shortly after this hybrid market was initiated in February, 2007, it became clear that the manual component was not needed. By the spring of 2007, the brokerage firms with people on the floor of the NYSE began laying off personnel while specialist firms consolidated and reduced employees on the floor.10

Longer term, the ECNs continued to spend on technology to enhance speed and reduce the cost of trading. In addition, there were numerous consolidations among the ECNs and the acquisition of ECNs by both the NYSE and NASDAQ.

**Algorithmic Trading (AT) Extended** As noted, algorithmic trading was initially used to separate large orders into small components for Direct+ and DOT, and was subsequently used for smart routing of these numerous small orders to alternative ECNs. Following these successful efforts, some hedge funds and other money managers recognized that it was also possible to create algorithms to rapidly trade stocks based on either specified trading rules that responded to technical market signals or prompt trades that reacted to economic and fundamental information. The point is, while investors or traders knew that the market responded to some events (e.g., mergers) or announcements (earning reports), it was a matter of how fast one could respond to these signals and implement the appropriate trade. The answer was to create an algorithm that would recognize the news event and immediately respond with an order in microseconds. The result was high-frequency trading (HFT) that involved thousands of orders daily and contributed to the explosion in volume noted earlier.

This combination of AT and HFT has been both praised and condemned. The positive view is that this increased volume provides liquidity for the market, smaller bid-ask spreads, and substantially lower transaction costs for everybody including retail investors. A study by Henderschott, Jones, and Menkveld (2011) documents the increased liquidity and information available—especially for large stocks.

The negative side of AT/HFT is concerned with the potential for major trading problems if there is ever an algorithmic glitch or a “fat finger” event when an operator hits the wrong key.

10 An article by Chapman (2007) contains a thorough discussion of the changes during this period and the effects on the staff of the NYSE and the members of the Exchange. Articles by Dowell (2007), Luccetti (2007), and Bergstrom (2007) contain additional details.
You must also indicate how long the limit order will be outstanding. Alternative time specifications are basically boundless. A limit order can be instantaneous (“fill or kill,” meaning fill the order instantly or cancel it). In the world of algorithmic trading, this is a popular time specification for high-frequency traders. It can also be good for part of a day, a full day, several days, a week, or a month. It can also be open ended, or good until canceled (GTC).

Rather than wait for a given price on a stock, because KO is listed on the NYSE your broker will give the limit order to the specialist, who will put it in a limit-order book and act as the broker’s representative. When and if the market price for KO reaches the limit-order price, the specialist will execute the order and inform your broker. The specialist receives a small part of the commission for rendering this service.

4.5.3 Special Orders

In addition to these general orders, there are several special types of orders. A **stop loss order** is a conditional market order whereby the investor directs the sale of a stock if it drops to a given price. Assume you buy a stock at $50 and expect it to go up. If you are wrong, you want to limit your losses. To protect yourself, you could put in a stop loss order at $45. In this case, if the stock dropped to $45, your stop loss order would become a market sell order, and the stock would be sold at the prevailing market price. The stop loss order does not guarantee that you will get the $45; you can get a little bit more or a little bit less. Because of the possibility of market disruption caused by a large number of stop loss orders, exchanges have, on occasion, canceled all such orders on certain stocks and not allowed brokers to accept further stop loss orders on those issues.

A related stop loss tactic for an investor who has entered into a short sale is a **stop buy order**. Such an investor who wants to minimize his or her loss if the stock begins to increase in value would enter this conditional buy order at a price above the short-sale price. Assume you sold a stock short at $50, expecting it to decline to $40. To protect yourself from an increase, you could put in a stop buy order to purchase the stock using a market buy order if it reached a price of $55. This conditional buy order would hopefully limit any loss on the short sale to approximately $5 a share.

4.5.4 Margin Transactions

When investors buy stock, they can pay for the stock with cash or borrow part of the cost, leveraging the transaction. Leverage is accomplished by buying on margin, which means the investor pays for the stock with some cash and borrows the rest through the broker, putting up the stock for collateral.

The dollar amount of margin credit extended by NYSE members has generally increased over time, but it is a fairly cyclical series that increases during rising markets and declines during falling markets. The interest rate charged on these loans by the investment firms is typically 1.50 percent above the rate charged by the bank making the loan. The bank rate, referred to as the **call money rate**, is generally about 1 percent below the prime rate. For example, in May 2011 the prime rate was 3.25 percent, and the call money rate was 2.00 percent.

Federal Reserve Board Regulations T and U determine the maximum proportion of any transaction that can be borrowed. This **margin requirement** (the proportion of total transaction value that must be paid in cash) has varied over time from 40 percent (allowing loans of 60 percent of the value) to 100 percent (allowing no borrowing). As of May 2011, the initial margin requirement specified by the Federal Reserve was 50 percent, although individual investment firms can require higher percents.

After the initial purchase, changes in the market price of the stock will cause changes in the investor’s equity, which is equal to the market value of the collateral stock minus the amount borrowed. Obviously, if the stock price increases, the investor’s equity as a proportion of the Chapter 4: Organization and Functioning of Securities Markets

and initiates a major blowout or crash. An example of such an event occurred on May 6, 2010, when the market experienced a “Flash Crash.” Specifically on the afternoon of May 6th when the major stock and futures indexes were already down over 4% for the day, prices suddenly declined a further 5–6% in a matter of minutes and, in turn this was followed by a very rapid recovery. The fact is, in a matter of minutes an algorithmic order by an investment firm in Kansas City caused numerous high frequency traders to automatically withdraw from the market. In turn, this reduced the market’s overall liquidity and caused numerous significant price declines—many of which were subsequently reversed. For a detailed discussion of what transpired, see both the preliminary and final reports prepared by the staffs of the Commodity Futures Trading Commission (CFTC) and the Security and Exchange Commission (SEC). Specifically, CFTC and SEC (May 18, 2010 and September 30, 2010).

**The Current Status** Given the numerous developments discussed, it is useful to summarize what has changed, what has not changed, and what is likely to change in the future. Because the discussion has concentrated on the changes that have occurred, they are the most obvious. The fact is, we now have a market that is generally more efficient because trading is easier, it is much faster, and is substantially cheaper than it was previously (e.g., 10 years ago). In the process, the NYSE has lost a lot of market power, the NASDAQ has grown in significance, and we have witnessed the creation of numerous ECNs that have reshaped our markets toward electronic trading.

What has not changed are the basic orders used to implement trading that will be described in the following section. What has started to change and will likely continue to change going forward is the basic makeup of the Exchanges, ECNs and ATSs—that is, there have been numerous mergers over the past decade and several more are in negotiations at this time. It is clear that more will transpire for reasons discussed in the final section of the chapter.

### 4.5 Alternative Types of Orders Available

It is important to understand the different types of orders available to investors irrespective of how the market is organized.

#### 4.5.1 Market Orders

The most frequent type of order is a **market order**, an order to buy or sell a stock at the best current price. An investor who enters a market sell order indicates a willingness to sell immediately at the highest bid available at the time the order reaches an exchange, a NASDAQ dealer, or an ECN. A market buy order indicates the investor is willing to pay the lowest offering price available at the time on the exchange, the NASDAQ, or an ECN. Market orders provide immediate liquidity for an investor willing to accept the prevailing market price.

Assume you are interested in General Electric (GE) and you call your broker to find out the current “market” on the stock. The quotation machine indicates that the prevailing best market is 30 bid–30.05 ask. This means that the highest current bid on the books of the specialist or an ECN is 30; that is, $30 is the most that anyone has offered to pay for GE. The lowest offer is 30.05; that is, this is the lowest price anyone is willing to accept to sell the stock. If you placed a market buy order for 100 shares, you would buy 100 shares at $30.05 a share (the lowest ask price) for a total cost of $3,005 plus commission. If you submitted a market sell order for 100 shares, you would sell the shares at $30 each and receive $3,000 less commission.

#### 4.5.2 Limit Orders

The individual placing a **limit order** specifies the buy or sell price. You might submit a limit-order bid to purchase 100 shares of Coca-Cola (KO) stock at $60 a share when the current market is 65 bid–65.10 ask, with the expectation that the stock will decline to $60 in the near future.
You must also indicate how long the limit order will be outstanding. Alternative time specifications are basically boundless. A limit order can be instantaneous (“fill or kill,” meaning fill the order instantly or cancel it). In the world of algorithmic trading, this is a popular time specification for high-frequency traders. It can also be good for part of a day, a full day, several days, a week, or a month. It can also be open ended, or good until canceled (GTC).

Rather than wait for a given price on a stock, because KO is listed on the NYSE your broker will give the limit order to the specialist, who will put it in a limit-order book and act as the broker’s representative. When and if the market price for KO reaches the limit-order price, the specialist will execute the order and inform your broker. The specialist receives a small part of the commission for rendering this service.

### 4.5.3 Special Orders

In addition to these general orders, there are several special types of orders. A stop loss order is a conditional market order whereby the investor directs the sale of a stock if it drops to a given price. Assume you buy a stock at $50 and expect it to go up. If you are wrong, you want to limit your losses. To protect yourself, you could put in a stop loss order at $45. In this case, if the stock dropped to $45, your stop loss order would become a market sell order, and the stock would be sold at the prevailing market price. The stop loss order does not guarantee that you will get the $45; you can get a little bit more or a little bit less. Because of the possibility of market disruption caused by a large number of stop loss orders, exchanges have, on occasion, canceled all such orders on certain stocks and not allowed brokers to accept further stop loss orders on those issues.

A related stop loss tactic for an investor who has entered into a short sale is a stop buy order. Such an investor who wants to minimize his or her loss if the stock begins to increase in value would enter this conditional buy order at a price above the short-sale price. Assume you sold a stock short at $50, expecting it to decline to $40. To protect yourself from an increase, you could put in a stop buy order to purchase the stock using a market buy order if it reached a price of $55. This conditional buy order would hopefully limit any loss on the short sale to approximately $5 a share.

### 4.5.4 Margin Transactions

When investors buy stock, they can pay for the stock with cash or borrow part of the cost, leveraging the transaction. Leverage is accomplished by buying on margin, which means the investor pays for the stock with some cash and borrows the rest through the broker, putting up the stock for collateral.

The dollar amount of margin credit extended by NYSE members has generally increased over time, but it is a fairly cyclical series that increases during rising markets and declines during falling markets. The interest rate charged on these loans by the investment firms is typically 1.50 percent above the rate charged by the bank making the loan. The bank rate, referred to as the call money rate, is generally about 1 percent below the prime rate. For example, in May 2011 the prime rate was 3.25 percent, and the call money rate was 2.00 percent.

Federal Reserve Board Regulations T and U determine the maximum proportion of any transaction that can be borrowed. This margin requirement (the proportion of total transaction value that must be paid in cash) has varied over time from 40 percent (allowing loans of 60 percent of the value) to 100 percent (allowing no borrowing). As of May 2011, the initial margin requirement specified by the Federal Reserve was 50 percent, although individual investment firms can require higher percents.

After the initial purchase, changes in the market price of the stock will cause changes in the investor’s equity, which is equal to the market value of the collateral stock minus the amount borrowed. Obviously, if the stock price increases, the investor’s equity as a proportion of the
In addition to the initial margin requirement, another important concept is the **maintenance margin**, which is the required proportion of your equity to the total value of the stock after the initial transaction; the maintenance margin protects the broker if the stock price declines. At present, the minimum maintenance margin specified by the Federal Reserve is 25 percent, but, again, individual brokerage firms can dictate higher margins for their customers. If the stock price declines to the point where your investor’s equity drops below 25 percent of the total value of the position, the account is considered undermargined, and you will receive a **margin call** to provide more equity. If you do not respond with the required funds in time, the stock will be sold to pay off the loan. The time allowed to meet a margin call varies between investment firms and is affected by market conditions. Under volatile conditions, the time allowed to respond to a margin call can be shortened drastically (e.g., one day).

Given a maintenance margin of 25 percent, when you buy on margin you must consider how far the stock price can fall before you receive a margin call. The computation for our example is as follows: If the price of the stock is \( P \) and you own 200 shares, the value of your position is \( 200P \) and the equity in your account is \( (200P - \$5,000) \). The percentage margin is \( \frac{200P - \$5,000}{200P} \).

To determine the price, \( P \), that is equal to 25 percent (0.25), we use the following equation:

\[
\frac{200P - \$5,000}{200P} = 0.25
\]

\[
200P - \$5,000 = 50P
\]

\[
150P = \$5,000
\]

\[
P = \$33.33
\]

Therefore, when the stock is at \$33.33, the equity value is exactly 25 percent; so if the stock declines from \$50 to below \$33.33, you will receive a margin call.

To continue the previous example, if the stock declines to \$30 a share, its total market value would be \$6,000 and your equity would be \$1,000, which is only about 17 percent of the total value \( \frac{\$1,000}{\$6,000} = 17\% \). You would receive a margin call for approximately \$667, which would give you equity of \$1,667, or 25 percent \( \frac{\$1,667}{\$6,667} \). If the stock declines further, you would receive additional margin calls.

**4.5.5 Short Sales**

Most investors purchase stock ("go long") expecting to derive their return from an increase in value. If you believe that a stock is overpriced, however, and want to take advantage of an expected decline in the price, you can sell the stock short. A **short sale** is the sale of stock that you do not own with the intent of purchasing it back later at a lower price. Specifically, you would **borrow** the stock from another investor through your broker and sell it in the market. Subsequently you would replace it by buying at a price lower (you hope) than the price at which you sold it (this is referred to as **covering your short position**).

Although a short sale has no time limit, the lender of the shares can decide to sell the shares, in which case your broker must find another investor willing to lend the shares. For discussions of both good and bad experiences with short-selling, see Power (1993), Loomis (1996), Weiss (1996), Beard (2001), and McKay (2005).

Two technical points affect short sales.

1. The first technical point concerns dividends. The short seller must pay any dividends due to the investor who lent the stock. The purchaser of the short-sale stock that you borrowed receives the dividend from the corporation, so the short seller must pay a similar dividend to the person who lent the stock.

2. Prior to June 2007 there was a rule that short sales of individual stocks could only be made on "upticks," meaning the price of the short sale had to be higher than the last trade price. As discussed in Jakab (2007), this rule was eliminated in 2007 by the SEC.
Secondly, short sellers must post the same margin as an investor who had acquired stock. This margin can be in cash or any unrestricted securities owned by the short seller. To illustrate this technique and demonstrate these technical points, consider the following example using Cara Corporation stock that is currently selling for $80 a share. You believe that the stock is overpriced and decide to sell 1,000 shares short at $80. Your broker borrows the Cara Corporation stock on your behalf, sells it at $80, and deposits the $80,000 (less commissions that we will ignore in this example) in your account. Although the $80,000 is in your account, you cannot withdraw it. In addition, you must post 50 percent margin ($40,000) as collateral. Your percent margin equals:

\[
\text{Percent Margin} = \frac{\text{Value of Your Equity}}{\text{Value of Stock Owed}}
\]

The value of your equity equals: the cash from the sale of stock ($80,000), plus the required margin deposited ($40,000), minus the value of the stock owed (1,000 \(P\)). Therefore, the percent margin at the initiation is:

\[
\text{Percent Margin} = \frac{\$80,000 + \$40,000 - \$80,000}{\$80,000} = 0.50
\]

Similar to the discussion under margin transactions, it is necessary to continue to compare the percent margin over time to the maintenance margin (assumed to be 25 percent). Notably, in the case of a short sale, a price decline is a positive event related to the percent margin. For example, if we assume that the price of Cara Corporation stock declines to $70, the percent margin would increase as follows:

\[
\text{Your Equity} = \text{Value of Stock Owed} = \frac{\$80,000 + \$40,000 - \$70,000}{\$70,000} = 0.71
\]

Alternatively, if the stock price increases to $90 a share, the percent margin would experience a decline as follows:

\[
\text{Your Equity} = \text{Value of Stock Owed} = \frac{\$80,000 + \$40,000 - \$90,000}{\$90,000} = 0.33
\]

As before, it is important to determine the stock price that would trigger a margin call, which is computed as follows:

\[
\text{Your Equity} = \text{Value of Stock Owed} = \frac{\$120,000 - 1,000 \times P}{1,000 \times P} = 0.25
\]

\[
\frac{200P - 5,000}{200P} = 0.25
\]

\[
200P - 5,000 = 50P
\]

\[
150P = 5,000
\]

\[
P = \$33.33
\]

Therefore, when the stock is at $33.33, the equity value is exactly 25 percent; so if the stock declines from $50 to below $33.33, you will receive a margin call.

To continue the previous example, if the stock declines to $30 a share, its total market value would be $6,000 and your equity would be $1,000, which is only about 17 percent of the total value ($1,000/$6,000). You would receive a margin call for approximately $667, which would give you equity of $1,667, or 25 percent of the total value of the account ($1,667/$6,667). If the stock declines further, you would receive additional margin calls.

orders along with selling a stock short to limit this loss and possibly avoid a margin call—that is, they would put in a stop-gain order at some price below 96.

4.5.6 Exchange Market-Makers

Earlier we discussed exchange "brokers" who bring buyers and sellers together to transact but never own the asset involved (real estate brokers are a popular example). We also discussed "dealers" who expedite transactions by buying and selling for their own account and make a living based on the bid-ask spread (the difference between what they paid for the asset [their bid price] and what they sell it for [the asking price]). As we will discuss subsequently, the NASDAQ market is composed of competing dealers who trade the stocks on that system. In contrast, the major market-makers on the U.S. listed exchanges (NYSE and AMEX) are referred to as "specialists" or "designated market makers (DMM)."

The specialist (DMM) is a member of the exchange who applies to the exchange to be assigned stocks to handle (generally 10–15). These DMMs have two major functions. First, they serve as brokers to match buy and sell orders and to handle special limit orders placed with other brokers—they transact when the market price reaches the limit price. The second major function is to act as a dealer to maintain a fair and orderly market by providing liquidity when the natural flow of orders is not adequate. As noted, as a dealer he or she must buy or sell for his or her own account when public supply or demand is not enough for a continuous liquid market.

4.5.7 New Trading Systems

As daily trading volume has gone from about 5 million shares to over 2 billion shares on both the NYSE and NASDAQ, it has become necessary to introduce new technology into the trading process. Following are some technological innovations that assist in the trading process.

On the NYSE:

- **Super Dot.** Super Dot is an electronic order-routing system through which member firms transmit market and limit orders in NYSE-listed securities directly to the posts where securities are traded or to the member firm's booth. After the order has been executed, a report of execution is returned directly to the member firm office over the same electronic circuit, and the execution is submitted directly to the comparison systems. Member firms can enter market orders up to 2,099 shares and limit orders in round or odd lots up to 30,099 shares. An estimated 85 percent of all market orders enter the NYSE through the Super Dot system.

- **The Display Book.** The Display Book is an electronic workstation that keeps track of all limit orders and incoming market orders. This includes incoming Super Dot limit orders.

- **Opening Automated Report Service (OARS).** OARS, the opening feature of the Super Dot system, accepts member firms' preopening market orders up to 30,099 shares. OARS automatically and continuously pairs buy and sell orders and presents the imbalance to the specialist prior to the opening of a stock. This system helps the specialist determine the opening price and the potential need for a preopening call market, as discussed earlier.

- **Market-Order Processing.** Super Dot's postopening market-order system is designed to accept member firms' postopening market orders up to 30,099 shares. The system provides rapid execution and reporting of market orders. During 2010, 94.5 percent of market orders were executed and reported in less than 20 seconds.

- **Limit-Order Processing.** The limit-order processing system electronically files orders to be executed when and if a specific price is reached. The system accepts limit orders up to 99,999 shares and electronically updates the Specialists' Display Book. Good-until-canceled orders that are not executed on the day of submission are automatically stored until executed or canceled.

Secondly, short sellers must post the same margin as an investor who had acquired stock. This margin can be in cash or any unrestricted securities owned by the short seller.

To illustrate this technique and demonstrate these technical points, consider the following example using Cara Corporation stock that is currently selling for $80 a share. You believe that the stock is overpriced and decide to sell 1,000 shares short at $80. Your broker borrows the Cara Corporation stock on your behalf, sells it at $80, and deposits the $80,000 (less commissions that we will ignore in this example) in your account. Although the $80,000 is in your account, you cannot withdraw it. In addition, you must post 50 percent margin ($40,000) as collateral. Your percent margin equals:

\[
\text{Percent Margin} = \frac{\text{Value of Your Equity}}{\text{Value of Stock Owed}}
\]

The value of your equity equals: the cash from the sale of stock ($80,000), plus the required margin deposited ($40,000), minus the value of the stock owed (1,000P). Therefore, the percent margin at the initiation is

\[
\text{Percent Margin} = \frac{80,000 + 40,000 - 80,000}{80,000} = \frac{40,000}{80,000} = 0.50
\]

Similar to the discussion under margin transactions, it is necessary to continue to compare the percent margin over time to the maintenance margin (assumed to be 25 percent). Notably, in the case of a short sale, a price decline is a positive event related to the percent margin. For example, if we assume that the price of Cara Corporation stock declines to $70, the percent margin would increase as follows:

\[
\frac{\text{Your Equity}}{\text{Value of Stock Owed}} = \frac{80,000 + 40,000 - 70,000}{70,000} = \frac{50,000}{70,000} = 0.71
\]

Alternatively, if the stock price increases to $90 a share, the percent margin would experience a decline as follows:

\[
\frac{\text{Your Equity}}{\text{Value of Stock Owed}} = \frac{80,000 + 40,000 - 90,000}{90,000} = \frac{30,000}{90,000} = 0.33
\]

As before, it is important to determine the stock price that would trigger a margin call, which is computed as follows:

\[
\frac{\text{Your Equity}}{\text{Value of Stock Owed}} = \frac{120,000 - 1,000P}{1,000P} = 0.25
\]

\[
= \frac{120,000 - 1,000P}{1,000P} = 250P
\]

\[
= 1,250P = 120,000
\]

\[
P = 96
\]

Therefore, if the stock price moves against your short sale and increases above $96, you will receive a margin call. Given this unlimited upside potential (which is a negative event for the short seller), it is easy to understand why many short-sellers consistently enter stop-gain
orders along with selling a stock short to limit this loss and possibly avoid a margin call—that is, they would put in a stop-gain order at some price below 96.

4.5.6 Exchange Market-Makers
Earlier we discussed exchange “brokers” who bring buyers and sellers together to transact but never own the asset involved (real estate brokers are a popular example). - **Small-Order Execution System (SOES).** Market makers receiving SOES orders must honor their bids for automatic executions up to 1,000 shares. SOES was introduced in 1984 and became compulsory following the October 1987 crash.

- **SelectNet.** SelectNet is an order-routing and execution service for institutional investors that allows brokers and dealers to communicate through NASDAQ terminals instead of the phone. Once two parties agree to a trade on SelectNet, the execution is automatic.

### 4.5.8 Exchange Merger Mania

While the basic purpose of security markets has not changed, and the alternative orders employed by investors and traders have been quite constant, a relatively recent phenomenon has been numerous mergers among exchanges both within countries and between countries. Equally important, it is envisioned that this phenomenon will continue into the future.

**Why Merger Mania?** There are two major reasons why exchange merger mania started and will continue. The first reason is caused by the trend suggested in Chapter 2—the trend toward portfolios that are diversified both between countries (globally) and among asset classes. Given this dual diversification, exchanges want to be able to service individual investors, but mainly institutional investors as they buy and sell different assets (e.g., stocks, bonds, and derivatives) in global markets. (The point is, the exchanges want to provide global one-stop investing).

The second reason is the economics of high-technology trading. Earlier we discussed the trend toward electronic (computerized) trading venues that employ very sophisticated computers and highly trained personnel to develop the advanced algorithms that provide fast, efficient trading. Two facts dominate: (1) this equipment and the personnel to operate it is very expensive, and (2) there are significant economies of scale in the operation of these systems. This combination of high cost and required scale leads to the need for mergers within a country and across countries and asset classes so the exchange can afford the equipment and the staff as well as attain the scale required to have a profitable operation.

**Some Past Mergers** Following the creation of a number of ECNs in the 1990s, there were mergers of these entities into something like Archipelago (a registered stock exchange), which then acquired PCX Holdings, an electronic trader of options. In early 2006 the NYSE acquired Archipelago Holdings Co., a public company, and became a publicly traded entity, the NYSE Group, Inc. This was followed by a major merger in 2007 with Euronext NV, which itself was the product of several earlier mergers of Lisbon and Oporto, Amsterdam, Brussels, and the Paris stock exchanges and Lifte, a derivatives exchange.

During this time, NASDAQ acquired the Instinet Group, an ECN, and became a public company that acquired the Philadelphia Stock Exchange and OMX, an ECN.

In the derivatives area, the Chicago Mercantile Exchange (CME) Holding went public in 2006, and subsequently the Chicago Board of Trade (CBT) also went public. In late 2007 these two exchanges merged to create the largest derivatives exchange, and were subsequently joined by the New York Mercantile Exchange in 2008.

Another active participant has been the London Stock Exchange that rejected several offers to be acquired and, in turn, acquired the Borsa Italiana in 2007. Subsequently it attempted a merger with the Toronto Exchange (TMX Group) but this was abandoned in June, 2011.

**The Present and Future** It seems clear that the future financial market landscape will be made up of a relatively few large holding companies that own global exchanges for stocks, bonds, and derivatives. A major step toward such an entity was announced in February 2011 when the German Stock Exchange (Deutsche Borse) and the NYSE announced a potential merger that would create a dominant U.S.-European stock and derivatives group.12 Shortly

---

12For details and discussion of the proposal, see Browning, Bunge and Lucchetti (February 10, 2011).
after this announcement, the NASDAQ and the Intercontinental Exchange (ICE) came out with a competing bid for the NYSE that was rejected by the NYSE. The NASDAQ and ICE came up with a sweetened bid but the proposal was rejected by regulators due to competitive concerns in June 2011. As of July 2011 the stockholders of both the NYSE and the Deutsche Borse had approved the merger which only left regulatory approval to be complete.

Another potential merger involved with a cross-border combination is between the Singapore Stock Exchange (SGX) and the Australian Stock Exchange (ASX). As one might expect, the major hurdle is from the regulators in both countries. For details, see Tharlow, Tudor, and Venkat (2010).

Because the two driving reasons for the merger mania are still true, we would envision continuing mergers within the major developed markets, but also in smaller, less developed sectors such as the Far East—for example, Singapore, China, India, Thailand, and Indonesia. Beyond mergers within these countries, someone will want to dominate regions such as Europe or Asia through mergers. Further, given the large list of ATSs in Exhibit 4.3 (20), it is almost certain there will be several mergers among these firms.

**SUMMARY**

- The securities market is divided into primary and secondary markets. While primary markets are important sources of new capital for the issuers of securities, the secondary markets provide the liquidity that is critical to the primary markets.

- The composition of the secondary bond market has experienced small changes over the past 20 years. In sharp contrast, the secondary equity market has experienced significant change and is continuing to evolve due to new technology and consolidation. In addition to several primary listing exchanges and several NASDAQ components, the secondary market includes several regional exchanges, a viable third market, and most recently, the creation, growth, and consolidation of numerous ECNs and ATSs that provide automatic electronic transactions for stocks on both exchanges and dealer markets.

- The components of a good exchange market include several types of membership as well as various types of orders. In addition, market makers play a critical role in maintaining the liquidity of the market.

- It appears that changes, especially those due to these technological innovations, have only just begun. Therefore, it is important for investors who will be involved in this market to understand how this market has evolved, what its current structure is, and how it can develop in the future. As an investor, you will need to understand how to analyze securities to find the best securities for your portfolio, but also you need to know the best way to buy/sell the security, that is, how and where to complete the transaction. Our discussion in this chapter should provide the background you need to make that trading decision.

1. Define *market* and briefly discuss the characteristics of a good market.

2. You own 100 shares of General Electric stock and you want to sell it because you need the money to make a down payment on a car. Assume there is absolutely no secondary market system in common stocks. How would you go about selling the stock? Discuss
5. You own 200 shares of Shamrock Enterprises that you bought at $25 a share. The stock is now selling for $45 a share.
   a. You put in a stop loss order at $40. Discuss your reasoning for this action.
   b. If the stock eventually declines in price to $30 a share, what would be your rate of return with and without the stop loss order?

6. Two years ago, you bought 300 shares of Kayleigh Milk Co. for $30 a share with a margin of 60 percent. Currently, the Kayleigh stock is selling for $45 a share. Assuming no dividends and ignoring commissions, compute (a) the annualized rate of return on this investment if you had paid cash, and (b) your rate of return with the margin purchase.

7. The stock of the Madison Travel Co. is selling for $28 a share. You put in a limit buy order at $24 for one month. During the month the stock price declines to $20, then jumps to $36. Ignoring commissions, what would have been your rate of return on this investment? What would be your rate of return if you had put in a market order? What if your limit order was at $18?

Use the Thomson One — Business School Edition Online Database to answer the following questions.

1. On which stock markets are the following firms traded: Abbott Labs, Apple Computer, ExxonMobil, Intel, Johnson & Johnson, Microsoft?

2. Suppose you purchased Microsoft stock on January 15, 2011, and sold it two months later on March 15, 2011. What would your percentage price return be? What would the percentage return be if you had used 75 percent margin? 50 percent margin?

3. Redo exercise 2 but this time assume you purchased Microsoft on March 15, 2011, and sold it two months later on May 15, 2011. What would the annualized returns be if you bought the stock with cash? If you used 75 percent margin? 50 percent margin?

PROBLEMS

1. You have $40,000 to invest in Sophie Shoes, a stock selling for $80 a share. The initial margin requirement is 60 percent. Ignoring taxes and commissions, show in detail the impact on your rate of return if the stock rises to $100 a share and if it declines to $40 a share assuming: (a) you pay cash for the stock, and (b) you buy it using maximum leverage.

2. Lauren has a margin account and deposits $50,000. Assume the prevailing margin requirement is 40 percent, commissions are ignored, and the Gentry Wine Corporation is selling at $35 per share.
   a. How many shares can Lauren purchase using the maximum allowable margin?
   b. What is Lauren’s profit (loss) if the price of Gentry’s stock
      i. rises to $45?
      ii. falls to $25?
   c. If the maintenance margin is 30 percent, to what price can Gentry Wine fall before Lauren will receive a margin call?

3. Suppose you buy a round lot of Francesca Industries stock on 55 percent margin when the stock is selling at $20 a share. The broker charges a 10 percent annual interest rate, and commissions are 3 percent of the stock value on the purchase and sale. A year later you receive a $0.50 per share dividend and sell the stock for $27 a share. What is your rate of return on Francesca Industries?

4. You decide to sell short 100 shares of Charlotte Horse Farms when it is selling at its yearly high of $56. Your broker tells you that your margin requirement is 45 percent and that the commission on the purchase is $155. While you are short the stock, Charlotte pays a $2.50 per share dividend. At the end of one year, you buy 100 shares of Charlotte at $45 to close out your position and are charged a commission of $145 and 8 percent interest on the money borrowed. What is your rate of return on the investment?
5. You own 200 shares of Shamrock Enterprises that you bought at $25 a share. The stock is now selling for $45 a share.

Assuming no dividends and ignoring commissions, compute (a) the annualized rate of return on this investment if you had paid cash, and (b) your rate of return with the margin purchase.

7. The stock of the Madison Travel Co. is selling for $28 a share. You put in a limit buy order at $24 for one month. During the month the stock price declines to $20, then jumps to $36. Ignoring commissions, what would have been your rate of return on this investment? What would be your rate of return if you had put in a market order? What if your limit order was at $18?

6. What are some of the composite stock-bond market indexes?
7. Where can you get historical and current data for all these indexes?
8. What is the relationship among many of these indexes during short run periods (monthly)?

A fair statement regarding security-market indexes—especially those outside the United States—is that everybody talks about them but few people understand them. Even those investors familiar with widely publicized stock-market series, such as the Dow Jones Industrial Average (DJIA), usually know little about indexes for the U.S. bond market or for non-U.S. stock markets such as Tokyo or London. Although portfolios are obviously composed of many different individual stocks, investors typically ask, "What happened to the market today?" The reason for this question is that if an investor owns more than a few stocks or bonds, it is cumbersome to follow each stock or bond individually to determine the composite performance of the portfolio. Also, there is an intuitive notion that most individual stocks or bonds move with the aggregate market. Therefore, if the overall market rose, an individual's portfolio probably also increased in value. To supply investors with a composite report on market performance, some financial publications or investment firms have created and maintain stock-market and bond-market indexes.

In the initial section of this chapter, we discuss several ways that investors use security-market indexes. An awareness of these significant functions should provide an incentive for becoming familiar with these indexes and indicates why we present a full chapter on this topic. In the second section, we consider what characteristics cause various indexes to differ. Investors need to understand these differences and why one index is preferable for a given task because of its characteristics. In the third section, we present the most well-known U.S. and global stock-market indexes, separated into groups based on the weighting scheme used. In the third section, we present the most well-known U.S. and global stock-market indexes, separated into groups based on the weighting scheme used. In section four, we consider bond-market indexes that are becoming a more important topic because the bond
market continues to grow in size and importance for individuals and institutions.\footnote{This significant growth is well documented in Chapter 17.} Again, we consider international bond indexes following the domestic indexes. In the fifth section, we consider composite stock market-bond market series. In our final section, we examine how alternative indexes relate to each other over monthly intervals. This comparison demonstrates the important factors that cause high or low correlation among series. With this background, you should be able to make an intelligent choice of the market index that is best for you based on how you want to use it.

## 5.1 Uses of Security-Market Indexes

Security-market indexes have at least five significant uses. A primary application is to use the index values to compute total returns and risk measures for an aggregate market or some component of a market over a specified time period. In turn, many investors use the computed return-risk results as a benchmark to judge the performance of individual portfolios. A basic assumption when evaluating portfolio performance is that any investor should be able to experience a risk-adjusted rate of return comparable to the market by randomly selecting a large number of stocks or bonds from the total market; hence, a superior portfolio manager should consistently do better than the market. Therefore, an aggregate stock or bond-market index can be used as a benchmark to judge the performance of professional money managers.

An obvious use of indexes is to develop an index portfolio. As we have discussed, it is difficult for most money managers to consistently outperform specified market indexes on a risk-adjusted basis over time.\footnote{Throughout this chapter and the book, we will use indicator series and indexes interchangeably, although indicator series is the more correct specification because it refers to a broad class of series; one popular type of series is an index, but there can be other types and many different indexes.} If this is true, an obvious alternative is to invest in a portfolio that will emulate this market portfolio. This notion led to the creation of index funds and exchange-traded funds (ETFs), whose purpose is to track the performance of the specified market series (index) over time. The original index funds were common-stock funds as discussed in Malkiel (2007), Chapter 14, and Mossavar-Rahmani (2005). The development of comprehensive, well-specified bond-market indexes and the inability of most bond-portfolio managers to outperform these indexes have led to a similar phenomenon in the fixed-income area (bond-index funds), as noted by Hawthorne (1986) and Dialynas (2001).

Securities analysts, portfolio managers, and academicians doing research use security-market indexes to examine the factors that influence aggregate security price movements (that is, the indexes are used to measure aggregate market movements) and to compare the risk-adjusted performance of alternative asset classes (e.g., stocks versus bonds versus real estate). An extension of this is to examine the relative performance within asset classes such as large-cap stocks versus small-cap stocks.

Another group interested in an aggregate market index is composed of “technicians,” who believe past price changes can be used to predict future price movements. For example, to project future stock price movements, technicians would plot and analyze price and volume changes for a stock-market series like the Dow Jones Industrial Average or the S&P 500 index.

Finally, work in portfolio and capital market theory has implied that the relevant risk for an individual risky asset is its systematic risk, which is the relationship between the rates of return for a risky asset and the rates of return for a market portfolio of risky assets.\footnote{This concept and its justification are discussed in Chapter 7 and Chapter 8. Subsequently, in Chapter 25, we consider the difficulty of finding an index that is an appropriate proxy for the theoretical market portfolio of risky assets.} Therefore, an aggregate market index is used as a proxy for the market portfolio of risky assets.
5.2 Differentiating Factors in Constructing Market Indexes

Because the indexes are intended to reflect the overall movements of a group of securities, we need to consider three factors that are important when constructing an index intended to represent a total population.

5.2.1 The Sample

The first factor is the sample used to construct an index. The size, the breadth, and the source of the sample are all important.

A small percentage of the total population will provide valid indications of the behavior of the total population if the sample is properly selected. In some cases, because of the economics of computers, virtually all the stocks on an exchange or market are included, with a few deletions of unusual securities. Assuming you are not including the total population, the sample should be representative of the total population; otherwise, its size will be meaningless. A large biased sample is no better than a small biased sample. The sample can be generated by completely random selection or by a nonrandom selection technique designed to incorporate the important characteristics of the desired population. Finally, the source of the sample is important if there are any differences between segments of the population, in which case samples from each segment are required.

5.2.2 Weighting Sample Members

The second factor is the weight given to each member in the sample. Four principal weighting schemes are used for security-market indexes: (1) a price-weighted index, (2) a market-value-weighted index, (3) an unweighted index, or what would be described as an equal-weighted index, and (4) a fundamental weighted index based on some operating variable like sales, earnings, or return on equity. We will discuss each of these in detail and consider examples of them.

5.2.3 Computational Procedure

The final consideration is the computational procedure used. One alternative is to take a simple arithmetic mean of the various members in the index. Another is to compute an index and have all changes, whether in price or value, reported in terms of the basic index. Finally, some prefer using a geometric mean of the components rather than an arithmetic mean.

5.3 Stock-Market Indexes

As mentioned previously, we hear a lot about what happens to the Dow Jones Industrial Average (DJIA) each day. You might also hear about other stock indexes, such as the S&P 500 index, the NASDAQ composite, or even the Nikkei Average of Japanese stocks. If you listen carefully, you will realize that these indexes experience different percentage changes (which is the way that the changes should be reported). Reasons for some differences are obvious, such as the DJIA versus the Nikkei Average, but others are not. In this section, we briefly review how the major series differ in terms of the characteristics discussed in the prior section, which will help you understand why the percent changes over time for alternative stock indexes should differ.

We have organized the discussion of the indexes by the weighting of the sample of stocks. We begin with the price-weighted index because some of the most popular indexes are in this category. The next group is the value-weighted index, which is the technique currently used for most indexes. This is followed by the unweighted indexes, and finally the fundamental indexes.
5.3.1 Price-Weighted Index

A **price-weighted index** is an arithmetic mean of current stock prices, which means that index movements are influenced by the differential prices of the components.

**Dow Jones Industrial Average** The best-known price-weighted index is also the oldest and certainly the most popular stock-market index, the Dow Jones Industrial Average (DJIA). The DJIA is a price-weighted average of 30 large, well-known industrial stocks that are generally the leaders in their industry (blue chips). The DJIA is computed by totaling the current prices of the 30 stocks and dividing the sum by a divisor that has been adjusted to take account of stock splits and changes in the sample over time. The divisor is adjusted so the index value will be the same before and after the split. An adjustment of the divisor is demonstrated in Exhibit 5.1. The equation for the index is

\[
DJIA_t = \sum_{i=1}^{30} \frac{P_{it}}{D_{adj}}
\]

where:

- \(DJIA_t\) = the value of the DJIA on day \(t\)
- \(P_{it}\) = the closing price of stock \(i\) on day \(t\)
- \(D_{adj}\) = the adjusted divisor on day \(t\)

In Exhibit 5.1, we employ three stocks to demonstrate the procedure used to derive a new divisor for the DJIA when a stock splits. When stocks split, the divisor becomes smaller, as shown. The cumulative effect of splits can be derived from the fact that the divisor was originally 30.0, but as of April 8, 2011 it was 0.132129493.

The adjusted divisor ensures that the new value for the index is the same as it would have been without the split. In this case, the presplit index value was 20. Therefore, after the split, given the new sum of prices, the divisor is adjusted downward to maintain this value of 20. The divisor is also changed when there is a change in the sample makeup of the index.

Because the index is price weighted, a high-priced stock carries more weight than a low-priced stock. As shown in Exhibit 5.2, a 10 percent change in a $100 stock ($10) will cause a larger change in the index than a 10 percent change in a $30 stock ($3). For Case A, when the $100 stock increases by 10 percent, the average rises by 5.5 percent; for Case B, when the $30 stock increases by 10 percent, the average rises by only 1.7 percent.

The DJIA has been criticized on several counts. First, the sample used for the index is limited to 30 nonrandomly selected large, mature blue-chip stocks that cannot be

A complete list of all events that have caused a change in the divisor since the DJIA went to 30 stocks on October 1, 1928, is contained in Phyllis S. Pierce, ed., *The Business One Irwin Investor’s Handbook* (Burr Ridge, IL: Dow Jones Books, annual).
A simple example for a three-stock index in Exhibit 5.3 indicates that there is an automatic adjustment for stock splits and other capital changes with a value-weighted index because the decrease in the stock price is offset by an increase in the number of shares outstanding. In a value-weighted index, the importance of individual stocks in the sample depends on the market value of the stocks. Therefore, a specified percentage change in the value of a large company has a greater impact than a comparable percentage change for a small company.

As shown in Exhibit 5.4, if we assume that the only change is a 20 percent increase in the value of stock A, which has a beginning value of $10 million, the ending index value would be $202 million, or an index value of 101. In contrast, if only stock C increases by 20 percent from $100 million, the ending value will be $220 million or an index value of 110. The point is, price changes for large market value stocks in a value-weighted index will dominate changes in the index value over time. Therefore, it is important to be aware of the large-value stocks in the index.

representative of the thousands of U.S. stocks. As a result, the DJIA has not been as volatile as other market indexes, and its long-run returns are not comparable to other NYSE stock indexes.

In addition, because the DJIA is price weighted, when companies have a stock split, their prices decline and therefore their weight in the DJIA is reduced—even though they may be large and growing. Therefore, the weighting scheme causes a downward bias in the DJIA because high-growth stocks will have higher prices and because such stocks tend to split, these stocks of growing companies will consistently lose weight within the index. For a discussion of specific differences between indexes, see Ip (1998b). Detailed reports of the averages are contained daily in The Wall Street Journal and weekly in Barron’s.

**Nikkei-Dow Jones Average** Also referred to as the Nikkei Stock Average Index, it is an arithmetic mean of prices for 225 stocks on the First Section of the Tokyo Stock Exchange (TSE) and shows stock price trends since the reopening of the TSE. Similar to the DJIA, it is a price-weighted index and is likewise criticized because the 225 stocks only comprise about 15 percent of all stocks on the First Section. It is reported daily in The Wall Street Journal and the Financial Times and weekly in Barron’s.

### 5.3.2 Value-Weighted Index

A **value-weighted index** is generated by deriving the initial total market value of all stocks used in the index (Market Value = Number of Shares Outstanding (or freely floating shares) × Current Market Price). Prior to 2004, the tradition was to consider all outstanding shares. In mid-2004, Standard & Poor’s began only considering “freely floating shares” that exclude shares held by insiders. This initial figure is typically established as the base and assigned an index value (typically the beginning index value is 100, but it can vary—say, 10, 50). Subsequently, a new market value is computed for all securities in the index, and the current market value is compared to the initial “base” market value to determine the percentage change, which in turn is applied to the beginning index value.

\[
\text{Index}_t = \sum \frac{P_t Q_t}{P_b Q_b} \times \text{Beginning Index Value}
\]

where:

- \(\text{Index}_t\) = index value on day \(t\)
- \(P_t\) = ending prices for stocks on day \(t\)
- \(Q_t\) = number of outstanding or freely floating shares on day \(t\)
- \(P_b\) = ending price for stocks on base day
- \(Q_b\) = number of outstanding or freely floating shares on base day
5.3.3 Unweighted Index

In an unweighted index, all stocks carry equal weight regardless of their price or market value. A $20 stock is as important as a $40 stock, and the total market value of the company is unimportant. Such an index can be used by individuals who randomly select stock for their portfolio or invest the same dollar amount in each stock. One way to visualize an unweighted index is to assume that equal dollar amounts are invested in each stock in the portfolio (for example, an equal $1,000 investment in each stock would work out to 50 shares of a $20 stock, 100 shares of a $10 stock, and 10 shares of a $100 stock). In fact, the actual movements in the index are typically based on the arithmetic mean of the percent changes in price or value for the stocks in the index. The use of percentage price changes means that the price level or the market value of the stock does not make a difference — each percentage change has equal weight.

Exhibit 5.5 demonstrates the computation of an equal weighted index using the average of the percent changes for each of the three stocks. There is also a comparison to the index value if market value weights are used. As shown, the equal weighting result gives a higher value because of the large percent increase in value for the stock with the smallest market value (the small-cap stock). In contrast, the market value weighted index did not do as well because the large-cap stock (that has a large weight) experienced the poorest performance.

In contrast to computing an arithmetic mean of percentage changes, both Value Line and the Financial Times compute a geometric mean of the holding period returns and derive the holding period yield from this calculation. Exhibit 5.6, which

*Stock split two-for-one during the year.

A simple example for a three-stock index in Exhibit 5.3 indicates that there is an automatic adjustment for stock splits and other capital changes with a value-weighted index because the decrease in the stock price is offset by an increase in the number of shares outstanding. In a value-weighted index, the importance of individual stocks in the sample depends on the market value of the stocks. Therefore, a specified percentage change in the value of a large company has a greater impact than a comparable percentage change for a small company. As shown in Exhibit 5.4, if we assume that the only change is a 20 percent increase in the value of stock A, which has a beginning value of $10 million, the ending index value would be $202 million, or an index value of 101. In contrast, if only stock C increases by 20 percent from $100 million, the ending value will be $220 million or an index value of 110. The point is, price changes for large market value stocks in a value-weighted index will dominate changes in the index value over time. Therefore, it is important to be aware of the large-value stocks in the index.

contains an example of an arithmetic and a geometric mean, demonstrates the downward bias of the geometric calculation. Specifically, the geometric mean of holding period yield (HPY) shows an average change of only 5.3 percent versus the actual change in wealth of 6 percent.

5.3.4 Fundamental Weighted Index

As noted, one of the rationales for using market-value weighting is that the market value of a firm is an obvious measure of its economic importance. In contrast, some observers contend that this weighting scheme results in overweighting overvalued stocks over time and underweighting undervalued stocks. A prime example is what transpired during the technology boom in the 1998–2000 period when technology stocks exploded in price and, in retrospect, were clearly overvalued—selling for 60-70-100 times earnings. As a result, the high valuations caused the weight of the technology sector in the indexes to almost double, the result was an overweight in overvalued stocks. You can envision an opposite example for undervalued stocks.

In response to this implicit problem with market-value weighting, some observers have suggested other measures of a company’s economic footprint. The leading advocates of an approach that weights firms based on company fundamentals are individuals involved with Research Affiliates, Inc. (Arnott, Hsu, and West, 2008). Their approach to creating a Fundamental Index is an example of employing some widely used fundamental factors. Specifically, they proposed four broad fundamental measures of size: (1) sales, (2) profits (cash flow), (3) net assets (book value), and (4) distributions to shareholders (dividends). Given these variables for a large sample of firms, they created an index of 1,000 of the largest firms and computed the percent of each firm’s sales, cash flow, book value, and dividends to the total for the sample and determined a company’s relative size (weight) by averaging the weights of the four size metrics across the trailing five years (to avoid the impact of cyclicality). The authors contend that this index (entitled Research Associates Fundamental Index [RAFI]) is representative, but also ensures high liquidity, high capacity, and low turnover.

As noted earlier, this is an example of such an index—other firms and authors can and have created indexes with single variables or a different set of fundamental variables to determine the weights. For an informative discussion, see (Geer, 2011).

5.3.5 Style Indexes

Financial service firms such as Dow Jones, Moody’s, Standard & Poor’s, Russell, and Wilshire Associates are generally very fast in responding to changes in investment practices. One example is the growth in popularity of small-cap stocks following academic research in the 1980s that suggested that over long-term periods, small-cap stocks outperformed large-cap stocks on a risk-adjusted basis. In response to this, Ibbotson Associates created the first small-cap stock index, and this was followed by small-cap indexes by Frank Russell Associates (the Russell 2000 Index), the Standard & Poor’s 600, the Wilshire 1750, and the Dow Jones Small-Cap Index. For a comparative analysis of these indexes, see Reilly and Wright (2002). This led to sets of size indexes, including large-cap, mid-cap, small-cap, and micro-cap. These new size indexes were used to evaluate the performance of money managers who concentrated in those size sectors.

The next innovation was for money managers to concentrate in types of stocks—that is, growth stocks or value stocks. We included a designation of these stocks in Chapter 2 in terms of what they are and how they are identified. As this money management innovation evolved, the financial services firms again responded by creating indexes of growth stocks and value stocks. For further discussion of the justification and details on the variables and construction, see Arnott, Hsu, and West, (2008).

5.3.4 Fundamental Weighted Index
As noted, one of the rationales for using market-value weighting is that the market value of a firm is an obvious measure of its economic importance. In contrast, some observers contend that this weighting scheme results in over weighting overvalued stocks over time and under weighting undervalued stocks. A prime example is what transpired during the technology boom in the 1998–2000 period when technology stocks exploded in price and, in retrospect, were clearly overvalued—selling for 60-70-100 times earnings. As a result, the high valuations caused the weight of the technology sector in the indexes to almost double, the result was an overweight in overvalued stocks. You can envision an opposite example for undervalued stocks.

In response to this implicit problem with market-value weighting, some observers have suggested other measures of a company’s economic footprint. The leading advocates of this approach are weights firms based on company fundamentals are individuals involved with Research Affiliates, Inc. (Arnott, Hsu, and West, 2008). Their approach to creating a Fundamental Index is an example of employing some widely used fundamental factors. Specifically, they proposed four broad fundamental measures of size: (1) sales, (2) profits (cash flow), (3) net assets (book value), and (4) distributions to shareholders (dividends). Given these variables for a large sample of firms, they created an index of 1,000 of the largest firms and computed the percent of each firm’s sales, cash flow, book value, and dividends to the total for the sample and determined a company’s relative size (weight) by averaging the weights of the four size metrics across the trailing five years (to avoid the impact of cyclicality). The authors contend that this index (entitled Research Associates Fundamental Index (RAFI)) is representative, but also ensures high liquidity, high capacity, and low turnover.

As noted earlier, this is an example of such an index—other firms and authors can and have created indexes with single variables or a different set of fundamental variables to determine the weights. For an informative discussion, see (Geer, 2011).

5.3.5 Style Indexes
Financial service firms such as Dow Jones, Moody’s, Standard & Poor’s, Russell, and Wilshire Associates are generally very fast in responding to changes in investment practices. One example is the growth in popularity of small-cap stocks following academic research in the 1980s that suggested that over long-term periods, small-cap stocks outperformed large-cap stocks on a risk-adjusted basis. In response to this, Ibbotson Associates created the first small-cap stock index, and this was followed by small-cap indexes by Frank Russell Associates (the Russell 2000 Index), the Standard & Poor’s 600, the Wilshire 1750, and the Dow Jones Small-Cap Index. For a comparative analysis of these indexes, see Reilly and Wright (2002). This led to sets of size indexes, including large-cap, mid-cap, small-cap, and micro-cap. These new size indexes were used to evaluate the performance of money managers who concentrated in those size sectors.

The next innovation was for money managers to concentrate in types of stocks—that is, growth stocks or value stocks. We included a designation of these stocks in Chapter 2 in terms of what they are and how they are identified. As this money management innovation evolved, the financial services firms again responded by creating indexes of growth stocks and value

by these indexes for different countries because of a lack of consistency among them in sample selection, weighting, or computational procedure. To solve these comparability problems, several investment data firms have computed a set of consistent country stock indexes. As a result, these indexes can be directly compared and combined to create various regional indexes (for example, Pacific Basin). We will describe the three major sets of global equity indexes.

**FT/S&P-Actuaries World Indexes**

The FT/S&P-Actuaries World Indexes are jointly compiled by the Financial Times Limited, Goldman Sachs & Company, and Standard & Poor’s (the “compilers”) in conjunction with the Institute of Actuaries and the Faculty of Actuaries. Approximately 2,500 equity securities in 30 countries are measured, covering at least 70 percent of the total value of all listed companies in each country. All securities included must allow direct holdings of shares by foreign nationals.

The indexes are market value weighted and have a base date of December 31, 1986 = 100. The index results are typically reported in U.S. dollars, but, on occasion, have been reported in other currencies.

stocks based on relative P/E, price-book value, price-cash flow ratios, and other metrics such as return on equity (ROE) and revenue growth rates.

Eventually, these two factors (size and type) were combined into six major style categories:

- Small-cap growth
- Small-cap value
- Mid-cap growth
- Mid-cap value
- Large-cap growth
- Large-cap value

Currently, most money managers identify their investment style as one of these, and consultants generally use these style categories to identify money managers.

The most recent style indexes are those created to track ethical funds referred to as socially responsible investment (SRI) funds. These SRI indexes are further broken down by country and include a global ethical stock index.

The best source for style stock indexes (both size and type of stock) is Barron’s.

Exhibit 5.7 shows the stock market indexes from The Wall Street Journal, which contains values for many of the U.S. stock indexes we have discussed. Exhibit 5.8 shows a table for numerous international stock indexes contained in The Wall Street Journal.

### 5.3.6 Global Equity Indexes

As shown in Exhibits 5.8 and 5A.2 (the latter is in this chapter’s appendix), there are stock-market indexes available for most individual foreign markets. While these local indexes are closely followed within each country, a problem arises in comparing the results implied
In U.K. pound sterling, Japanese yen, euros, and the local currency of the country. In addition to the individual countries and the world index, there are several geographic subgroups, subgroups by market value, and by industry sectors. These indexes are available daily in the Financial Times.

**Morgan Stanley Capital International (MSCI) Indexes**
The Morgan Stanley Capital International Indexes consist of three international, 22 national, and 38 international industry indexes. The indexes consider some 1,673 companies listed on stock exchanges in 22 countries, with a combined market capitalization that represents approximately 60 percent of the aggregate market value of the stock exchanges of these countries. All the indexes are market value weighted.

The following relative valuation information is available: (1) price-to-book value (P/BV) ratio, (2) price-to-cash earnings (earnings plus depreciation) (P/CE) ratio, (3) price-to-earnings (P/E) ratio, and (4) dividend yield (YLD). These ratios help in analyzing different valuation levels among countries and over time for specific countries.

Notably, the Morgan Stanley group index for Europe, Australia, and the Far East (EAFE) is the basis for futures and options contracts on the Chicago Mercantile Exchange and the Chicago Board Options Exchange.

**Dow Jones Wilshire Global Indexes**
The Dow Jones Wilshire Global Indexes is composed of more than 2,200 companies worldwide and organized into 120 industry groups. The index includes 35 countries representing more than 80 percent of the combined capitalization of these countries. In addition to the 35 individual countries shown in Exhibit 5.9, the countries are grouped into three major regions: Americas, Europe, and Pacific Region and some subregions. Finally, each country’s index is calculated in its own currency as well as in U.S. dollars. The index for the individual countries is reported daily in The Wall Street Journal and the full presentations as shown in Exhibit 5.9 is published weekly in Barron’s.

**Comparison of World Stock Indexes**
As shown in Exhibit 5.10, the correlations between the three series since December 31, 1991, when the DJ series became available, indicate that the results with the various world stock indexes are quite comparable.

A summary of the characteristics of the major price-weighted, market-value-weighted, and equal-weighted stock price indexes for the United States and major foreign countries is contained in Exhibit 5A.1 in the chapter appendix. As shown, the major differences are the number of stocks in alternative indexes, but more important is the source of the sample (e.g., stocks from the NYSE, NASDAQ, all U.S. stocks, or stocks from a foreign country such as the United Kingdom or Japan).

### 5.4 Bond-Market Indexes
Investors know little about the growing number of bond-market indexes currently available because these indexes are relatively new and not widely published. Still, knowledge regarding these indexes is important because of the growth of fixed-income money managers and mutual funds and the consequent need to have a reliable set of benchmarks to use in evaluating their performance. Also, because the performance of many fixed-income money managers has been unable to match that of the aggregate bond market, interest has been growing in bond-index funds, which requires appropriate indexes to emulate as discussed by Dialynas (2001) and Volpert (2005).

The discussion in this section draws heavily from Reilly and Wright (2012).

**Dow Jones Wilshire Global Indexes** The Dow Jones Wilshire Global Indexes is composed of more than 2,200 companies worldwide and organized into 120 industry groups. The index includes 35 countries representing more than 80 percent of the combined capitalization of these countries. In addition to the 35 individual countries shown in Exhibit 5.9, the countries are grouped into three major regions: Americas, Europe, and Pacific Region and some subregions. Finally, each country’s index is calculated in its own currency as well as in U.S. dollars. The index for the individual countries is reported daily in *The Wall Street Journal* and the full presentations as shown in Exhibit 5.9 is published weekly in *Barron’s*.

**Comparison of World Stock Indexes** As shown in Exhibit 5.10, the correlations between the three series since December 31, 1991, when the DJ series became available, indicate that the results with the various world stock indexes are quite comparable.

A summary of the characteristics of the major price-weighted, market-value-weighted, and equal-weighted stock price indexes for the United States and major foreign countries is contained in Exhibit 5A.1 in the chapter appendix. As shown, the major differences are the number of stocks in alternative indexes, but more important is the source of the sample (e.g., stocks from the NYSE, NASDAQ, all U.S. stocks, or stocks from a foreign country such as the United Kingdom or Japan).

### 5.4 Bond-Market Indexes

Investors know little about the growing number of bond-market indexes currently available because these indexes are relatively new and not widely published. Still, knowledge regarding these indexes is important because of the growth of fixed-income money managers and mutual funds and the consequent need to have a reliable set of benchmarks to use in evaluating their performance. Also, because the performance of many fixed-income money managers has been unable to match that of the aggregate bond market, interest has been growing in bond-index funds, which requires appropriate indexes to emulate as discussed by Dialynas (2001) and Volpert (2005).

Notably, it is more difficult to create and compute a bond-market index than a stock-market index for several reasons. First, the universe of bonds is much broader than that of stocks, ranging from U.S. Treasury securities to bonds in default. Second, the universe of bonds is changing constantly because of new issues, bond maturities, calls, and bond sinking funds. Third, the volatility of prices for individual bonds and bond portfolios changes because bond price volatility is affected by duration, which is likewise changing constantly because of changes in maturity, coupon, and market yield. Finally, significant problems can arise in correctly pricing the individual bond issues in an index (especially corporate and mortgage bonds) compared to the current and continuous transactions prices available for most stocks used in stock indexes.

Our subsequent discussion is divided into the following three subsections: (1) U.S. investment-grade bond indexes, including Treasuries; (2) U.S. high-yield bond indexes; and (3) global government bond indexes. All of these indexes indicate total rates of return for the portfolio of bonds and are market value weighted. Exhibit 5.11 contains a summary of the characteristics for the indexes available for these three segments of the bond market.

### 5.4.1 U.S. Investment-Grade Bond Indexes

As shown in Exhibit 5.11, four investment firms have created and maintain indexes for Treasury bonds and other bonds considered investment grade, that is, the bonds are rated BBB (or Baa) or higher. As demonstrated in a subsequent section, the relationship among the returns for these investment-grade bonds is strong (that is, correlations average about 0.95), regardless of the segment of the market.

### 5.4.2 High-Yield Bond Indexes

One of the fastest-growing segments of the U.S. bond market during the past 30 years has been the high-yield bond market, which includes bonds that are not investment grade—that is, they are rated Ba, B, Caa, Ca, and C. Because of this growth, four investment firms created indexes related to this market. A summary of the characteristics for these indexes is included in Exhibit 5.11. For an analysis of the alternative high-yield bond benchmarks, see Reilly and Wright (1994); for an overall analysis of this market, see Reilly, Wright, and Gentry (2009).

### 5.4.3 Global Government Bond Indexes

The global bond market has experienced significant growth in size and importance during the past 15 years. Notably, this global bond segment is dominated by government (sovereign) bonds because most non-U.S. countries do not have a viable corporate bond market. Once again, several major investment firms have created indexes that reflect the performance for the global bond market. As shown in Exhibit 5.11, although the various indexes have similar

A combination of asset classes such as stocks and bonds in addition to diversifying within the asset classes of stocks or bonds. There are two such indexes available. First, a market-value-weighted index called Merrill Lynch-Wilshire Capital Markets Index (ML-WCMI) measures the total return performance of the combined U.S. taxable fixed-income and equity markets. It is basically a combination of the Merrill Lynch fixed-income indexes and the Dow Jones Total Stock Market common-stock index. As such, it tracks more than 10,000 U.S. stocks and bonds and, as of early 2011, the relative weights are about 40 percent bonds and 60 percent stocks.

The second composite index is the Brinson Partner Global Security Market Index (GSMI), which contains U.S. stocks and bonds as well as non-U.S. equities and nondollar bonds. The specific breakdown as of April, 2011 was:

The index is balanced to the policy weights monthly. Because the GSMI contains both U.S. and international stocks and bonds, it is clearly the most diversified benchmark available with a weighting scheme that approaches market values. As such, it is closest to the theoretically specified "market portfolio of risky assets" referred to in the CAPM literature. This index was used in Reilly and Akhtar (1995) to demonstrate the impact of alternative benchmarks when evaluating global portfolio performance and when calculating systematic risk (beta) measures.

5.6 COMPARISON OF INDEXES OVER TIME

We now look at price movements in the different indexes for monthly intervals.

5.6.1 Correlations between Monthly Equity Price Changes

Exhibit 5.13 contains a listing of the correlation coefficients of the monthly percentage of price changes for a set of U.S. and non-U.S. equity-market indexes with the Dow Jones Total Stock Market Index during the 31-year period from 1980 to 2010. The correlation differences are mainly attributable to the different sample of firms listed on the various stock exchanges. All of the indexes are market-value-weighted indexes that include a large number of stocks. Therefore, the computational procedure is generally similar and the sample sizes are large or all-encompassing. Thus, the major difference between the indexes is that the samples of stocks are from different segments of the U.S. stock market or from different countries.

There is a high positive correlation (0.98 – 0.99) between the Dow Jones Total Stock Market Index and the several comprehensive U.S. equity indexes: the S&P 500, and the Russell 3000 and Russell 1000 large cap index. In contrast, there are lower correlations with various style indexes such as the Russell 2000 Small-Cap index (0.828).

The correlations between the Dow Jones Total Stock Market Index and the several non-U.S. indexes are clearly lower ranging from 0.462 (Pacific Basin) to 0.726 (Europe). All of these support the case for global investing. These diversification results were confirmed with the composite international series— with the MSCI EAFE (0.645) and the IFC Emerging Market (0.542).

Given the several uses of security-market indexes, it is important to know how they are constructed and the differences between them. To determine how the market is doing, you need to be aware of what market you are dealing with so you can select the appropriate index. For example, are you only interested in the NYSE or do you also want to consider NASDAQ? Beyond the U.S. market, are you interested in Japanese or U.K. stocks, or do you want to examine the total world market? This choice is discussed in Merjos (1990).

Indexes are also used as benchmarks to evaluate portfolio performance. In this case, you must be sure the index (benchmark) is consistent with your investing universe. If you are investing worldwide, you should not judge your performance relative to the DJIA, which is limited to 30 U.S. blue-chip stocks. For a bond portfolio, the index should likewise match your investment philosophy. Finally, if your portfolio contains both stocks and bonds, you must evaluate your performance against an appropriate combination of indexes.

Investors need to examine numerous market indexes to evaluate the performance of their investments. The selection of the appropriate indexes for information or evaluation will depend on how knowledgeable you are about the various indexes. The background from this chapter should help you understand what to look for and how to make the right decision in this area.

### QUESTIONS

1. Discuss briefly several uses of security-market indexes.
2. What major factors must be considered when constructing a market index? Put another way, what characteristics differentiate indexes?
3. Explain how a market index is price weighted. In such a case, would you expect a $100 stock to be more important than a $25 stock? Give an example.
4. Explain how to compute a value-weighted index.
5. Explain how a price-weighted index and a value-weighted index adjust for stock splits.
6. Describe an unweighted price index and describe how you would construct such an index. Assume a 20 percent price change in GM ($40/share; 50 million shares outstanding) and Coors Brewing ($25/share and 15 million shares outstanding). Explain which stock’s change will have the greater impact on this index.
7. If you correlated percentage changes in the Dow Jones Total Stock Market Index with percentage changes in the NYSE composite and the NASDAQ composite index, would you expect a difference in the correlations? Why or why not?
8. There are high correlations between the monthly percentage price changes for the alternative NYSE indexes. Discuss the reason for this similarity: is it size of sample, source of sample, or method of computation?
9. Assume a correlation of 0.82 between the Nikkei and the TSE Composite Index. Examine the correlation between the MSCI Pacific Basin Index and the DJTSM in Exhibit 5.13. Explain why these relationships differ.

### 5.6.2 Correlations between Monthly Bond Index Returns

The correlations with the monthly Barclay Capital (BC) Govt. bond return index in Exhibit 5.13 consider a variety of bond indexes. The correlations with the U.S. investment-grade bond indexes ranged from about 0.94 to 0.98, confirming that although the level of interest rates differ due to the risk premium, the overriding determinate of rates of return for investment-grade bonds over time are Treasury interest rates.

In contrast, the correlations with high-yield bonds indicate a significantly weaker relationship (correlations about 0.51) caused by strong equity characteristics of high-yield bonds as shown in Reilly, Wright, and Gentry (2009). Finally, the low and diverse relationships among U.S. investment-grade bonds and all world government bonds (0.57) and world government bonds without the United States (about 0.37) reflect different interest rate movements and exchange rate effects (these non-U.S. government results are presented in U.S. dollar terms). Again, these results support the benefits of global diversification of bond portfolios alone or with stock portfolios.

### 5.6.3 Mean Annual Security Returns and Risk

The use of security indexes to measure returns and risk was demonstrated in Exhibit 3.8 and 3.9, which showed the average annual price change, or rate of return, and risk measure for a large set of asset indexes.
10. You learn that the Dow Jones Total Stock Market market-value-weighted index increased by 16 percent during a specified period, whereas a Dow Jones Total Stock Market equal-weighted index increased by 23 percent during the same period. Discuss what this difference in results implies.

11. Why is it contended that bond-market indexes are more difficult to construct and maintain than stock-market indexes?

12. Suppose the Dow Jones Total Stock Market market-value-weighted index increased by 5 percent, whereas the Merrill Lynch-Dow Jones Capital Markets Index increased by 15 percent during the same period. What does this difference in results imply?

13. Suppose the Russell 1000 increased by 8 percent during the past year, whereas the Russell 2000 increased by 15 percent. Discuss the implication of these results.

14. Based on what you know about the Financial Times (FT) World Index, the Morgan Stanley Capital International World Index, and the Dow Jones World Stock Index, what level of correlation would you expect between monthly rates of return? Discuss the reasons for your answer based on the factors that affect indexes.

15. How would you explain that the ML High-Yield Bond Index was more highly correlated with the NYSE composite stock index than the ML Aggregate Bond Index?

16. Assuming that the mandate to a portfolio manager was to invest in a broadly diversified portfolio of U.S. stocks, which two or three indexes should be considered as an appropriate benchmark? Why?

   a. Construct a price-weighted index for these three stocks, and compute the percentage change in the index for the period from T to T + 1.

   b. Construct a value-weighted index for these three stocks, and compute the percentage change in the index for the period from T to T + 1.

   c. Briefly discuss the difference in the results for the two indexes.

2. a. Given the data in Problem 1, construct an equal-weighted index by assuming $1,000 is invested in each stock. What is the percentage change in wealth for this portfolio?

   b. Compute the percentage of price change for each of the stocks in Problem 1. Compute the arithmetic mean of these percentage changes. Discuss how this answer compares to the answer in Part a.

   c. Compute the geometric mean of the percentage changes in Part b. Discuss how this result compares to the answer in Part b.

3. For the past five trading days, on the basis of figures in The Wall Street Journal, compute the daily percentage price changes for the following stock indexes.

   a. DJIA
   b. S&P 500
   c. NASDAQ Composite Index
   d. FT-100 Share Index
   e. Nikkei 225 Stock Price Average

   f. Discuss the difference in results for Parts a and b, a and c, a and d, a and e, and d and e. What do these differences imply regarding diversifying within the United States versus diversifying between countries?

SUMMARY

- Given the several uses of security-market indexes, it is important to know how they are constructed and the differences between them. To determine how the market is doing, you need to be aware of what market you are dealing with so you can select the appropriate index. For example, are you only interested in the NYSE or do you also want to consider NASDAQ? Beyond the U.S. market, are you interested in Japanese or U.K. stocks, or do you want to examine the total world market? This choice is discussed in Merjios (1990).

- Indexes are also used as benchmarks to evaluate portfolio performance. In this case, you must be sure the index (benchmark) is consistent with your investing universe. If you are investing worldwide, you should not judge your performance relative to the DJIA, which is limited to 30 U.S. blue-chip stocks. For a bond portfolio, the index should likewise match your investment philosophy. Finally, if your portfolio contains both stocks and bonds, you must evaluate your performance against an appropriate combination of indexes.

- Investors need to examine numerous market indexes to evaluate the performance of their investments. The selection of the appropriate indexes for information or evaluation will depend on how knowledgeable you are about the various indexes. The background from this chapter should help you understand what to look for and how to make the right decision in this area.

THOMSON REUTERS

Use the Thomson One—Business School Edition Online Database to answer the following questions.

1. Collect price and number of outstanding share data from the past 10 days on the following firms: Amazon (AMZN), Family Dollar (FDO), J.C. Penney (JCP), Target (TGT), and Walmart (WMT). Using this data, create a “retail sales stock index” by computing a value-weighted index. What is the overall percent change of the index over the 10 days?

2. Using the market values for each stock on day 1, compute the relative weight for each of the five stocks. Which stock has the largest weight and which stock has the smallest weight?

Chapter 9
Multifactor Models of Risk and Return
The chapters in Part 1 provided background on why individuals invest their funds and what they expect to derive from this activity. We also argued very strongly for a global investment program, described the major instruments and capital markets in a global investment environment, and showed the relationship among these instruments and markets.

We now are ready to discuss how to analyze and value the various investment instruments available. In turn, valuation requires the estimation of expected returns (cash flows) and a determination of the risk involved in the securities. Before we can begin the analysis, we need to understand several major developments in investment theory that have influenced how we specify and measure risk in the valuation process. The purpose of the four chapters in Part 2 is to provide this background on risk and asset valuation.

Chapter 6 describes the concept of efficient capital markets, which hypothesizes that security prices reflect the effect of all information. This chapter considers why markets should be efficient, discusses how one goes about testing this hypothesis, and describes the results of numerous tests that both support the hypotheses and indicate the existence of anomalies that are inconsistent with the hypotheses. There is also a consideration of behavioral finance, which has experienced a growth in reputation because it provides a rationale for some of the results. We conclude the chapter with an extensive discussion of the implications of the results for those engaged in technical and fundamental analysis as well as portfolio management.

Chapter 7 provides an introduction to portfolio theory, which was developed by Harry Markowitz. This theory provided the first rigorous measure of risk for investors and showed how one selects alternative assets to diversify and reduce the risk of a portfolio. Markowitz also derived a risk measure for individual securities within the context of an efficient portfolio.

Following the development of the Markowitz portfolio model, William Sharpe and several other academicians extended the Markowitz model into a general equilibrium asset pricing model that included an alternative risk measure for all risky assets. Chapter 8 contains a detailed description of these developments and an explanation of the relevant risk measure implied by this valuation model, referred to as the capital asset pricing model (CAPM). We introduce the CAPM at this early point in the book because the risk measure implied by this model has been used extensively in various valuation models. Although the CAPM has long been the preeminent theoretical explanation in finance for the connection between risk and expected return, the past several decades have seen the rise of several competing models.

Chapter 9 is devoted to exploring several of these alternative asset pricing models, which differ from the CAPM primarily by specifying multiple risk factors in lieu of a single market portfolio-based variable. The chapter begins with an examination of the arbitrage pricing theory (APT), which is the conceptual foundation for virtually all of the subsequent multifactor asset pricing models. The APT, which was developed by Steve Ross in response to criticisms of the CAPM, suggests a linear relationship between a stock’s expected return and many systematic risk factors.

One severe challenge for investors attempting to use the APT in practice is that it offers no theoretical guidance as to either the number or the identity of the risk factors. To overcome this problem, researchers have developed several multifactor models, which attempt to link a stock’s realized returns to market data on a collection of prespecified variables that are believed to proxy for the APT risk factors. In specifying these variables, both macroeconomic and microeconomic approaches and risk factors have been adopted. After explaining these various approaches, we demonstrate how they are used by investors to both evaluate individual companies and assess the investment styles of money managers and mutual funds.
Chapter 6
Efficient Capital Markets

After you read this chapter, you should be able to answer the following questions:

- What does it mean to say that capital markets are efficient?
- Why should capital markets be efficient?
- What factors contribute to an efficient market?
- Given the overall efficient market hypothesis (EMH), what are the three subhypotheses and what are the implications of each of them?
- How do you test the three efficient market subhypotheses and what are the results of the tests?
- For each set of tests, which results support the EMH and which results indicate an anomaly related to the hypothesis?
- What is behavioral finance and how does it relate to the EMH?
- What are some of the major findings of behavioral finance and what are the implications of these findings for the EMH?
- What are the implications of the efficient market hypothesis test results for the following?
  - Technical analysis
  - Fundamental analysis
  - Portfolio managers with superior analysts
  - Portfolio managers with inferior analysts

An efficient capital market is one in which security prices adjust rapidly to the arrival of new information, and, therefore, the current prices of securities reflect all information about the security. Some of the most interesting and important academic research during the past 30 years has analyzed whether our capital markets are efficient. This extensive research is important because its results have significant real-world implications for investors and portfolio managers. In addition, the question of whether capital markets are efficient is one of the most controversial areas in investment research. A new dimension has been added to the controversy because of the rapidly expanding research in behavioral finance that has major implications regarding the concept of efficient capital markets and has provided some intriguing insights on reasons for many of the anomalies identified.

Because of its importance and controversy, you need to understand the meaning of the terms efficient capital markets and the efficient market hypothesis (EMH). You should understand the analysis performed to test the EMH and the results of studies that either support or contradict the hypothesis. Finally, you should be aware of the implications of these results when you analyze alternative investments and work to construct a portfolio.
We are considering the topic of efficient capital markets at this point for two reasons. First, the prior discussion indicated how the capital markets function, so now it seems natural to consider the efficiency of these markets in terms of how security prices react to new information. Second, the overall evidence on capital market efficiency is best described as mixed; some studies support the hypothesis, and others do not. The implications of these diverse results are important for you as an investor involved in analyzing securities, estimating intrinsic value, and building a portfolio.

This chapter contains five major sections. The first discusses why we would expect capital markets to be efficient and the factors that contribute to an efficient market where the prices of securities reflect available information.

The efficient market hypothesis has been divided into three subhypotheses to facilitate testing. The second section describes these three subhypotheses and the implications of each of them.

The third section is the largest section because it contains a discussion of the results of numerous studies. This review of the research reveals that a large body of evidence supports the EMH, but a growing number of other studies do not support the hypotheses.

In the fourth section, we discuss the concept of behavioral finance, the studies that have been done in this area related to efficient markets, and the conclusions as they relate to the EMH.

The final section discusses what these results imply for an investor who uses either technical analysis or fundamental analysis or what they mean for a portfolio manager who has access to superior or inferior analysts. We conclude with a brief discussion of the evidence for markets in foreign countries.

6.1 Why Should Capital Markets Be Efficient?

As noted earlier, in an efficient capital market, security prices adjust rapidly to the infusion of new information, and, therefore, current security prices fully reflect all available information.

To be absolutely correct, this is referred to as an informationally efficient market. Although the idea of an efficient capital market is relatively straightforward, we often fail to consider why capital markets should be efficient. What set of assumptions imply an efficient capital market?

An initial and important premise of an efficient market requires that a large number of profit-maximizing participants analyze and value securities, each independently of the others. A second assumption is that new information regarding securities comes to the market in a random fashion, and the timing of one announcement is generally independent of others. The third assumption is especially crucial: the buy and sell decisions of all those profit-maximizing investors cause security prices to adjust rapidly to reflect the effect of new information. Although the price adjustment may be imperfect, it is unbiased. This means that sometimes the market will over adjust and other times it will under adjust, but you cannot predict which will occur at any given time. Security prices adjust rapidly because the many profit-maximizing investors are competing against one another to profit from the new information.

---

1New information, by definition, must be information that was not known before and is not predictable. If it were predictable, it would have been impounded in the security price.
The combined effect of (1) information coming in a random, independent, unpredictable fashion and (2) numerous competing investors adjusting stock prices rapidly to reflect this new information means that one would expect price changes to be independent and random. Clearly, the adjustment process requires a large number of investors following the movements of the security, analyzing the impact of new information on its value, and buying or selling the security until its price adjusts to reflect the new information. This scenario implies that informationally efficient markets require some minimum amount of trading and that more trading by numerous competing investors should cause a faster price adjustment, making the market more efficient. We will return to this need for trading and investor attention when we discuss some anomalies of the EMH. The reader is also reminded of the discussion in Chapter 4 regarding the significant increase in transactions and trading volume over the past decade as well as the reduction in the cost of trading.

Finally, because security prices adjust to all new information, these security prices should reflect all information that is publicly available at any point in time. Therefore, the security prices that prevail at any time should be an unbiased reflection of all currently available information, including the risk involved in owning the security. Therefore, in an efficient market, the expected returns implicit in the current price of the security should reflect its risk, which means that investors who buy at these informationally efficient prices should receive a rate of return that is consistent with the perceived risk of the security. Put another way, in terms of the CAPM that is discussed in Chapter 8, all securities should lie on the SML such that their expected rates of return are consistent with their perceived risk.

6.2 Alternative Efficient Market Hypotheses

Most of the early work related to efficient capital markets was based on the random walk hypothesis, which contended that changes in stock prices occurred randomly. This early academic work contained extensive empirical analysis without much theory behind it. An article by Fama (1970) attempted to formalize the theory and organize the growing empirical evidence. Fama presented the efficient market theory in terms of a fair game model, contending that investors can be confident that a current market price fully reflects all available information about a security and, therefore, the expected return based upon this price is consistent with its risk.

In his original article, Fama divided the overall efficient market hypothesis (EMH) and the empirical tests of the hypothesis into three subhypotheses depending on the information set involved: (1) weak-form EMH, (2) semistrong-form EMH, and (3) strong-form EMH.

In a subsequent review article, Fama (1991a) again divided the empirical results into three groups but shifted empirical results between the prior categories. Therefore, the following discussion uses the original categories, noted above, but organizes the presentation of results using the new categories.

In the remainder of this section, we describe the three subhypotheses and the implications of each of them. As noted, the three subhypotheses are based on alternative information sets. In the following section, we briefly describe how researchers have tested these hypotheses and summarize the results of these tests.

6.2.1 Weak-Form Efficient Market Hypothesis

The weak-form EMH assumes that current stock prices fully reflect all security market information, including the historical sequence of prices, rates of return, trading volume data, and other market-generated information, such as odd-lot transactions and transactions by market-makers. Because it assumes that current market prices already reflect all past returns and any other security market information, this hypothesis implies that past rates of return and other
market in a random, independent fashion, and security prices adjust rapidly to this new information. Two major statistical tests have been employed to verify this independence. First, autocorrelation tests of independence measure the significance of positive or negative correlation in returns over time. Does the rate of return on day \( t \) correlate with the rate of return on day \( t-1 \), \( t-2 \), or \( t-3 \)? Those who believe that capital markets are efficient would expect insignificant correlations for all such combinations. Several researchers have examined the serial correlations among stock returns for several relatively short time horizons including 1 day, 4 days, 9 days, and 16 days. The results typically indicated insignificant correlation in stock returns over time. Some recent studies that considered portfolios of stocks of different market size have indicated that the autocorrelation is stronger for portfolios of small market size stocks. Therefore, although the older results tend to support the hypothesis, the more recent studies cast doubt on it for portfolios of small firms, although these results could be offset by the higher transaction costs of small-cap stocks and nonsynchronous trading for small-cap stocks.

The second statistical test of independence as discussed by DeFusco et al. (2004), is the runs test. Given a series of price changes, each price change is either designated a plus (+) if it is an increase in price or a minus (−) if it is a decrease in price. The result is a set of pluses and minuses as follows: + + + − + − − + + − − + +. A run occurs when two consecutive changes are the same; two or more consecutive positive or negative price changes constitute one run. When the price changes in a different direction, such as when a negative price change is followed by a positive price change, the run ends and a new run may begin. To test for independence, you would compare the number of runs for a given series to the number in a table of expected values for the number of runs that should occur in a random series. Studies that have examined stock price runs have confirmed the independence of stock price changes over time. The actual number of runs for stock price series consistently fell into the range expected for a random series. Therefore, these statistical tests of stocks on the NYSE and on the NASDAQ market have likewise confirmed the independence of stock price changes over time.

Although short-horizon stock returns (monthly, weekly, and daily) have generally supported the weak-form EMH, several studies that examined price changes for individual transactions on the NYSE found significant serial correlations. Some of the original studies indicated that the serial correlation meant that momentum could be used to generate excess risk-adjusted returns, but they also concluded that the substantial transaction costs wiped out the profits. In contrast, more recent studies that recognized the substantially lower transaction costs in the current environment as discussed in Chapter 4 indicate that return momentum can be a viable trading technique. Subsequently, Heston, Korajczyk, and Sadka (2010) found intra-day patterns of returns and volume persisted for relatively long periods (40 trading days), and they attribute this to systematic trading and institutional fund flows.

Tests of Trading Rules
The second group of tests of the weak-form EMH were developed in response to the assertion that some of the prior statistical tests of independence were too rigid to identify the intricate price patterns examined by technical analysts. As we will discuss in Chapter 15, technical analysts do not expect a set number of positive or negative price changes as a signal of a move to a new equilibrium in the market. They typically look for a general consistency in the price trends over time. Such a trend might include both positive and negative changes. Therefore, technical analysts believed that their sophisticated trading rules could not be properly tested by rigid statistical tests.

In response to this objection, investigators attempted to examine alternative technical trading rules through simulation. Advocates of an efficient market hypothesized that investors should have no relationship with future rates of return (that is, rates of return should be independent). Therefore, this hypothesis contends that you should gain little from using any trading rule which indicates that you should buy or sell a security based on past rates of return or any other past security market data.

### 6.2.2 Semistrong-Form Efficient Market Hypothesis
The semistrong-form EMH asserts that security prices adjust rapidly to the release of all public information; that is, current security prices fully reflect all public information. The semistrong hypothesis encompasses the weak-form hypothesis, because all the market information considered by the weak-form hypothesis, such as stock prices, rates of return, and trading volume, is public. Notably, public information also includes all nonmarket information, such as earnings and dividend announcements, price-to-earnings (P/E) ratios, dividend-yield (D/P) ratios, price-book value (P/BV) ratios, stock splits, news about the economy, and political news. This hypothesis implies that investors who base their decisions on any important new information after it is public should not derive above-average risk-adjusted profits from their transactions, considering the cost of trading because the security price should immediately reflect all such new public information.

### 6.2.3 Strong-Form Efficient Market Hypothesis
The strong-form EMH contends that stock prices fully reflect all information from public and private sources. This means that no group of investors has monopolistic access to information relevant to the formation of prices. Therefore, this hypothesis contends that no group of investors should be able to consistently derive above-average risk-adjusted rates of return. The strong-form EMH encompasses both the weak-form and the semistrong-form EMH. Further, the strong-form EMH extends the assumption of efficient markets, in which prices adjust rapidly to the release of new public information, to assume perfect markets, in which all information is cost-free and available to everyone at the same time.

### 6.3 Tests and Results of Efficient Market Hypotheses
Now that you understand the three components of the EMH and what each of them implies regarding the effect on security prices of different sets of information, we can consider the tests used to see whether the data support the hypotheses. Therefore, in this section we discuss the specific tests and summarize the results of these tests.

Like most hypotheses in finance and economics, the evidence on the EMH is mixed. Some studies have supported the hypotheses and indicate that capital markets are efficient. Results of other studies have revealed some anomalies related to these hypotheses, indicating results that do not support the hypotheses.

#### 6.3.1 Weak-Form Hypothesis: Tests and Results
Researchers have formulated two groups of tests of the weak-form EMH. The first category involves statistical tests of independence between rates of return. The second set of tests entails a comparison of risk-return results for trading rules that make investment decisions based on past market information relative to the results from a simple buy-and-hold policy, which assumes that you buy stock at the beginning of a test period and hold it to the end.

**Statistical Tests of Independence** As discussed earlier, the EMH contends that security returns over time should be independent of one another because new information comes to the
could not derive abnormal profits above a buy-and-hold policy using any trading rule that depended solely on past market information. The trading rule studies compared the risk–return results derived from trading-rule simulations, including transaction costs, to the results from a simple buy-and-hold policy. Three major pitfalls can negate the results of a trading-rule study:

1. The investigator should use only publicly available data when implementing the trading rule. As an example, the trading activities of some set of traders/investors for some period ending December 31 may not be publicly available until February 1. Therefore, you should not factor in information about the trading activity until the information is public.

2. When computing the returns from a trading rule, you should include all transaction costs involved in implementing the trading strategy because most trading rules involve many more transactions than a simple buy-and-hold policy.

3. You must adjust the results for risk because a trading rule might simply select a portfolio of high-risk securities that should experience higher returns.

Researchers have encountered two operational problems in carrying out these tests of specific trading rules. First, some trading rules require too much subjective interpretation of data to simulate mechanically. Second, the almost infinite number of potential trading rules makes it impossible to test all of them. As a result, only the better-known technical trading rules that can be programmed into a computer have been examined.

Another factor that should be recognized is that the simulation studies have typically been restricted to relatively simple trading rules, which many technicians contend are rather naïve. In addition, many of the early studies employed readily available data from the NYSE, which is biased toward well-known, heavily traded stocks that certainly should trade in efficient markets. Recall that markets should be more efficient when there are numerous aggressive, profit-maximizing investors attempting to adjust stock prices to reflect new information, so market efficiency will be related to trading volume. Specifically, more trading in a security should promote market efficiency. Alternatively, for securities with relatively few stockholders and limited trading activity, the market could be inefficient simply because fewer investors would be analyzing the effect of any new information. This limited interest would result in insufficient trading activity to move the price of the security quickly to a new equilibrium value that reflects the new information. Therefore, using only active, heavily traded stocks when testing a trading rule could bias the results toward finding efficiency.

Results of Simulations of Specific Trading Rules

One of the most popular trading techniques is the filter rule, wherein an investor trades a stock when the price change exceeds a filter value set for it. As an example, an investor using a 5 percent filter would identify a positive breakout if the stock were to rise 5 percent from some base, suggesting that the stock price would continue to rise. A technician would acquire the stock to take advantage of the expected increase. In contrast, a 5 percent decline from some peak price would be considered a negative breakout, and the technician would expect a further price decline and would sell any holdings of the stock and possibly even sell the stock short.

Studies of this trading rule have used a range of filters from 0.5 percent to 50 percent. The results indicated that small filters would yield above-average profits before taking account of trading commissions. However, small filters generate numerous trades and, therefore, substantial trading costs. When the pre-2000 trading costs were considered, all the trading profits turned to losses. It is possible that using recent lower trading costs (post-2011), the results could be different. Alternatively, trading using larger filters did not yield returns above those of a simple buy-and-hold policy.

Tests of Trading Rules

The second group of tests of the weak-form EMH were developed in response to the assertion that some of the prior statistical tests of independence were too rigid to identify the intricate price patterns examined by technical analysts. As we will discuss in Chapter 15, technical analysts do not expect a set number of positive or negative price changes as a signal of a move to a new equilibrium in the market. They typically look for a general consistency in the price trends over time. Such a trend might include both positive and negative changes. Therefore, technical analysts believed that their sophisticated trading rules could not be properly tested by rigid statistical tests.

In response to this objection, investigators attempted to examine alternative technical trading rules through simulation. Advocates of an efficient market hypothesized that investors

---

2For a discussion of tests of time-series independence, see DeFusco, McLevey, Pinto, and Runkle (2004), Chapter 10.
Researchers have simulated other trading rules that used past market data other than stock prices. Trading rules have been devised that consider advanced-decline ratios, short sales, short positions, and specialist activities.

These simulation tests have generated mixed results. Most of the early studies using higher commission fees suggested that these trading rules generally would not outperform a buy-and-hold policy on a risk-adjusted basis after commissions. In contrast, several recent studies have indicated support for specific trading rules. Therefore, most evidence from simulations of specific trading rules indicates that most trading rules tested have not been able to beat a buy-and-hold policy. Therefore, the early test results generally support the weak-form EMH, but the results are clearly not unanimous, especially if one considers the substantially lower commissions that currently exist.

6.3.2 Semistrong-Form Hypothesis: Tests and Results

Recall that the semistrong-form EMH asserts that security prices adjust rapidly to the release of all public information; that is, security prices fully reflect all public information. Studies that have tested the semistrong-form EMH can be divided into the following sets of studies:

1. Studies to predict future rates of return using available public information beyond pure market information such as prices and trading volume considered in the weak-form tests. These studies can involve either time-series analysis of returns or the cross-section distribution of returns for individual stocks. Advocates of the EMH contend that it would not be possible to predict future returns using past returns or to predict the distribution of future returns (e.g., the top quartile or decile of returns) using public information.

2. Event studies that examine how fast stock prices adjust to specific significant economic events. A corollary approach would be to test whether it is possible to invest in a security after the public announcement of a significant event (e.g., earnings, stock splits, major economic data) and experience significant abnormal rates of return. Again, advocates of the EMH would expect security prices to adjust rapidly, such that it would not be possible for investors to experience superior risk-adjusted returns by investing after the public announcement and paying normal transaction costs.

Adjustment for Market Effects

For any of these tests, you need to adjust the security’s rate of return for the rates of return of the overall market during the period considered. The point is that a 5 percent return in a stock during the period surrounding an announcement is meaningless until you know what the aggregate stock market did during the same period and how this stock normally acts under such conditions. If the market had experienced a 10 percent return during this announcement period, the 5 percent return for the stock may be lower than expected.

Early studies (pre-1980) generally recognized the need to make adjustments for market movements by assuming that the individual stocks should experience returns equal to the aggregate stock market. Thus, the market-adjustment process simply entailed subtracting the market return from the return for the individual security to derive its abnormal rate of return, as follows:

\[
AR_{it} = R_{it} - R_{mt}
\]

where:

- \(AR_{it}\) = abnormal rate of return on security \(i\) during period \(t\)
- \(R_{it}\) = rate of return on security \(i\) during period \(t\)
- \(R_{mt}\) = rate of return on a market index during period \(t\)

In the example where the stock experienced a 5 percent increase while the market increased 10 percent, the stock’s abnormal return would be minus 5 percent.

Results of Simulations of Specific Trading Rules

One of the most popular trading techniques is the filter rule, wherein an investor trades a stock when the price change exceeds a filter value set for it. As an example, an investor using a 5 percent filter would identify a positive breakout if the stock were to rise 5 percent from some base, suggesting that the stock price would continue to rise. A technician would acquire the stock to take advantage of the expected increase. In contrast, a 5 percent decline from some peak price would be considered a negative breakout, and the technician would expect a further price decline and would sell any holdings of the stock and possibly even sell the stock short.

Studies of this trading rule have used a range of filters from 0.5 percent to 50 percent. The results indicated that small filters would yield above-average profits before taking account of trading commissions. However, small filters generate numerous trades and, therefore, substantial trading costs. When the pre-2000 trading costs were considered, all the trading profits turned to losses. It is possible that using recent lower trading costs (post-2011), the results could be different. Alternatively, trading using larger filters did not yield returns above those of a simple buy-and-hold policy.
Researchers have simulated other trading rules that used past market data other than stock prices. Trading rules have been devised that consider advanced-decline ratios, short sales, short positions, and specialist activities. These simulation tests have generated mixed results. Most of the early studies using higher commission fees suggested that these trading rules generally would not outperform a buy-and-hold policy on a risk-adjusted basis after commissions. In contrast, several recent studies have indicated support for specific trading rules. Therefore, most evidence from simulations of specific trading rules indicates that most trading rules tested have not been able to beat a buy-and-hold policy. Therefore, the early test results generally support the weak-form EMH, but the results are clearly not unanimous, especially if one considers the substantially lower commissions that currently exist.

6.3.2 Semistrong-Form Hypothesis: Tests and Results
Recall that the semistrong-form EMH asserts that security prices adjust rapidly to the release of all public information; that is, security prices fully reflect all public information. Studies that have tested the semistrong-form EMH can be divided into the following sets of studies:

1. Studies to predict future rates of return using available public information beyond pure market information such as prices and trading volume considered in the weak-form tests. These studies can involve either time-series analysis of returns or the cross-section distribution of returns for individual stocks. Advocates of the EMH contend that it would not be possible to predict future returns using past returns or to predict the distribution of future returns (e.g., the top quartile or decile of returns) using public information.

2. Event studies that examine how fast stock prices adjust to specific significant economic events. A corollary approach would be to test whether it is possible to invest in a security after the public announcement of a significant event (e.g., earnings, stock splits, major economic data) and experience significant abnormal rates of return. Again, advocates of the EMH would expect security prices to adjust rapidly, such that it would not be possible for investors to experience superior risk-adjusted returns by investing after the public announcement and paying normal transaction costs.

Adjustment for Market Effects For any of these tests, you need to adjust the security’s rates of return for the rates of return of the overall market during the period considered. The point is that a 5 percent return in a stock during the period surrounding an announcement is meaningless until you know what the aggregate stock market did during the same period and how this stock normally acts under such conditions. If the market had experienced a 10 percent return during this announcement period, the 5 percent return for the stock may be lower than expected.

Early studies (pre-1980) generally recognized the need to make adjustments for market movements by assuming that the individual stocks should experience returns equal to the aggregate stock market. Thus, the market-adjustment process simply entailed subtracting the market return from the return for the individual security to derive its abnormal rate of return, as follows:

\[ AR_{it} = R_{it} - R_{mt} \]

where:

\[ AR_{it} \] = abnormal rate of return on security \( i \) during period \( t \)

\[ R_{it} \] = rate of return on security \( i \) during period \( t \)

\[ R_{mt} \] = rate of return on a market index during period \( t \)

In the example where the stock experienced a 5 percent increase while the market increased 10 percent, the stock’s abnormal return would be minus 5 percent.

Many of these trading rules are discussed in Chapter 15, which deals with technical analysis.
Recent authors have adjusted the rates of return for securities by an amount different from the market rate of return because they recognize that, based on work with the CAPM, all stocks do not change by the same amount as the market. That is, as will be discussed in Chapter 8, some stocks are more volatile than the market, and some are less volatile. These possibilities mean that you must determine an expected rate of return for the stock based on the market rate of return and the stock's relationship with the market (its beta). As an example, suppose a stock is generally 20 percent more volatile than the market (that is, it has a beta of 1.20). In such a case, if the market experiences a 10 percent rate of return, you would expect this stock to experience a 12 percent rate of return. Therefore, you would determine the abnormal rate of return by computing the difference between the stock's actual rate of return and its expected rate of return as follows:

\[ AR_{it} = R_{it} - E(R_{it}) \]

where:

\[ E(R_{it}) = \text{the expected rate of return for stock } i \text{ during period } t \text{ based on the market rate of return and the stock's normal relationship with the market (its beta)} \]

Continuing with the example, if the stock that was expected to have a 12 percent return (based on a market return of 10 percent and a stock beta of 1.20) had only a 5 percent return, its abnormal rate of return during the period would be minus 7 percent. Over the normal long-run period, you would expect the abnormal returns for a stock to sum to zero. Specifically, during one period the returns may exceed expectations and the next period they may fall short of expectations.

**Alternate Semistrong Tests** Given this understanding of the market adjustment, recall that there are two sets of tests of the semistrong-form EMH. The first set are referred to as return prediction studies. In these studies, investigators attempt to predict the time series of future rates of return for individual stocks or the aggregate market using public information. For example, is it possible to predict abnormal returns over time for the market based on public information such as changes in the aggregate dividend yield or the risk premium spread for bonds? Another example would be event studies that examine abnormal rates of return for a period immediately after an announcement of a significant economic event, such as a stock split, a proposed merger, or a stock or bond issue, to determine whether an investor can derive above-average risk-adjusted rates of return by investing after the release of public information.

Another set of studies attempt to predict cross-sectional returns by examining public information regarding individual stocks that will allow investors to predict the cross-sectional distribution of future risk-adjusted rates of return. For example, they test whether it is possible to use variables such as the price-earnings ratio, market value size, the price/book-value ratio, the P/E/growth rate (PEG) ratio, or the dividend yield to predict which stocks will experience above-average (e.g., top quartile) or below-average risk-adjusted rates of return in the future.

In both sets of tests, the emphasis is on the analysis of abnormal rates of return that deviate from long-term expectations.

**Results of Return Prediction Studies** The time-series analysis assumes that in an efficient market the best estimate of future rates of return will be the long-run historical rates of return. The tests attempt to determine whether any public information will provide superior estimates of returns for a short-run horizon (one to six months) or a long-run horizon (one to five years).

**Risk Premium Proxies** These studies have indicated limited success in predicting short-horizon returns, but the analysis of long-horizon returns has been quite successful. A prime example is dividend yield studies. After postulating that the aggregate dividend yield \((D/P)\)
was a proxy for the risk premium on stocks, they found a positive relationship between the 
\( D/P \) and future long-run stock market returns.

In addition, several studies have considered two variables related to the term structure of interest rates: (1) a default spread, which is the difference between the yields on lower-grade and Aaa-rated long-term corporate bonds (this spread has been used in earlier chapters of this book as a proxy for a market risk premium), and (2) the term structure spread, which is the difference between the long-term Treasury bond yield and the yield on one-month Treasury bills. These variables have been used to predict stock returns and bond returns. Similar variables have also been useful for predicting returns for foreign common stocks.

The reasoning for these empirical results is as follows: When the two most significant variables—the dividend yield \( (D/P) \) and the bond default spread—are high, it implies that investors are requiring a high return on stocks and bonds. Notably, this occurs during poor economic environments that imply a low-wealth environment wherein investors perceive an increase in risk for investments. As a result, for investors to invest and shift consumption from the present to the future, they will require a high rate of return (i.e., a high-risk premium) that will cause a decline in prices for risky assets. Therefore, if you invest during this risk-averse period, your subsequent returns will be above normal. In contrast, when dividend yields and yield spreads are small, it implies that investors have reduced their risk premium and required rates of return, and, therefore, their future returns will be below normal. The results of studies that support this expectation would be evidence against the EMH because they indicate you can use public information on dividend yields and yield spreads to predict future abnormal returns.

### Quarterly Earnings Reports

Studies that address quarterly reports are considered part of the times-series analysis. Specifically, these studies examine whether it is possible to predict future individual stock returns based on publicly available information on changes in quarterly earnings that differed from expectations.

The results generally indicated that there were abnormal stock returns during the 13 or 26 weeks following the announcement of a large unanticipated earnings change—referred to as an earnings surprise. These results indicate that an earnings surprise is not instantaneously reflected in security prices.

An extensive analysis by Rendleman, Jones, and Latané (1982) and a follow-up by Jones, Rendleman, and Latané (1985) using a large sample and daily data from 20 days before a quarterly earnings announcement to 90 days after the announcement indicated that 31 percent of the total response in stock returns came before the earnings announcement, 18 percent on the day of the announcement, and 51 percent after the announcement.

Several subsequent studies by Benesh and Peterson (1986), Bernard and Thomas (1989), and Baruch (1989) contended that the reason for the stock price drift was the earnings revisions that followed the earnings surprises and these revisions contributed to the positive correlations of prices.

In summary, these results indicate that the market has not adjusted stock prices to reflect the release of quarterly earnings surprises as fast as expected by the semistrong EMH, which implies that earnings surprises and earnings revisions can be used to predict returns for individual stocks. These results are evidence against the EMH.\(^4\)

These results have also been enhanced by research from Campbell, Ramadorai, and Schwartz (2009), that showed institutions are able to anticipate earning surprises and also a study by Vega (2006) which contents that the post-announcement drift is also affected by whether the information is associated with the arrival rate of informed and uniformed traders. It was also determined that earning surprises have a larger affect on small firms.

---

\(^4\)Academic studies such as these, which have indicated the importance of earnings surprises, have led The Wall Street Journal to publish a section on earnings surprises in connection with regular quarterly earnings reports.
In addition, there have been some “calendar studies” that questioned whether some regularities in the rates of return during the calendar year would allow investors to predict returns on stocks. This research included numerous studies on “the January anomaly” and studies that consider a variety of other daily and weekly regularities.

**The January Anomaly** Several years ago, Branch (1977) and Branch and Chang (1985) proposed a unique trading rule for those interested in taking advantage of tax selling. Investors (including institutions) tend to engage in tax selling toward the end of the year to establish losses on stocks that have declined. After the new year, the tendency is to reacquire these stocks or to buy similar stocks that look attractive. This scenario would produce downward pressure on stock prices in late November and December and positive pressure in early January. Such a seasonal pattern is inconsistent with the EMH since it should be eliminated by arbitrageurs who would buy in December and sell in early January.

A supporter of the hypothesis found that December trading volume was abnormally high for stocks that had declined during the previous year and that significant abnormal returns occurred during January for stocks that had experienced losses during the prior year. It was concluded that, because of transaction costs, arbitrageurs must not be eliminating the January tax-selling anomaly. Subsequent analysis showed that most of the January effect was concentrated in the first week of trading, particularly on the first day of the year.

Several studies provided support for a January effect but were inconsistent with the tax-selling hypothesis because of what happened in foreign countries that did not have our tax laws or a December year-end. They found abnormal returns in January, but the results could not be explained by tax laws. It has also been shown that the classic relationship between risk and return is strongest during January and there is a year-end trading volume bulge in late December–early January.

Another facet of the January effect (referred to as “the other January effect”) is related to aggregate market returns where in it is contended that stock market returns in January are a predictor to the return over the next 11 months of the year. A study by Cooper, McConnell, and Ouchinnikou (2006) finds strong support for this contention.

**Other Calendar Effects** Several other “calendar” effects have been examined, including a monthly effect, a weekend/day-of-the-week effect, and an intraday effect. One study found a significant monthly effect wherein all the market’s cumulative advance occurred during the first half of trading months.

An analysis of the weekend effect found that the mean return for Monday was significantly negative during five-year subperiods and a total period. In contrast, the average return for the other four days was positive.

A study decomposed the Monday effect that is typically measured from Friday close to Monday close into a weekend effect (from Friday close to Monday open), and a pure Monday trading effect (from Monday open to the Monday close). It was shown that the negative Monday effect found in prior studies actually occurs from the Friday close to the Monday open (it is really a weekend effect). After adjusting for the weekend effect, the pure Monday trading effect was positive. Subsequently, it was shown that the Monday effect was on average positive in January and negative for all other months.

Finally, for large firms, the negative Monday effect occurred before the market opened (it was a weekend effect), whereas for smaller firms most of the negative Monday effect occurred during the day on Monday (it was a Monday trading effect).

**Predicting Cross-Sectional Returns** Assuming an efficient market, all securities should have equal risk-adjusted returns because security prices should reflect all public information that would influence the security’s risk. Therefore, studies in this category attempt to determine if
you can use public information to predict what stocks will enjoy above-average or below-average risk-adjusted returns.

These studies typically examine the usefulness of alternative measures of size or quality to rank stocks in terms of risk-adjusted returns. Keep in mind that all of these tests involve a joint hypothesis because they not only consider the efficiency of the market but also are dependent on the asset pricing model that provides the measure of risk used in the test. Specifically, if a test determines that it is possible to predict risk-adjusted returns, these results could occur because the market is not efficient, or they could be because the measure of risk is faulty and, therefore, the measures of risk-adjusted returns are wrong.

**Price-Earnings Ratios** Several studies beginning with Basu (1977) have examined the relationship between the historical price-earnings (P/E) ratios for stocks and the returns on the stocks. Some have suggested that low P/E stocks will outperform high P/E stocks because growth companies enjoy high P/E ratios, but the market tends to overestimate the growth potential and thus overvalues these growth companies, while undervaluing low-growth firms with low P/E ratios. A relationship between the historical P/E ratios and subsequent risk-adjusted market performance would constitute evidence against the semistrong EMH, because it would imply that investors could use publicly available information regarding P/E ratios to predict future abnormal returns.

Performance measures that consider both return and risk indicated that low P/E ratio stocks experienced superior risk-adjusted results relative to the market, whereas high P/E ratio stocks had significantly inferior risk-adjusted results.\(^5\) Subsequent analysis concluded that publicly available P/E ratios possess valuable information regarding future returns, which is inconsistent with semistrong efficiency.

Peavy and Goodman (1983) examined P/E ratios with adjustments for firm size, industry effects, and infrequent trading and likewise found that the risk-adjusted returns for stocks in the lowest P/E ratio quintile were superior to those in the highest P/E ratio quintile.

**Price-Earnings/Growth Rate (PEG) Ratios** During the past decade, there has been a significant increase in the use of the ratio of a stock’s price-earnings ratio divided by the firm’s expected growth rate of earnings (referred to as the PEG ratio) as a relative valuation tool, especially for stocks of growth companies that have P/E ratios substantially above average. Advocates of the PEG ratio hypothesize an inverse relationship between the PEG ratio and subsequent rates of return—that is, they expect that stocks with relatively low PEG ratios (i.e., less than one) will experience above-average rates of return while stocks with relatively high PEG ratios (i.e., in excess of three or four) will have below-average rates of return. A study by Peters (1991) using quarterly rebalancing supported the hypothesis of an inverse relationship. These results would constitute an anomaly and would not support the EMH. A subsequent study by Reilly and Marshall (1999) assumed annual rebalancing and divided the sample on the basis of a risk measure (beta), market value size, and by expected growth rate. Except for stocks with low betas and very low expected growth rates, the results were not consistent with the hypothesis of an inverse relationship between the PEG ratio and subsequent rates of return.

In summary, the results related to using the PEG ratio to select stocks are mixed—several studies that assume either monthly or quarterly rebalancing indicate an anomaly because the authors use public information and derive above-average rates of return. In contrast, a study with more realistic annual rebalancing indicated that no consistent relationship exists between the PEG ratio and subsequent rates of return.

**The Size Effect** Banz (1981) examined the impact of size (measured by total market value) on the risk-adjusted rates of return. The risk-adjusted returns for extended periods (20 to 35

\(^5\)Composite performance measures are discussed in Chapter 25.
years) indicated that the small firms consistently experienced significantly larger risk-adjusted returns than the larger firms. Reinganum (1981) contended that it was the size, not the P/E ratio, that caused the results discussed in the prior subsection, but this contention was disputed by Basu (1983).

Recall that abnormal returns may occur because the markets are inefficient or because the market model provides incorrect estimates of risk and expected returns. It was suggested that the riskiness of the small firms was improperly measured because small firms are traded less frequently. An alternative risk measure technique confirmed that the small firms had much higher risk than previously measured, but the consideration of the higher betas still did not account for the large difference in rates of return.

A study by Stoll and Whaley (1983) that examined the impact of transaction costs confirmed the size effect but also found that firms with small market value generally have low stock prices. Because transaction costs vary inversely with price per share, these costs must be considered when examining the small-firm effect. They found a significant difference in the percentage total transaction cost for large firms (2.71 percent) versus small firms (6.77 percent). This differential in transaction costs, assuming frequent trading, can have a significant impact on the results. Assuming daily transactions, the original small-firm effects are reversed. The point is, size-effect studies must consider realistic transaction costs and specify holding period assumptions. A study by Reinganum (1983) that considered both factors over long periods demonstrated that infrequent rebalancing (about once a year) is almost ideal—the results beat long-run buy-and-hold and avoid frequent rebalancing that causes excess costs. In summary, small firms outperformed large firms after considering higher risk and realistic transaction costs (assuming annual rebalancing).

Most studies on the size effect employed large databases and long time periods (over 50 years) to show that this phenomenon has existed for many years. In contrast, a study that examined the performance over various intervals of time concluded that the small-firm effect is not stable. During most periods investigators found the negative relationship between size and return; but, during selected periods (such as 1967 to 1975), they found that large firms outperformed the small firms. Notably, this positive relationship held during the following recent periods: 1984–1987; 1989–1990; 1995–1998; and during 2005–2009 on a risk-adjusted basis. Reinganum (1992) acknowledges this instability but contends that the small-firm effect is still a long-run phenomenon.

In summary, firm size is a major efficient market anomaly. The two strongest explanations are higher risk measurements due to infrequent trading and the higher transaction costs. Depending on the frequency of trading, these two factors may account for much of the differential. Keim (1983) also related it to seasonality. These results indicate that the size effect must be considered in any event study that considers long time periods and contains a sample of firms with significantly different market values.

**Neglected Firms and Trading Activity** Arbel and Strebel (1983) considered an additional influence beyond size—attention or neglect. They measured attention in terms of the number of analysts who regularly follow a stock and divided the stocks into three groups: (1) highly followed, (2) moderately followed, and (3) neglected. They confirmed the small-firm effect but also found a neglected-firm effect caused by the lack of information and limited institutional interest. The neglected-firm concept applied across size classes. Contrary results are reported by Beard and Sias (1997) who found no evidence of a neglected firm premium after controlling for capitalization.

James and Edminster (1983) examined the impact of trading volume by considering the relationship between returns, market value, and trading activity. The results confirmed the standard deviation for large-cap stocks at 20.4 percent versus 32.6 percent for small-cap stocks.
relationship between size and rates of return, but the results indicated no significant difference between the mean returns of the highest and lowest trading activity portfolios. A subsequent study hypothesized that firms with less information require higher returns. Using the period of listing as a proxy for information, they found a negative relationship between returns and the period of listing after adjusting for firm size and the January effect.

**Book Value—Market Value Ratio** This ratio relates the book value (BV) of a firm’s equity to the market value (MV) of its equity. Rosenberg, Reid, and Lanstein (1985) found a significant positive relationship between current values for this ratio and future stock returns and contended that such a relationship between available public information on the BV/MV ratio and future returns was evidence against the EMH.7

Strong support for this ratio was provided by Fama and French (1992) who evaluated the joint effects of market beta, size, E/P ratio, leverage, and the BV/MV ratio (referred to as BE/ME) on a cross section of average returns. They analyzed the hypothesized positive relationship between beta and expected returns and found that this positive relationship held pre-1969 but disappeared during the period 1963 to 1990. In contrast, the negative relationship between size and average return was significant by itself and significant after inclusion of other variables.

In addition, they found a significant positive relationship between the BV/MV ratio and average return that persisted even when other variables are included. Most importantly, both size and the BV/MV ratio are significant when included together and they dominate other ratios. Specifically, although leverage and the E/P ratio were significant by themselves or with size, they become insignificant when both size and the BV/MV ratio are considered.

The results in Exhibit 6.1 show the separate and combined effect of the two variables. As shown, going across the Small-ME (small size) row, BV/MV captures strong variation in average returns (0.70 to 1.92 percent). Alternatively, controlling for the BV/MV ratio leaves a size effect in average returns (the high BV/MV results decline from 1.92 to 1.18 percent when going from small to large). These positive results for the BV/MV ratio were replicated for returns on Japanese stocks.

In summary, studies that have used publicly available ratios to predict the cross section of expected returns for stocks have provided substantial evidence in conflict with the semistrong-form EMH. Significant results were found for P/E ratios, market value size, and BV/MV ratios. Although the research by Fama and French indicated that the optimal combination appears to be size and the BV/MV ratio, a study by Jensen, Johnson, and Mercer (1997) indicates that this combination only works during periods of expansive monetary policy.

**Results of Event Studies** Recall that the intent of event studies is to examine abnormal rates of return surrounding significant economic information. Those who advocate the EMH would expect returns to adjust quickly to announcements of new information such that investors cannot experience positive abnormal rates of return by acting after the announcement. Because of space constraints, we can only summarize the results for some of the more popular events considered.

The discussion of results is organized by event or item of public information. Specifically, we will examine the price movements and profit potential surrounding stock splits, the sale of initial public offerings, exchange listings, unexpected world or economic events, and the announcements of significant accounting changes. Notably, the results for most of these studies have supported the semistrong-form EMH.

---

7Many studies define this ratio as “book-to-market value” (BV/MV) because it implies a positive relationship, but most practitioners refer to it as the “price-to-book value” (P/B) ratio. Obviously the concept is the same, but the sign changes.
Initial Public Offerings (IPOs)

During the past 20 years, a number of closely held companies have gone public by selling some of their common stock. Because of uncertainty about the appropriate offering price and the risk involved in underwriting such issues, it has been hypothesized that the underwriters would tend to underprice these new issues. Given this general expectation of underpricing, the studies in this area have generally considered three sets of questions: (1) How great is the underpricing on average? Does the underpricing vary over time? If so, why? (2) What factors cause different amounts of underpricing for alternative issues? (3) How fast does the market adjust the price for the underpricing?

The answer to the first question is an average underpricing of about 17 percent, but it varies over time as shown by the results in Exhibit 6.2 for the total period 1980–2010 and for various subperiods. The major variables that cause differential underpricing seem to be various risk measures, the size of the firm, the prestige of the underwriter, and the status of the firm’s accounting firm. On the question of direct interest to the EMH, results in Miller and Reilly (1987) and Ibbotson, Sindelar, and Ritter (1994) indicate that the price adjustment to the underpricing takes place within one day after the offering. Therefore, it appears that some underpricing occurs based on the original offering price, but the ones who benefit from this underpricing are basically the investors who receive allocations of the original issue. More specifically, institutional investors captured most (70 percent) of the short-term profits. This rapid adjustment of the initial underpricing would support the semistrong EMH. Finally, studies by Ritter (1991); Carter, Dark, and Singh (1998); and Loughran and Ritter (1995) that examined the long-run returns on IPOs indicate that investors who acquire the stock after the initial adjustment do not experience positive long-run abnormal returns.

Exchange Listing

A significant economic event for a firm is listing its stock on a national exchange, especially the NYSE. Such a listing is expected to increase the market liquidity of the stock and add to its prestige. An important question is, can an investor derive abnormal returns from investing in the stock when a new listing is announced or around the time of the actual listing? The results regarding abnormal returns from such investing were mixed. All the studies agreed that (1) the stocks’ prices increased before any listing announcements, and (2) stock prices consistently declined after the actual listing. The crucial question is: What happens between the announcement of the application for listing and the actual listing (a period of four to six weeks)? A study by McConnell and Sanger (1989) points toward profit opportunities immediately after the announcement that a firm is applying for listing and there is the possibility of excess returns from price declines after the actual listing. Finally, studies that have examined the impact of listing on the risk of the securities found no significant change in systematic risk or the firm’s cost of equity.

In summary, because listing studies provide evidence of short-run profit opportunities for investors using public information, these studies would not support the semistrong-form EMH.

Unexpected World Events and Economic News

The results of several studies that examined the response of security prices to world or economic news have supported the semistrong-form EMH. An analysis of the reaction of stock prices to unexpected world events, such as the Eisenhower heart attack, the Kennedy assassination, and military events, found that prices adjusted to the news before the market opened or before it reopened after the announcement (generally, as with the World Trade Center attack, the Exchanges are closed immediately for various time periods—e.g., one to four days). A study by Pierce and Roley (1985) that examined the response of stock prices to announcements about money supply, inflation, real economic activity, and the discount rate found an impact that did not persist beyond the announcement day. Finally, Jain (1988) did an analysis of an hourly response of stock returns and trading volume to surprise announcements and found that unexpected information about

**Stock Split Studies** Many investors believe that the prices of stocks that split will increase in value because the shares are priced lower, which increases demand for them. In contrast, advocates of efficient markets would not expect a change in value because the firm has simply issued additional stock and nothing fundamentally affecting the value of the firm has occurred.

The classic study by Fama, Fisher, Jensen, and Roll (1969), referred to hereafter as FFJR, hypothesized no significant price change following a stock split, because any relevant information (such as earnings growth) that caused the split would have already been discounted. The FFJR study analyzed abnormal price movements surrounding the time of the split and divided the stock split sample into those stocks that did or did not raise their dividends. Both groups experienced positive abnormal price changes prior to the split. Stocks that split but did not increase their dividend experienced abnormal price declines following the split and within 12 months lost all their accumulated abnormal gains. In contrast, stocks that split and increased their dividend experienced no abnormal returns after the split.

These results support the semistrong EMH because they indicate that investors cannot gain from the information on a stock split after the public announcement. These results were confirmed by most (but not all) subsequent studies. In summary, most studies found no short-run or long-run positive impact on security returns because of a stock split, although the results are not unanimous.
Initial Public Offerings (IPOs) During the past 20 years, a number of closely held companies have gone public by selling some of their common stock. Because of uncertainty about the appropriate offering price and the risk involved in underwriting such issues, it has been hypothesized that the underwriters would tend to underprice these new issues.

Given this general expectation of underpricing, the studies in this area have generally considered three sets of questions: (1) How great is the underpricing on average? Does the underpricing vary over time? If so, why? (2) What factors cause different amounts of underpricing for alternative issues? (3) How fast does the market adjust the price for the underpricing?

The answer to the first question is an average underpricing of about 17 percent, but it varies over time as shown by the results in Exhibit 6.2 for the total period 1980–2010 and for various subperiods. The major variables that cause differential underpricing seem to be various risk measures, the size of the firm, the prestige of the underwriter, and the status of the firm’s accounting firm. On the question of direct interest to the EMH, results in Miller and Reilly (1987) and Ibbotson, Sindelar, and Ritter (1994) indicate that the price adjustment to the underpricing takes place within one day after the offering. Therefore, it appears that some underpricing occurs based on the original offering price, but the ones who benefit from this underpricing are basically the investors who receive allocations of the original issue. More specifically, institutional investors captured most (70 percent) of the short-term profits. This rapid adjustment of the initial underpricing would support the semistrong EMH. Finally, studies by Ritter (1991); Carter, Dark, and Singh (1998); and Loughran and Ritter (1995) that examined the long-run returns on IPOs indicate that investors who acquire the stock after the initial adjustment do not experience positive long-run abnormal returns.

Exchange Listing A significant economic event for a firm is listing its stock on a national exchange, especially the NYSE. Such a listing is expected to increase the market liquidity of the stock and add to its prestige. An important question is, can an investor derive abnormal returns from investing in the stock when a new listing is announced or around the time of the actual listing? The results regarding abnormal returns from such investing were mixed. All the studies agreed that (1) the stocks’ prices increased before any listing announcements, and (2) stock prices consistently declined after the actual listing. The crucial question is: What happens between the announcement of the application for listing and the actual listing (a period of four to six weeks)? A study by McConnell and Sanger (1989) points toward profit opportunities immediately after the announcement that a firm is applying for listing and there is the possibility of excess returns from price declines after the actual listing. Finally, studies that have examined the impact of listing on the risk of the securities found no significant change in systematic risk or the firm’s cost of equity.

In summary, because listing studies provide evidence of short-run profit opportunities for investors using public information, these studies would not support the semistrong-form EMH.

Unexpected World Events and Economic News The results of several studies that examined the response of security prices to world or economic news have supported the semistrong-form EMH. An analysis of the reaction of stock prices to unexpected world events, such as the Eisenhower heart attack, the Kennedy assassination, and military events, found that prices adjusted to the news before the market opened or before it reopened after the announcement (generally, as with the World Trade Center attack, the Exchanges are closed immediately for various time periods—e.g., one to four days). A study by Pierce and Roley (1985) that examined the response of stock prices to announcements about money supply, inflation, real economic activity, and the discount rate found an impact that did not persist beyond the announcement day. Finally, Jain (1988) did an analysis of an hourly response of stock returns and trading volume to surprise announcements and found that unexpected information about
should react quickly and predictably to announcements of accounting changes that affect the economic value of the firm. An accounting change that affects reported earnings but has no economic significance should not affect stock prices. For example, when a firm changes its depreciation accounting method for reporting purposes from accelerated to straight line, the firm should experience an increase in reported earnings, but there is no economic consequence. An analysis of stock price movements surrounding this specific accounting change supported the EMH because there were no positive price changes following the change. In fact, there were some negative price changes because firms making such an accounting change are typically performing poorly.

During periods of high inflation, many firms will change their inventory method from first-in, first-out (FIFO) to last-in, first-out (LIFO), which causes a decline in reported earnings but benefits the firm because it reduces the firm’s taxable earnings and, therefore, tax expenses. Advocates of efficient markets would expect positive price changes because of the tax savings, and study results confirmed this expectation.

Therefore, studies such as those by Bernard and Thomas (1990) and Ou and Penman (1989) indicate that the securities markets react quite rapidly to accounting changes and adjust security prices as expected on the basis of changes in true value (that is, analysts pierce the accounting veil and value securities on the basis of relevant economic events).

Corporate Events

Corporate finance events such as mergers and acquisitions, spin-offs, reorganization, and various security offerings (common stock, straight bonds, convertible bonds) have been examined, relative to two general questions: (1) What is the market impact of these alternative events? (2) How fast does the market adjust the security prices?

Regarding the reaction to corporate events, the answer is very consistent—stock prices react as one would expect based on the underlying economic impact of the action. For example, the reaction to mergers is that the stock of the firm being acquired increases in line with the premium offered by the acquiring firm, whereas the stock of the acquiring firm typically declines because of the concern that they overpaid for the firm. On the question of speed of reaction, the evidence indicates fairly rapid adjustment— that is, the adjustment period declines as shorter interval data are analyzed (using daily data, most studies find that the price adjustment is completed in about three days). Studies related to financing decisions are reviewed by Smith (1986). Studies on corporate control that consider mergers and reorganizations are reviewed by Jensen and Warner (1988). Numerous corporate spin-offs have generated interesting stock performance as shown by Desai and Jain (1999) and Chemmanur and Yan (2004).

Summary on the Semistrong-Form EMH

Clearly, the evidence from tests of the semistrong EMH is mixed. The hypothesis receives almost unanimous support from the numerous event studies on a range of events including stock splits, initial public offerings, world events and economic news, accounting changes, and a variety of corporate finance events. About the only mixed results come from exchange listing studies.

In sharp contrast, the numerous studies on predicting rates of return over time or for a cross section of stocks presented evidence counter to semistrong efficiency. This included time-series studies on risk premiums, calendar patterns, and quarterly earnings surprises. Similarly, the results for cross-sectional predictors such as size, the $\frac{BV}{MV}$ ratio (when there is expansive monetary policy), and $\frac{P}{E}$ ratios indicated anomalies that are not consistent with market efficiency.

6.3.3 Strong-Form Hypothesis: Tests and Results

The strong-form EMH contends that stock prices fully reflect all information, public and private. This implies that no group of investors has access to private information that will allow them to consistently experience above-average profits. This extremely rigid hypothesis requires

money supply impacted stock prices within one hour. For a review of studies that considered the impact of news on individual stocks, see Chan (2003).

Announcements of Accounting Changes Numerous studies have analyzed the impact of announcements of accounting changes on stock prices. In efficient markets, security prices
should react quickly and predictably to announcements of accounting changes that affect the economic value of the firm. An accounting change that affects reported earnings but has no economic significance should not affect stock prices. For example, when a firm changes its depreciation accounting method for reporting purposes from accelerated to straight line, the firm should experience an increase in reported earnings, but there is no economic consequence. **6.3.3 Strong-Form Hypothesis: Tests and Results**
The strong-form EMH contends that stock prices fully reflect *all information*, public and private. This implies that no group of investors has access to *private information* that will allow them to consistently experience above-average profits. This extremely rigid hypothesis requires
not only that stock prices must adjust rapidly to new public information but also that no
group has access to private information.

Tests of the strong-form EMH have analyzed returns over time for different identifiable in-
vestment groups to determine whether any group consistently received above-average risk-ad-
justed returns. Such a group must have access to and act upon important private information
or an ability to act on public information before other investors, which would indicate that
security prices were not adjusting rapidly to all new information.

Investigators have tested this form of the EMH by analyzing the performance of the follow-
ing three major groups of investors: (1) corporate insiders, (2) security analysts at Value Line
and elsewhere, and (3) professional money managers. Prior editions of this book included tests
that considered stock exchange specialists. This discussion is not included in this edition be-
cause the discussion in Chapter 4 indicates that the specialist involvement in stock trading is
currently almost nonexistent due to the significant growth of electronic trading.

**Corporate Insider Trading** Corporate insiders are required to report monthly to the SEC on
their transactions (purchases or sales) in the stock of the firm for which they are insiders. In-
siders include major corporate officers, members of the board of directors, and owners of 10
percent or more of any equity class of securities. About six weeks after the reporting period,
this insider trading information is made public by the SEC. These insider trading data have
been used to identify how corporate insiders have traded and determine whether they bought
on balance before abnormally good price movements and sold on balance before poor market
periods for their stock. The results of studies including Chowdhury, Howe, and Lin (1993) and
Petit and Venkatesh (1995) have generally indicated that corporate insiders consistently en-
joyed above-average profits, heavily dependent on selling prior to low returns and not selling
before strong returns. This implies that many insiders had private information from which
they derived above-average returns on their company stock.

In addition, an earlier study found that public investors who consistently traded with the
insiders based on announced insider transactions would have enjoyed excess risk-adjusted re-
turns (after commissions), although a subsequent study concluded that the market had elimi-
nated this inefficiency after considering total transaction costs. Unfortunately, there are no
recent studies that have examined this question assuming the very low transaction costs since
2006.

Overall, these results provide mixed support for the EMH because several studies indicate
that insiders experience abnormal profits, while subsequent studies pre-2006 indicate it is no
longer possible for noninsiders to use this information to generate excess returns. Notably, be-
cause of investor interest in these insider trading data as a result of academic research, The
Wall Street Journal currently publishes a monthly column entitled “Inside Track” that dis-
cusses the largest insider transactions.

**Security Analysts** Several tests have considered whether it is possible to identify a set of ana-
lysts who have the ability to select undervalued stocks. The analysis involves determining
whether, after a stock recommendation by an analyst is made known, a significant abnormal
return is available to those who follow these recommendations. These studies and those that
discuss performance by money managers are more realistic and relevant than those that con-
sider corporate insiders because these analysts and money managers are full-time investment
professionals with no obvious advantage except emphasis and training. If anyone should be
able to select undervalued stocks, it should be these “pros.” We initially examine Value Line
rankings and then analyze the usefulness of recommendations by individual analysts.

**The Value Line Enigma** Value Line (VL) is a large well-known advisory service that publishes
financial information on approximately 1,700 stocks. Included in its report is a timing rank,
which indicates Value Line’s expectation regarding a firm’s common stock performance over
the coming 12 months. A rank of 1 is the most favorable performance metric and 5 is the worst. This ranking system, initiated in April 1965, assigns numbers based on four factors:

1. An earnings and price rank of each security relative to all others
2. A price momentum factor
3. Year-to-year relative changes in quarterly earnings
4. A quarterly earnings “surprise” factor (actual quarterly earnings compared with VL estimated earnings)

The firms are ranked based on a composite score for each firm. The top and bottom 100 are ranked 1 and 5, respectively; the next 300 from the top and bottom are ranked 2 and 4; and the rest (approximately 900) are ranked 3. Rankings are assigned every week based on the latest data. Notably, all the data used to derive the four factors are public information.

Several years after the ranking was started, Value Line contended that the stocks rated 1 substantially outperformed the market and the stocks rated 5 seriously underperformed the market (the performance figures did not include dividend income but also did not charge commissions).

Early studies on the Value Line enigma indicated that there was information in the VL rankings (especially either rank 1 or 5) and in changes in the rankings (especially going from 2 to 1). Recent evidence indicates that the market is fairly efficient, because the abnormal adjustments appear to be complete by Day + 2. An analysis of study results over time likewise indicates a faster adjustment to the rankings during recent years. Also, despite statistically significant price changes, some evidence indicates that it is not possible to derive abnormal returns from these announcements after considering pre-2006 transaction costs. As before, it would be informative to reconsider those results with current transaction costs. The strongest evidence regarding not being able to use this information is that Value Line’s Centurion Fund, which concentrates on investing in rank-1 stocks, has typically underperformed the market.

Analysts’ Recommendations There is evidence in favor of the existence of superior analysts who apparently possess private information. A study by Womack (1996) found that analysts appear to have both market timing and stock-picking ability, especially in connection with relatively rare sell recommendations. Jegadeesh et al. (2004) found that consensus recommendations do not contain incremental information for most stocks beyond other available signals (momentum and volume), but changes in consensus recommendations are useful. Alternatively, research by Ivkovic and Jegadeesh (2004) indicated that the most useful information consisted of upward earning revisions in the week prior to earnings announcements. A recent study by Goff, Hultab, Kessler, and Walsh (2008) examined the information content of analyst recommendations after the passage of Regulation Fair Disclosure (REGFD) and concluded that recommendation changes continue to be informative.

Performance of Professional Money Managers The studies of professional money managers are more realistic and widely applicable than the analysis of insiders because money managers typically do not have monopolistic access to important new information but are highly trained professionals who work full time at investment management. Therefore, if any “normal” set of investors should be able to derive above-average profits, it should be this group. Also, if any nonsider should be able to derive inside information, professional money managers should, because they conduct extensive management interviews and they may have the benefit of input from some superior analysts noted above.

Most studies on the performance of money managers have examined mutual funds because performance data are readily available for them. Recently, data have become available for bank trust departments, insurance companies, and investment advisers. The original mutual fund studies indicated that most funds did not match the performance of a buy-and-hold policy. These studies and others on this topic are reviewed in Chapter 24.
When risk-adjusted returns were examined without considering commission costs, slightly more than half of the money managers did better than the overall market. When commission costs, load fees, and management costs were considered, approximately two-thirds of the mutual funds did not match aggregate market performance. It was also found that successful funds during individual years were inconsistent in their performance over time.

Now that it is possible to get performance data for pension plans and endowment funds, several studies have documented that the performances of pension plans likewise did not match that of the aggregate market. The performance by endowments is interesting. Specifically, the results for a large sample of endowments confirm the inability to outperform the market. In contrast, the largest endowments in terms of size experienced superior risk-adjusted performance because of their ability and willingness to consider a wide variety of asset classes such as venture capital, unique hedge funds, real estate, and commodities on a global basis.

The figures in Exhibit 6.3 provide a rough demonstration of rate of return results for recent periods. These data are collected by Mellon Performance and Risk Analytics as part of its performance evaluation service. Exhibit 6.3 contains the median rates of return for several investment groups compared to a set of Russell indexes, including the very broad Russell 3000 index. While it is difficult to do a specific comparison between “universes” and the benchmarks, the overall results seem to

*The results for these individual accounts have an upward bias because they consider only accounts retained (e.g., if a firm or bank does a poor job on an account and the client leaves, those results would not be included).*
While it is still being debated whether there is a unified theory of behavioral finance, the emphasis has been twofold. First, on identifying portfolio anomalies that can be explained by various psychological traits in individuals and, second, identifying groups or pinpointing instances when it is possible to experience above-normal rates of return by exploiting the biases of investors, analysts, or portfolio managers.

6.4.1 Explaining Biases

Over time it has been noted that investors have a number of biases that negatively affect their investment performance. Advocates of behavioral finance have been able to explain a number of these biases based on psychological characteristics. One major bias documented by Scott, Stumpp, and Xu (1999) is the propensity of investors to hold on to "losers" too long and sell "winners" too soon. Apparently, investors fear losses much more than they value gains—a tendency toward loss aversion. This aversion is explained by prospect theory, which contends that utility depends on deviations from moving reference points rather than absolute wealth.

There are two related biases that seriously impact analysis and investment decisions. The first is belief perseverance, which means that once people have formed an opinion (on a company or stock) they cling to it too tightly and for too long. As a result, they are reluctant to search for contradictory beliefs, and even when they find such evidence, they are very skeptical about it or even misinterpret such information. A related bias is anchoring, wherein individuals who are asked to estimate something, start with an initial arbitrary (casual) value and then adjust away from it. The problem is that the adjustment is often insufficient. Therefore, if your initial estimate is low, you may raise it with information, but it is likely you will not raise it enough and thus will still end up below the "best estimates."

Another bias documented by Solt and Statman (1989) and Shefrin and Statman (1996) for growth companies is overconfidence in forecasts, which causes analysts to overestimate the rates of growth and its duration for growth companies and overemphasize good news and ignore negative news for these firms. Analysts and many investors also suffer from representativeness, which causes them to believe that the stocks of growth companies will be "good" stocks. This bias is also referred to as confirmation bias, whereby investors look for information that supports prior opinions and decisions they have made. They also experience sample size neglect wherein they are prone to extrapolate the high growth results from a few past years (e.g., 4–6 years) for long-term periods. As a result, they will misvalue the stocks of these generally popular companies. Overconfidence is also related to self-attribution bias where people have a tendency to ascribe any success to their own talents while blaming any failure on "bad luck," which causes them to overestimate their talent (Gervais and Odean, 2001). Overconfidence is also nurtured by hindsight bias, which is a tendency after an event for an individual to believe that he or she predicted it, which causes people to think that they can predict better than they can.

A study by Brown (1999) examined the effect of noise traders (nonprofessionals with no special information) on the volatility of closed-end mutual funds. When there is a shift in sentiment, these traders move together, which increases the prices and the volatility of these securities during trading hours. Also, Clarke and Statman (1998) find that noise traders tend to follow newsletter writers, who in turn tend to "follow the herd." These writers and "the herd" are almost always wrong, which contributes to excess volatility.

Shefrin (2001) describes escalation bias, which causes investors to put more money into a failure that they feel responsible for rather than into a success. This leads to the relatively popular investor practice of "averaging down" on an investment that has declined in value since the initial purchase rather than consider selling the stock if it was a mistake. The thinking is that if it was a buy at $40, it is a screaming bargain at $30. Obviously, an alternative solution is to reevaluate the stock to see if some important bad news was missed in the initial valuation.

6.4 Behavioral Finance

Our discussion up to this point has dealt with standard finance theory and how to test within this theoretical context whether capital markets are informationally efficient. However, in the 1990s, a new branch of financial economics was added to the mix. Behavioral finance considers how various psychological traits affect how individuals or groups act as investors, analysts, and portfolio managers. As noted by Olsen (1998), behavioral finance advocates recognize that the standard finance model of rational behavior and profit maximization can be true within specific boundaries, but they assert that it is an incomplete model since it does not consider individual behavior. It is argued that some financial phenomena can be better explained using models where it is recognized that some investors are not fully rational or realize that it is not possible for arbitrageurs to offset all instances of mispricing (Barberis and Thaler, 2003). Specifically, according to Olsen (1998), behavioral finance

\[ \text{seeks to understand and predict systematic financial market implications of psychological decisions processes ... behavioral finance is focused on the implication of psychological and economic principles for the improvement of financial decision-making. (p. 11)} \]

In the preface for Wood (2010), the editor provides a helpful description of behavioral finance, alluding to a river with three tributaries that form the river of behavioral finance: (1) psychology that focuses on individual behavior, (2) social psychology, which is the study of how we behave and make decisions in the presence of others, and (3) neurofinance, which is the anatomy, mechanics, and functioning of the brain. It is contended that the goal of research in this area is to help us understand how and why we make choices.

\footnote{The discussion in this section was enhanced by two survey articles by Barberis and Thaler (2003) and by Hirschleifer (2001). Also by wonderful presentations at the CFA Research Foundation Workshop in Vancouver (May 2008), and finally a monograph from the Research Foundation of CFA Institute that contains a set of insightful articles edited by Arnold S. Wood (2010), entitled Behavioral Finance and Investment Management.}
While it is still being debated whether there is a unified theory of behavioral finance, the emphasis has been twofold. First, on identifying portfolio anomalies that can be explained by various psychological traits in individuals and, second, identifying groups or pinpointing instances when it is possible to experience above-normal rates of return by exploiting the biases of investors, analysts, or portfolio managers.

There are two related biases that seriously impact analysis and investment decisions. The first is belief perseverance, which means that once people have formed an opinion (on a company or stock) they cling to it too tightly and for too long. As a result, they are reluctant to search for contradictory beliefs, and even when they find such evidence, they are very skeptical about it or even misinterpret such information. A related bias is anchoring, wherein individuals who are asked to estimate something, start with an initial arbitrary (casual) value and then adjust away from it. The problem is that the adjustment is often insufficient. Therefore, if your initial estimate is low, you may raise it with information, but it is likely you will not raise it enough and thus will still end up below the “best estimates.”

Another bias documented by Solt and Statman (1989) and Shefrin and Statman (1996) for growth companies is overconfidence in forecasts, which causes analysts to overestimate the rates of growth and its duration for growth companies and overemphasize good news and ignore negative news for these firms. Analysts and many investors also suffer from representativeness, which causes them to believe that the stocks of growth companies will be “good” stocks. This bias is also referred to as confirmation bias, whereby investors look for information that supports prior opinions and decisions they have made. They also experience sample size neglect wherein they are prone to extrapolate the high growth results from a few past years (e.g., 4–6 years) for long-term periods. As a result, they will misvalue the stocks of these generally popular companies. Overconfidence is also related to self-attribution bias where people have a tendency to ascribe any success to their own talents while blaming any failure on “bad luck,” which causes them to overestimate their talent (Gervais and Odean, 2001). Overconfidence is also nurtured by hindsight bias, which is a tendency after an event for an individual to believe that he or she predicted it, which causes people to think that they can predict better than they can.

A study by Brown (1999) examined the effect of noise traders (nonprofessionals with no special information) on the volatility of closed-end mutual funds. When there is a shift in sentiment, these traders move together, which increases the prices and the volatility of these securities during trading hours. Also, Clarke and Statman (1998) find that noise traders tend to follow newsletter writers, who in turn tend to “follow the herd.” These writers and “the herd” are almost always wrong, which contributes to excess volatility.

Shefrin (2001) describes escalation bias, which causes investors to put more money into a failure that they feel responsible for rather than into a success. This leads to the relatively popular investor practice of “averaging down” on an investment that has declined in value since the initial purchase rather than consider selling the stock if it was a mistake. The thinking is that if it was a buy at $40, it is a screaming bargain at $30. Obviously, an alternative solution is to reevaluate the stock to see if some important bad news was missed in the initial valuation.
analyze information and act immediately. This process takes time. Therefore, they hypothesize that stock prices move to a new equilibrium after the release of new information in a gradual manner, which causes trends in stock price movements that persist.

Technical analysts believe that nimble traders can develop systems to detect the beginning of a movement to a new equilibrium (called a "breakout"). Hence, they hope to buy or sell the stock immediately after its breakout to take advantage of the subsequent, gradual price adjustment. The belief in this pattern of price adjustment directly contradicts advocates of the EMH who believe that security prices adjust to new information very rapidly. These EMH advocates do not contend, however, that prices adjust perfectly, which implies a chance of overadjustment or underadjustment. Still, because it is uncertain whether the market will over- or under-adjust at any time, you cannot derive abnormal profits from adjustment errors.

If the capital market is weak-form efficient as indicated by most of the results, then prices fully reflect all relevant market information so technical trading systems that depend only on past trading data cannot have any value. By the time the information is public, the price adjustment has taken place. Therefore, a purchase or sale using a technical trading rule should not generate abnormal returns after taking account of risk and transaction costs. Still, recall the discussion in Chapter 4 regarding the dramatic decline in transaction costs due to the increase in trade volume and the significant new technology. Given this new environment, it is important to acknowledge that prior results that depended heavily on high transaction costs need to be reconsidered.

6.5 Efficient Markets and Fundamental Analysis

As you know from our prior discussion, fundamental analysts believe that, at any time, there is a basic intrinsic value for the aggregate stock market, various industries, or individual securities and that these values depend on underlying economic factors. Therefore, investors should determine the intrinsic value of an investment asset at a point in time by examining the variables that determine value such as future earnings or cash flows, interest rates, and risk variables. If the prevailing market price differs from the estimated intrinsic value by enough to cover transaction costs, you should take appropriate action: You buy if the market price is substantially below intrinsic value and do not buy, or you sell, if the market price is above the intrinsic value. Investors who are engaged in fundamental analysis believe that, occasionally, market price and intrinsic value differ but eventually investors recognize the discrepancy and correct it. An investor who can do a superior job of estimating intrinsic value can consistently make superior market timing (asset allocation) decisions or acquire undervalued securities and generate above-average returns. Fundamental analysis involves aggregate market analysis, industry analysis, company analysis, and portfolio management. The divergent results from the EMH research have important implications for all of these components.

Aggregate Market Analysis with Efficient Capital Markets

Chapter 11 makes a strong case that intrinsic value analysis should begin with aggregate market analysis. Still, the EMH implies that if you examine only past economic events, it is unlikely that you will outperform a buy-and-hold policy because the market rapidly adjusts to known economic events. Evidence suggests that the market experiences long-run price movements; but, to take advantage of these movements in an efficient market, you must do a superior job of estimating the relevant variables that cause these long-run movements. Put another way, if you only use historical data to estimate future values and invest on the basis of these "old news" estimates, you will not experience superior, risk-adjusted returns.

Industry and Company Analysis with Efficient Capital Markets

As we discuss in Chapter 13, the wide distribution of returns from different industries and from different companies in an industry clearly justifies industry and company analysis. Again, the EMH implies that if you examine only past economic events, it is unlikely that you will outperform a buy-and-hold policy because the market rapidly adjusts to known economic events. Evidence suggests that the market experiences long-run price movements; but, to take advantage of these movements in an efficient market, you must do a superior job of estimating the relevant variables that cause these long-run movements. Put another way, if you only use historical data to estimate future values and invest on the basis of these "old news" estimates, you will not experience superior, risk-adjusted returns.

6.5 Implications of Efficient Capital Markets

Having reviewed the results of numerous studies related to different facets of the EMH, the important question is: What does this mean to individual investors, financial analysts, portfolio managers, and institutions? Overall, the results of many studies indicate that the capital markets are efficient as related to numerous sets of information. At the same time, research has uncovered a substantial number of instances where the market fails to adjust prices rapidly to public information. Given these mixed results regarding the existence of efficient capital markets, it is important to consider the implications of this contrasting evidence of market efficiency.

The following discussion considers the implications of both sets of evidence. Specifically given results that support the EMH, we consider what techniques will not work and what you should do if you cannot beat the market. In contrast, because of the evidence that fails to support the EMH, we discuss what information and psychological biases should be considered when attempting to derive superior investment results through active security valuation and portfolio management.

6.5.1 Efficient Markets and Technical Analysis

The assumptions of technical analysis directly oppose the notion of efficient markets. A basic premise of technical analysis is that stock prices move in trends that persist. Techniques believe that when new information comes to the market, it is not immediately available to everyone but is typically disseminated from the informed professional to the aggressive investor public and then to the great bulk of investors. Also, technicians contend that investors do not

analyze information and act immediately. This process takes time. Therefore, they hypothesize that stock prices move to a new equilibrium after the release of new information in a gradual manner, which causes trends in stock price movements that persist.

Technical analysts believe that nimble traders can develop systems to detect the beginning of a movement to a new equilibrium (called a “breakout”). Hence, they hope to buy or sell the stock immediately after its breakout to take advantage of the subsequent, gradual price adjustment.

The belief in this pattern of price adjustment directly contradicts advocates of the EMH who believe that security prices adjust to new information very rapidly. These EMH advocates do not contend, however, that prices adjust perfectly, which implies a chance of overadjustment or underadjustment. Still, because it is uncertain whether the market will over- or under-adjust at any time, you cannot derive abnormal profits from adjustment errors.

If the capital market is weak-form efficient as indicated by most of the results, then prices fully reflect all relevant market information so technical trading systems that depend only on past trading data cannot have any value. By the time the information is public, the price adjustment has taken place. Therefore, a purchase or sale using a technical trading rule should not generate abnormal returns after taking account of risk and transaction costs. Still, recall the discussion in Chapter 4 regarding the dramatic decline in transaction costs due to the increase in trade volume and the significant new technology. Given this new environment, it is important to acknowledge that prior results that depended heavily on high transaction costs need to be reconsidered.

### 6.5.2 Efficient Markets and Fundamental Analysis

As you know from our prior discussion, fundamental analysts believe that, at any time, there is a basic intrinsic value for the aggregate stock market, various industries, or individual securities and that these values depend on underlying economic factors. Therefore, investors should determine the intrinsic value of an investment asset at a point in time by examining the variables that determine value such as future earnings or cash flows, interest rates, and risk variables. If the prevailing market price differs from the estimated intrinsic value by enough to cover transaction costs, you should take appropriate action: You buy if the market price is substantially below intrinsic value and do not buy, or you sell, if the market price is above the intrinsic value. Investors who are engaged in fundamental analysis believe that, occasionally, market price and intrinsic value differ but eventually investors recognize the discrepancy and correct it.

An investor who can do a superior job of estimating intrinsic value can consistently make superior market timing (asset allocation) decisions or acquire undervalued securities and generate above-average returns. Fundamental analysis involves aggregate market analysis, industry analysis, company analysis, and portfolio management. The divergent results from the EMH research have important implications for all of these components.

**Aggregate Market Analysis with Efficient Capital Markets** Chapter 11 makes a strong case that intrinsic value analysis should begin with aggregate market analysis. Still, the EMH implies that if you examine only past economic events, it is unlikely that you will outperform a buy-and-hold policy because the market rapidly adjusts to known economic events. Evidence suggests that the market experiences long-run price movements, but, to take advantage of these movements in an efficient market, you must do a superior job of estimating the relevant variables that cause these long-run movements. Put another way, if you only use historical data to estimate future values and invest on the basis of these “old news” estimates, you will not experience superior, risk-adjusted returns.

**Industry and Company Analysis with Efficient Capital Markets** As we discuss in Chapter 13, the wide distribution of returns from different industries and from different companies in an industry clearly justifies industry and company analysis. Again, the EMH
Conclusions about Fundamental Analysis

A text on investments can indicate the relevant variables that you should analyze and describe the important analysis techniques, but actually estimating the relevant variables is as much an art and a product of hard work as it is a science. If the estimates could be done on the basis of some mechanical formula, you could program a computer to do it, and there would be no need for analysts. Therefore, the superior analyst or successful investor must understand what variables are relevant to the valuation process and have the ability and work ethic to do a superior job of estimating values for these important valuation variables. There is no magic formula for superior estimation. Many times it simply means digging deeper and wider in your analysis to derive a better understanding of the economy, the industry and the firm. Alternatively, one can be superior if he or she has the ability to interpret the impact or estimate the effect of some public information better than others due to this better understanding.

6.5.3 Efficient Markets and Portfolio Management

As noted, studies have indicated that the majority of professional money managers cannot beat a buy-and-hold policy on a risk-adjusted basis. One explanation for this generally inferior performance is that there are no superior analysts and the cost of research and trading forces the results of merely adequate analysis into the inferior category. Another explanation, which is favored by the authors and has some empirical support from the Value Line and analyst recommendation results, is that money management firms employ both superior and inferior analysts and the gains from the recommendations by the few superior analysts are offset by the costs and the poor results derived from the recommendations of the inferior analysts. This raises the question: Should a portfolio be managed actively or passively? The following discussion indicates that the decision of how to manage the portfolio (actively or passively) depends on whether the manager (or an investor) has access to superior analysts. A portfolio manager with superior analysts or an investor who believes that he or she has the time and expertise to be a superior investor can manage a portfolio actively by looking for undervalued or overvalued securities and trading accordingly. In contrast, without access to superior analysts or the time and ability to be a superior investor, you should manage passively and assume that all securities are properly priced based on their levels of risk.

Portfolio Management with Superior Analysts

A portfolio manager with access to superior analysts who have unique insights and analytical ability should follow their recommendations. The superior analysts should make investment recommendations for a certain proportion of the portfolio, and the portfolio manager should ensure that the risk preferences of the client are maintained. Also, the superior analysts should be encouraged to concentrate their efforts in mid-cap and small-cap stocks that possess the liquidity required by institutional portfolio managers. But because these stocks typically do not receive the attention given the top-tier stocks, the markets for these neglected stocks may be less efficient than the market for large well-known stocks that are being analyzed by numerous analysts.

Recall that capital markets are expected to be efficient because many investors receive new information and analyze its effect on security values. If the number of analysts following a stock differ, one could conceive of differences in the efficiency of the markets. New information on top-tier stocks is well publicized and rigorously analyzed so the price of these securities should adjust rapidly to reflect the new information. In contrast, mid-cap and small-cap stocks receive less publicity and fewer analysts follow these firms, so prices may differ from intrinsic value for one of two reasons. First, because of less publicity, there is less information available on these firms. Second, there are fewer analysts following these firms so the adjustment to the new information is slowed. Therefore, the possibility of finding temporarily undervalued securities among these neglected stocks is greater. Again, in line with the cross-section study does not contradict the potential value of such analysis but implies that you need to (1) understand the relevant variables that affect rates of return, and (2) do a superior job of estimating future values for these relevant valuation variables. To demonstrate this, Malkiel and Cragg (1970) developed a model that did an excellent job of explaining past stock price movements using historical data. When this valuation model was employed to project future stock price changes using past company data, however, the results were consistently inferior to a buy-and-hold policy. This implies that, even with a good valuation model, you cannot select stocks that will provide superior future returns using only past data as inputs. The point is, most analysts are aware of the several well-specified valuation models, so the factor that differentiates superior from inferior analysts is the ability to provide more accurate estimates of the critical inputs to the valuation models and be different from the consensus.

A study by Benes and Peterson (1986) showed that the crucial difference between the stocks that enjoyed the best and worst price performance during a given year was the relationship between expected earnings of professional analysts and actual earnings (that is, it was earnings surprises). Specifically, stock prices increased if actual earnings substantially exceeded expected earnings and stock prices fell if actual earnings were below expected levels. As suggested by Fogler (1993), if you can do a superior job of projecting earnings and your expectations differ from the consensus (i.e., you project earnings surprises), you will have a superior stock selection record. To summarize this discussion, there are two factors that are required to be a superior analyst: (1) you must be correct in your estimates, and (2) you must be different from the consensus. Remember, if you are only correct and not different, that assumes you were predicting the consensus and the consensus was correct, which implies no surprise and no abnormal price movement.

The quest to be a superior analyst holds some good news and some suggestions. The good news is related to the strong-form tests that indicated the likely existence of superior analysts. It was shown that the rankings by Value Line contained information value, even though it might not be possible to profit from the work of these analysts after transaction costs. Also, the price adjustments to the publication of analyst recommendations also point to the existence of superior analysts. The point is, there are some superior analysts, but only a limited number, and it is not an easy task to be among this select group. Most notably, to be a superior analyst you must do a superior job of estimating the relevant valuation variables and predicting earnings surprises, which implies that you differ from the consensus, then you should consistently identify undervalued or overvalued securities.

The suggestions for those involved in fundamental analysis are based on the studies that considered the cross section of future returns. As noted, these studies indicated that P/E ratios, size, and the BV/MV ratios were able to differentiate future return patterns with size and the BV/MV ratio appearing to be the optimal combination. Therefore, these factors should be considered when selecting a universe or analyzing firms. In addition, the evidence suggests that neglected firms should be given extra consideration. Although these ratios and characteristics have been shown to be useful in isolating superior stocks from a large sample, it is our suggestion that they are best used to derive a viable sample to analyze from the total universe (e.g., select 200 stocks to analyze from a universe of 3,000). Then the 200 stocks should be rigorously valued using the techniques discussed in subsequent chapters.

How to Evaluate Analysts or Investors If you want to determine if an individual is a superior analyst or investor, you should examine the performance of numerous securities that this analyst or investor recommends over time in relation to the performance of a set of randomly selected stocks of the same risk class. The stock selections of a superior analyst or investor should consistently outperform the randomly selected stocks. The consistency requirement is crucial because you would expect a portfolio developed by random selection to outperform the market about half the time.
Conclusions about Fundamental Analysis A text on investments can indicate the relevant variables that you should analyze and describe the important analysis techniques, but actually estimating the relevant variables is as much an art and a product of hard work as it is a science. If the estimates could be done on the basis of some mechanical formula, you could program a computer to do it, and there would be no need for analysts. Therefore, the possibility of finding temporarily undervalued securities among these neglected stocks is greater. Again, in line with the cross-section study
results, these superior analysts should pay particular attention to the BV/MV ratio, to the size of stocks being analyzed, and to the monetary policy environment.

**Portfolio Management without Superior Analysts** A portfolio manager (or investor) who does not have access to superior analysts should proceed as follows. First, he or she should measure the risk preferences of his or her clients, then build a portfolio to match this risk level by investing a certain proportion of the portfolio in risky assets and the rest in a risk-free asset, as discussed in Chapter 8.

The risky asset portfolio must be completely diversified on a global basis so it moves consistently with the world market. In this context, proper diversification means eliminating all unsystematic (unique) variability. In our prior discussion, it was estimated that it required about 20 securities to gain most of the benefits (more than 90 percent) of a completely diversified portfolio. More than 100 stocks are required for complete diversification. To decide how many securities to actually include in your global portfolio, you must balance the added benefits of complete worldwide diversification against the costs of research for the additional stocks.

Finally, you should minimize transaction costs. Assuming that the portfolio is completely diversified and is structured for the desired risk level, excessive transaction costs that do not generate added returns will detract from your expected rate of return. Three factors are involved in minimizing total transaction costs:

1. **Minimize taxes.** Methods of accomplishing this objective vary, but it should receive prime consideration.
2. **Reduce trading turnover.** Trade only to sell overvalued stock out of the portfolio or add undervalued stock while maintaining a given risk level.
3. **When you trade, minimize liquidity costs by trading relatively liquid stocks.** To accomplish this, submit limit orders to buy or sell several stocks at prices that approximate the market-makers quote. That is, you would put in limit orders to buy stock at the bid price or sell at the ask price. The stock bought or sold first is the most liquid one; all other orders should be withdrawn.

In summary, if you lack access to superior analysts, you should do the following:

1. Determine and quantify your risk preferences.
2. Construct the appropriate risk portfolio by dividing the total portfolio between risk-free assets and a risky asset portfolio.
3. Diversify completely on a global basis to eliminate all unsystematic risk.
4. Maintain the specified risk level by rebalancing when necessary.
5. Minimize total transaction costs.

**The Rationale and Use of Index Funds and Exchange-Traded Funds** As discussed, efficient capital markets and a lack of superior analysts imply that many portfolios should be managed passively to match the performance of the aggregate market, minimizing the costs of research and trading. In response to this demand, several institutions have introduced index funds, which are security portfolios designed to duplicate the composition, and performance, of a selected market index series.

Notably, this concept of stock-market index funds has been extended to other areas of investments and, as discussed by Gastineau (2001) and Kostovetsky (2003), has been enhanced by the introduction of exchange-traded funds (ETFs). Index bond funds attempt to emulate the bond-market indexes discussed in Chapter 5. Also, some index funds focus on specific segments of the market such as international bond-index funds, international stock-index funds that target specific countries, and index funds that target small-cap stocks in the United States and Japan. When financial planners want a given asset class in their portfolios, they often use
During the past decade, there has been significant research in behavioral finance by investigators who contend that the standard finance theory model is incomplete since it does not consider implications of psychological decisions made by individuals that help explain many anomalies, identify the existence of several biases, and provide opportunities for excess returns. It is important to be aware of a number of biases for two reasons: first, they can lead to inferior performance as an analyst and portfolio manager; second, it is possible to exploit them for excess returns.

Given the mixed results from the numerous studies discussed in this chapter, it is important to consider the implications of all of this for technical or fundamental analysts and for portfolio managers. The EMH indicates that technical analysis should be of no value. All forms of fundamental analysis are useful, but they are difficult to implement because they require the ability to estimate future values for relevant economic variables. Superior analysis is possible but difficult because it requires superior projections that differ from the consensus. Those who manage portfolios should constantly evaluate investment advice to determine whether it is superior.

Without access to superior analytical advice, you should run your portfolio like an index fund or an ETF. In contrast, those with superior analytical ability should be allowed to make decisions, but they should concentrate their efforts on mid-cap firms and neglected firms where there is a higher probability of discovering misvalued stocks. The analysis should be particularly concerned with a firm’s BV/MV ratio, its size, and the monetary environment.

This chapter contains some good news and some bad news. The good news is that the practice of investment analysis and portfolio management is not an art that has been lost to the great computer in the sky. Viable professions still await those willing to extend the effort and able to accept the pressures. The bad news is that many bright, hardworking people with extensive resources make the game tough. In fact, those competitors have created a fairly efficient capital market in which it is extremely difficult for most analysts and portfolio managers to consistently achieve superior results.

**SUMMARY**

- The efficiency of capital markets has implications for the investment analysis and management of your portfolio. Capital markets should be efficient because numerous rational, profit-maximizing investors react quickly to the release of new information. Assuming prices reflect new information, they are unbiased estimates of the securities’ true, intrinsic value, and there should be a consistent relationship between the return on an investment and its risk.
- The voluminous research on the EMH has been divided into three segments that have been tested separately. The weak-form EMH states that stock prices fully reflect all market information, so any trading rule that uses past market data to predict future returns should have no value. The results of most studies supported this hypothesis.
- The semistrong-form EMH asserts that security prices adjust rapidly to the release of all public information. The tests of this hypothesis either examine the opportunities to predict future rates of return (either a time series or a cross section) or they involve event studies in which investigators analyzed whether investors could derive above-average returns from trading on the basis of public information. The test results for this hypothesis were clearly mixed. On the one hand, the results for almost all the event studies related to economic events such as stock splits, initial public offerings, and accounting changes consistently supported the semistrong hypothesis. In contrast, several studies that examined the ability to predict rates of return on the basis of unexpected quarterly earnings, P/E ratios, size, neglected stocks, and the BV/MV ratio, as well as several calendar effects, generally did not support the hypothesis.
- The strong-form EMH states that security prices reflect all information. This implies that nobody has private information, so no group should be able to derive above-average returns consistently. Studies that examined the results for corporate insiders did not support the strong-form hypothesis. An analysis of individual analysts as represented by Value Line or by recommendations published in *The Wall Street Journal* give mixed results. The results indicated that the Value Line rankings have significant information but it may not be possible to profit from it, whereas the recommendations by analysts indicated the existence of private information. In contrast, the performance by professional money managers supported the EMH because their risk-adjusted investment performance (whether mutual funds or pension funds) was typically inferior to results achieved with buy-and-hold policies.

QUESTIONS

1. Discuss the rationale for expecting an efficient capital market. What factor would you look for to differentiate the market efficiency for two alternative stocks?
2. Define and discuss the weak-form EMH. Describe the two sets of tests used to examine the weak-form EMH.
3. Define and discuss the semistrong-form EMH. Describe the two sets of tests used to examine the semistrong-form EMH.
4. What is meant by the term abnormal rate of return?
5. Describe how you would compute the abnormal rate of return for a stock for a period surrounding an economic event. Give a brief example for a stock with a beta of 1.40.
6. Assume you want to test the EMH by comparing alternative trading rules to a buy-and-hold policy. Discuss the three common mistakes that can bias the results against the EMH.
7. Describe the results of a study that supported the semistrong-form EMH. Discuss the nature of the test and specifically why the results support the hypothesis.
8. Describe the results of a study that did not support the semistrong-form EMH. Discuss the nature of the test and specifically why the results did not support the hypothesis.
9. For many of the EMH tests, it is really a test of a “joint hypothesis.” Discuss what is meant by this concept. What are the joint hypotheses being tested?
10. Define and discuss the strong-form EMH. Why do some observers contend that the strong-form hypothesis really requires a perfect market in addition to an efficient market? Be specific.
11. Discuss how you would test the strong-form EMH. Why are these tests relevant? Give a brief example.
12. Describe the results of a study that did not support the strong-form EMH. Discuss the test involved and specifically why the results reported did not support the hypothesis.
13. Describe the results of a study that did support the strong-form EMH. Discuss the test involved and specifically why these results support the hypothesis.

What would you recommend that he do to run his portfolio?
23. Tom Max, TMP’s quantitative analyst, has developed a portfolio construction model about which he is excited. To create the model, Max made a list of the stocks currently
in the S&P 500 Stock Index and obtained annual operating cash flow, price, and total return data for each issue for the past five years. As of each year-end, this universe was divided into five equal-weighted portfolios of 100 issues each, with selection based solely on the price/cash flow rankings of the individual stocks. Each portfolio's average annual return was then calculated.

During this five-year period, the linked returns from the portfolios with the lowest price/cash flow ratio generated an annualized total return of 19.0 percent, or 3.1 percentage points better than the 15.9 percent return on the S&P 500 Stock Index. Max also noted that the lowest price-cash-flow portfolio had a below-market beta of 0.91 over this same time span.

a. Briefly comment on Max's use of the beta measure as an indicator of portfolio risk in light of recent academic tests of its explanatory power with respect to stock returns.

24. a. Briefly explain the concept of the efficient market hypothesis (EMH) and each of its three forms—weak, semistrong, and strong—and briefly discuss the degree to which existing empirical evidence supports each of the three forms of the EMH.

b. Briefly discuss the implications of the efficient market hypothesis for investment policy as it applies to:
   (i) technical analysis in the form of charting, and
   (ii) fundamental analysis.

c. Briefly explain two major roles or responsibilities of portfolio managers in an efficient market environment.

**PROBLEMS**

1. Compute the abnormal rates of return for the following stocks during period \( t \) (ignore differential systematic risk):

<table>
<thead>
<tr>
<th>Stock</th>
<th>( R_{it} )</th>
<th>( R_{mt} )</th>
</tr>
</thead>
<tbody>
<tr>

<tr>
<td>C</td>
<td>12.0</td>
<td>15.3</td>
</tr>
<tr>
<td>E</td>
<td>15.9</td>
<td>12.4</td>
</tr>
</tbody>
</table>

\( R_{it} = \text{return for stock } i \text{ during period } t \)

\( R_{mt} = \text{return for the aggregate market during period } t \)

2. Compute the abnormal rates of return for the five stocks in Problem 1 assuming the following systematic risk measures (betas):

<table>
<thead>
<tr>
<th>Stock</th>
<th>( \beta_i )</th>
</tr>
</thead>
<tbody>
<tr>
<td>B</td>
<td>0.95</td>

</tbody>
</table>

3. Compare the abnormal returns in Problems 1 and 2 and discuss the reason for the difference in each case.
4. Look up the daily trading volume for the following stocks during a recent five-day period:
   - Merck
   - Caterpillar
   - Intel
   - McDonald's
   - General Electric

Randomly select five stocks from the NYSE, and examine their daily trading volume for the same five days.

a. What are the average volumes for the two samples?
b. Would you expect this difference to have an impact on the efficiency of the markets for the two samples? Why or why not?
CHAPTER 7
An Introduction to Portfolio Management

After you read this chapter, you should be able to answer the following questions:

- What do we mean by risk aversion, and what evidence indicates that investors are generally risk averse?
- What are the basic assumptions behind the Markowitz portfolio theory?
- What do we mean by risk, and what are some measures of risk used in investments?
- How do we compute the expected rate of return for a portfolio of assets?
- How do we compute the standard deviation of rates of return for an individual risky asset?
- What do we mean by the covariance between rates of return, and how is it computed?
- What is the relationship between covariance and correlation?
- What is the formula for the standard deviation for a portfolio of risky assets, and how does it differ from the standard deviation of an individual risky asset?
- Given the formula for the standard deviation of a portfolio, how do we diversify a portfolio?
- What happens to the portfolio standard deviation when the correlation between the assets changes?
- What is the risk-return efficient frontier of risky assets?
- Why do different investors select different portfolios from the set of portfolios on the efficient frontier?
- What determines which portfolio an investor selects on the efficient frontier?

One of the major advances in the investment field during the past few decades has been the recognition that you cannot create an optimum investment portfolio by simply combining numerous individual securities that have desirable risk-return characteristics. Specifically, it has been shown that an investor must consider the relationship among the investments to build an optimum portfolio that will meet investment objectives. The recognition of how to create an optimum portfolio was demonstrated in the derivation of portfolio theory.

In this chapter we explain portfolio theory in detail by introducing the basic portfolio risk formula for combining different assets. When you understand this formula and its implications, you will understand why and how you should diversify your portfolio.

7.1 SOME BACKGROUND ASSUMPTIONS
We begin by clarifying some general assumptions of portfolio theory. This includes not only what we mean by an optimum portfolio but also what we mean by the terms risk aversion and risk.

One basic assumption of portfolio theory is that investors want to maximize the returns from the total set of investments for a given level of risk. To understand such an assumption requires certain ground rules. First, your portfolio should include all of your assets and
liabilities, not only your marketable securities but also your car, house, and less marketable investments such as coins, stamps, art, antiques, and furniture. The full spectrum of investments must be considered because the returns from all these investments interact, and this relationship among the returns for assets in the portfolio is important. Hence, a good portfolio is not simply a collection of individually good investments.

### 7.1.1 Risk Aversion

Portfolio theory also assumes that investors are basically risk averse, meaning that, given a choice between two assets with equal rates of return, they will select the asset with the lower level of risk. Evidence that most investors are risk averse is that they purchase various types of insurance, including life insurance, car insurance, and health insurance. Buying insurance basically involves an outlay of a known dollar value to guard against an uncertain, possibly larger, outlay in the future. Further evidence of risk aversion is the difference in promised yield (the required rate of return) for different grades of bonds with different degrees of credit risk. Specifically, the promised yield on corporate bonds increases from AAA (the lowest risk class) to AA to A, and so on, indicating that investors require a higher rate of return to accept higher risk.

This does not imply that everybody is risk averse, or that investors are completely risk averse regarding all financial commitments. The fact is, not everybody buys insurance for everything. Some people have no insurance against anything, either by choice or because they cannot afford it. In addition, some individuals buy insurance related to some risks such as auto accidents or illness, but they also buy lottery tickets and gamble at race tracks or in casinos, where it is known that the expected returns are negative (which implies that participants are willing to pay for the excitement of the risk involved). This combination of risk preference and risk aversion can be explained by an attitude toward risk that depends on the amount of money involved. Researchers such as Friedman and Savage (1948) speculate that this is the case for people who like to gamble for small amounts (in lotteries or slot machines) but buy insurance to protect themselves against large losses such as fire or accidents.

While recognizing such attitudes, we assume that most investors with a large investment portfolio are risk averse. Therefore, we expect a positive relationship between expected return and expected risk, which is consistent with the historical results shown in Chapter 3.

### 7.1.2 Definition of Risk

Although there is a difference in the specific definitions of risk and uncertainty, for our purposes and in most financial literature the two terms are used interchangeably. For most investors, risk means the uncertainty of future outcomes. An alternative definition might be the probability of an adverse outcome. In our subsequent discussion of portfolio theory, we consider several measures of risk that are used when developing and applying the theory.

### 7.2 Markowitz Portfolio Theory

In the early 1960s, the investment community talked about risk, but there was no specific measure for the term. To build a portfolio model, however, investors had to quantify their risk variable. The basic portfolio model was developed by Harry Markowitz (1952, 1959), who derived the expected rate of return for a portfolio of assets and an expected risk measure. Markowitz showed that the variance of the rate of return was a meaningful measure of portfolio risk under a reasonable set of assumptions. More important, he derived the formula for computing the variance of a portfolio. This portfolio variance formula not only indicated the importance of diversifying investments to reduce the total risk of a portfolio but also showed
how to effectively diversify. The Markowitz model is based on several assumptions regarding investor behavior:

1. Investors consider each investment alternative as being represented by a probability distribution of expected returns over some holding period.
2. Investors maximize one-period expected utility, and their utility curves demonstrate diminishing marginal utility of wealth.
3. Investors estimate the risk of the portfolio on the basis of the variability of expected returns.
4. Investors base decisions solely on expected return and risk, so their utility curves are a function of expected return and the expected variance (or standard deviation) of returns only.
5. For a given risk level, investors prefer higher returns to lower returns. Similarly, for a given level of expected return, investors prefer less risk to more risk.

Under these assumptions, a single asset or portfolio of assets is considered to be efficient if no other asset or portfolio of assets offers higher expected return with the same (or lower) risk or lower risk with the same (or higher) expected return.

7.2.1 Alternative Measures of Risk

One of the best-known measures of risk is the variance, or standard deviation of expected returns. It is a statistical measure of the dispersion of returns around the expected value whereby a larger variance or standard deviation indicates greater dispersion. The idea is that the more dispersed the expected returns, the greater the uncertainty of future returns.

Another measure of risk is the range of returns. It is assumed that a larger range of expected returns, from the lowest to the highest, means greater uncertainty regarding future expected returns.

Instead of using measures that analyze all deviations from expectations, some observers believe that investors should be concerned only with returns below expectations, which means only deviations below the mean value. A measure that only considers deviations below the mean is the semivariance. An extension of the semivariance measure only computes expected returns below zero (that is, negative returns), or returns below the returns of some specific asset such as T-bills, the rate of inflation, or a benchmark. These measures of risk implicitly assume that investors want to minimize the damage (regret) from returns less than some target rate. Assuming that investors would welcome returns above some target rate, the returns above such a target rate are not considered when measuring risk.

Although there are numerous potential measures of risk, we will use the variance or standard deviation of returns because (1) this measure is somewhat intuitive, (2) it is a correct and widely recognized risk measure, and (3) it has been used in most of the theoretical asset pricing models.

7.2.2 Expected Rates of Return

We compute the expected rate of return for an individual investment as shown in Exhibit 7.1 and discussed in Chapter 1. The expected return for an individual risky asset with the set of potential returns and an assumption of the different probabilities used in the example would be 10.3 percent.

The expected rate of return for a portfolio of investments is simply the weighted average of the expected rates of return for the individual investments in the portfolio. The weights are the proportion of total value for the individual investment.

The expected rate of return for a hypothetical portfolio with four risky assets is shown in Exhibit 7.2. The expected return for this portfolio of investments would be 11.5 percent. The effect of adding or dropping any investment from the portfolio would be easy to determine; we

---

1We consider the variance and standard deviation as one measure of risk because the standard deviation is the square root of the variance.
The computation of the variance and standard deviation of returns for the individual risky asset in Exhibit 7.1 is set forth in Exhibit 7.3. Therefore, you would describe this asset as having an expected return of 10.3 percent and a standard deviation of 2.1237 percent.

### 7.2.4 Variance (Standard Deviation) of Returns for a Portfolio

Two basic concepts in statistics, covariance and correlation, must be understood before we discuss the formula for the variance of the rate of return for a portfolio.

#### Covariance of Returns

In this subsection we discuss what the covariance of returns is intended to measure, give the formula for computing it, and present an example of its computation.

**Covariance** is a measure of the degree to which two variables move together relative to their individual mean values over time. In portfolio analysis, we usually are concerned with the covariance of rates of return rather than prices or some other variable.

A positive covariance means that the rates of return for two investments tend to move in the same direction relative to their individual means during the same time period. In contrast, a negative covariance indicates that the rates of return for two investments tend to move in different directions relative to their means during specified time intervals over time. The magnitude of the covariance depends on the variances of the individual return series, as well as on the relationship between the series.

Exhibit 7.4 contains the monthly rates of return values for U.S. stocks (measured using the Dow Jones Total Stock Market index) and U.S. bonds (measured by the Barclays Capital Treasury Bond Index). Both indexes are total return indexes—that is, the stock index includes dividends paid and the bond index includes accrued interest, as discussed in Chapter 5. Using end-of-month values for each index, we compute the percentage change in the index each month, which equals its monthly rates of return during 2010. Exhibits 7.5 and 7.6 contain a time-series plot of these monthly rates of return. Although the rates of return for the two assets moved together during some months, in other months they moved in opposite directions. The covariance statistic provides an absolute measure of how they moved together over time.

For two assets, \( i \) and \( j \), we define the covariance of rates of return as:

\[
\text{Cov}_{ij} = \sum_{t=1}^{T} (R_{it} - \mu_{i}) (R_{jt} - \mu_{j}) P_{t}
\]

where:
- \( w_{i} \) = the weight of an individual asset in the portfolio, or the percent of the portfolio in Asset 1
- \( R_{i} \) = the expected rate of return for Asset 1

### 7.2.3 Variance (Standard Deviation) of Returns for an Individual Investment

As noted, we will be using the variance or the standard deviation of returns as the measure of risk. Therefore, at this point we demonstrate how to compute the standard deviation of returns for an individual investment. Subsequently, after discussing some other statistical concepts, we will consider the determination of the standard deviation for a portfolio of investments.

The variance, or standard deviation, is a measure of the variation of possible rates of return \( R_{i} \) from the expected rate of return \( E(R_{i}) \) as follows:

\[
\text{Variance} = \sigma^{2} = \sum_{i=1}^{n} [R_{i} - E(R_{i})]^{2} P_{i}
\]

where:
- \( P_{i} \) = probability of the possible rate of return \( R_{i} \)

\[
\text{Standard Deviation} = \sigma = \sqrt{\sum_{i=1}^{n} [R_{i} - E(R_{i})]^{2} P_{i}}
\]

Variance = \( \sigma^2 = 0.000451 \)

Standard Deviation = \( \sigma = 0.021237 = 2.1237\% \)

The computation of the variance and standard deviation of returns for the individual risky asset in Exhibit 7.1 is set forth in Exhibit 7.3.

Therefore, you would describe this asset as having an expected return of 10.3 percent and a standard deviation of 2.1237 percent.

### 7.2.4 Variance (Standard Deviation) of Returns for a Portfolio

Two basic concepts in statistics, covariance and correlation, must be understood before we discuss the formula for the variance of the rate of return for a portfolio.

**Covariance of Returns** In this subsection we discuss what the covariance of returns is intended to measure, give the formula for computing it, and present an example of its computation. **Covariance** is a measure of the degree to which two variables move together relative to their individual mean values over time. In portfolio analysis, we usually are concerned with the covariance of rates of return rather than prices or some other variable.\(^2\) A positive covariance means that the rates of return for two investments tend to move in the same direction relative to their individual means during the same time period. In contrast, a negative covariance indicates that the rates of return for two investments tend to move in different directions relative to their means during specified time intervals over time. The magnitude of the covariance depends on the variances of the individual return series, as well as on the relationship between the series.

Exhibit 7.4 contains the monthly rates of return values for U.S. stocks (measured using the Dow Jones Total Stock Market index) and U.S. bonds (measured by the Barclays Capital Treasury Bond Index). Both indexes are total return indexes—that is, the stock index includes dividends paid and the bond index includes accrued interest, as discussed in Chapter 5. Using end-of-month values for each index, we compute the percentage change in the index each month, which equals its monthly rates of return during 2010. Exhibits 7.5 and 7.6 contain a time-series plot of these monthly rates of return. Although the rates of return for the two assets moved together during some months, in other months they moved in opposite directions. The covariance statistic provides an *absolute* measure of how they moved together over time.

For two assets, \( i \) and \( j \), we define the covariance of rates of return as

\[
\text{Cov}_{ij} = E \left( (R_i - E(R_i)) (R_j - E(R_j)) \right)
\]

\(^2\)Returns, of course, can be measured in a variety of ways, depending on the type of asset. You will recall that we defined returns \( (R_i) \) in Chapter 1 as:

\[
R_i = \frac{EV - BV + CF}{BV}
\]

where \( EV \) is ending value, \( BV \) is beginning value, and \( CF \) is the cash flow during the period.
Note that when we apply formula 7.4 to actual sample data, we use the sample mean as an estimate of the expected return and divide the values by \((n-1)\) rather than by \(n\) to avoid statistical bias.

As can be seen, if the rates of return for one asset are above (below) its mean rate of return during a given period and the returns for the other asset are likewise above (below) its mean rate of return during this same period, then the product of these deviations from the mean is positive. If this happens consistently, the covariance of returns between these two assets will be some large positive value. If, however, the rate of return for one of the securities is above its mean return, while the return on the other security is below its mean return, the product will be negative. If this contrary movement happens consistently, the covariance between the rates of return for the two assets will be a large negative value.

Exhibit 7.7 includes the monthly rates of return during 2010 contained in Exhibit 7.4. One might expect returns for the two asset indexes to have reasonably low covariance because of the differences in the nature of these assets. The arithmetic means of the monthly returns were

\[
\bar{R}_i = \frac{1}{11} \sum_{t=1}^{12} R_{it}
\]

for stocks and

\[
\bar{R}_j = \frac{1}{11} \sum_{t=1}^{12} R_{jt}
\]

for bonds. We rounded all figures to the nearest hundredth of 1 percent, so there may be small rounding errors. The average monthly return was 1.32 percent for the Dow Jones Total Stock Market Index and 0.48 percent for the Barclays Capital Treasury bond index. The results in Exhibit 7.7 show that the covariance between the rates of return for these two assets was

\[
\text{Cov}_{ij} = \frac{1}{11} \sum_{t=1}^{12} [R_{it} - \bar{R}_i][R_{jt} - \bar{R}_j]
\]

When we apply this formula to the monthly rates of return for the Dow Jones Total Stock Market and the Treasury bond indexes during 2010, it becomes

\[
\frac{1}{11} \sum_{t=1}^{12} [R_{it} - \bar{R}_i][R_{jt} - \bar{R}_j]
\]

Exhibit 7.5 Time-Series Plot of the Monthly Returns for Dow Jones Total Stock Market Index, 2010
Interpretation of a number such as $-5.06$ is difficult; is it high or low for covariance? We know the relationship between the two assets is clearly negative, but it is not possible to be more specific.

Exhibit 7.8 contains a scatterplot with paired values of $R_i$ and $R_j$ plotted against each other. This plot demonstrates the linear nature and strength of the relationship. It is not surprising that the relationship during 2010 was a fairly strong negative value since during nine of the twelve months the two assets moved counter to each other as shown in Exhibit 7.7. As a result, the overall covariance was a definite negative value.

Covariance and Correlation

Covariance is affected by the variability of the two individual return indexes. Therefore, a number such as the $-5.06$ in our example might indicate a weak negative relationship if the two individual indexes were volatile, but would reflect a strong negative relationship if the two indexes were relatively stable. Obviously, we want to standardize this covariance measure. We do so by taking into consideration the variability of the two individual return indexes, as follows:

$$r_{ij} = \frac{\text{Cov}(R_i, R_j)}{\sigma_i \sigma_j}$$

where:

- $r_{ij}$ = the correlation coefficient of returns
- $\sigma_i$ = the standard deviation of $R_i$
- $\sigma_j$ = the standard deviation of $R_j$

Standardizing the covariance by the product of the individual standard deviations yields the correlation coefficient $r_{ij}$, which can vary only in the range $-1$ to $+1$. A value of $+1$ indicates a perfect positive linear relationship between $R_i$ and $R_j$, meaning the returns for the two assets move together in a completely linear manner. A value of $-1$ indicates a perfect negative relationship between the two return indexes, so that when one asset’s rate of return is above its mean, the other asset’s rate of return will be below its mean by a comparable amount.

Exhibit 7.6 Time-Series Plot of the Monthly Returns for Barclays Capital Treasury Bond Index, 2010

Note that when we apply formula 7.4 to actual sample data, we use the sample mean ($\bar{R}$) as an estimate of the expected return and divide the values by $(n - 1)$ rather than by $n$ to avoid statistical bias.

As can be seen, if the rates of return for one asset are above (below) its mean rate of return ($\bar{R}$) during a given period and the returns for the other asset are likewise above (below) its mean rate of return during this same period, then the product of these deviations from the mean is positive. If this happens consistently, the covariance of returns between these two assets will be some large positive value. If, however, the rate of return for one of the securities is above its mean return, while the return on the other security is below its mean return, the product will be negative. If this contrary movement happens consistently, the covariance between the rates of return for the two assets will be a large negative value.

Exhibit 7.7 includes the monthly rates of return during 2010 contained in Exhibit 7.4. One might expect returns for the two asset indexes to have reasonably low covariance because of the differences in the nature of these assets. The arithmetic means of the monthly returns were

$$(\bar{R}_i) = \frac{1}{11} \sum_{j=1}^{12} R_{ij} = 1.32 \text{ (stocks)}$$

and

$$(\bar{R}_j) = \frac{1}{11} \sum_{j=1}^{12} R_{jj} = 0.48 \text{ (bonds)}$$

We rounded all figures to the nearest hundredth of 1 percent, so there may be small rounding errors. The average monthly return was 1.32 percent for the Dow Jones Total Stock Market Index and 0.48 percent for the Barclays Capital Treasury bond index. The results in Exhibit 7.7 show that the covariance between the rates of return for these two assets was

$$\text{Cov}_{ij} = \frac{1}{11} \times -55.67 = -5.06$$
in Exhibit 7.7. We can square each of these values and sum them as shown in Exhibit 7.9 to calculate the variance of each return series; again, we divide by \( (n - 1) \) to avoid statistical bias.

\[
\sigma^2_i = \frac{\sum (R_i - \bar{R}_i)^2}{n - 1}
\]

and

\[
\sigma^2_j = \frac{\sum (R_j - \bar{R}_j)^2}{n - 1}
\]

\( \text{sum} = 340.11 \) \( \text{sum} = 16.29 \)

\( \sigma_i = \sqrt{\sigma^2_i} = 30.92 \)

\( \sigma_j = \sqrt{\sigma^2_j} = 1.48 \)

\( \text{sum} = 340.11 \) \( \text{sum} = 16.29 \)

\( \text{variance} = 340.11 \) \( \text{variance} = 16.29 \)

\( \text{Standard Deviation} = \sqrt{\text{variance}} \)

\( \sigma_i = 30.92 \)

\( \sigma_j = 1.48 \)

\( \text{Cov}_{ij} = -55.67 \)

Interpretation of a number such as \(-5.06\) is difficult; is it high or low for covariance? We know the relationship between the two assets is clearly negative, but it is not possible to be more specific. Exhibit 7.8 contains a scatterplot with paired values of \( R_i \) and \( R_j \) plotted against each other. This plot demonstrates the linear nature and strength of the relationship. It is not surprising that the relationship during 2010 was a fairly strong negative value since during nine of the twelve months the two assets moved counter to each other as shown in Exhibit 7.7. As a result, the overall covariance was a definite negative value.

**Covariance and Correlation** Covariance is affected by the variability of the two individual return indexes. Therefore, a number such as the \(-5.06\) in our example might indicate a weak negative relationship if the two individual indexes were volatile, but would reflect a strong negative relationship if the two indexes were relatively stable. Obviously, we want to standardize this covariance measure. We do so by taking into consideration the variability of the two individual return indexes, as follows:

\[
r_{ij} = \frac{\text{Cov}_{ij}}{\sigma_i \sigma_j}
\]

where:

\( r_{ij} \) = the correlation coefficient of returns

\( \sigma_i \) = the standard deviation of \( R_i \)

\( \sigma_j \) = the standard deviation of \( R_j \)

Standardizing the covariance by the product of the individual standard deviations yields the correlation coefficient \( r_{ij} \) which can vary only in the range \(-1\) to \(+1\). A value of \(+1\) indicates a perfect positive linear relationship between \( R_i \) and \( R_j \), meaning the returns for the two assets move together in a completely linear manner. A value of \(-1\) indicates a perfect negative relationship between the two return indexes, so that when one asset’s rate of return is above its mean, the other asset’s rate of return will be below its mean by a comparable amount.

To calculate this standardized measure of the relationship, we need to compute the standard deviation for the two individual return indexes. We already have the values for \( (R_i - \bar{R}_i) \) and \( (R_j - \bar{R}_j) \)
The standard deviation for each index is the square root of the variance for each, as follows:

$$\sigma_i = \sqrt{30.92}$$

$$\sigma_j = \sqrt{1.22}$$

As expected, the stock index series is more volatile than the Treasury bond series. Thus, based on the covariance between the two indexes and the individual standard deviations, we can calculate the correlation coefficient between returns for common stocks and Treasury bonds during 2010:

$$r_{ij} = \frac{\text{Cov}_{ij}}{\sigma_i \sigma_j} = \frac{-5.06}{5.56 \times 1.22} = -0.746$$

Obviously, this formula also implies that

$$\text{Cov}_{ij} = r_{ij} \sigma_i \sigma_j = \left(-0.746\right)\left(5.56\right)\left(1.22\right) = -5.06$$

As noted, a correlation of +1.0 indicates perfect positive correlation, and a value of -1.0 means that the returns moved in completely opposite directions. A value of zero means that the returns had no linear relationship, that is, they were uncorrelated statistically. That does not mean that they are independent. The value of

$$r_{ij} = -0.746$$

is significantly different from zero. This significant negative correlation is not unusual for stocks versus bonds during a short time period such as one year.

### 7.2.5 Standard Deviation of a Portfolio

**Portfolio Standard Deviation Formula**

Now that we have discussed the concepts of covariance and correlation, we can consider the formula for computing the standard deviation of returns for a portfolio of assets, our measure of risk for a portfolio. In Exhibit 7.2, we showed that the expected rate of return of the portfolio was the weighted average of the expected returns for the individual assets in the portfolio; the weights were the percentage of value of the portfolio. One might assume it is possible to derive the standard deviation of the portfolio in the same manner, that is, by computing the weighted average of the standard deviations for the individual assets. This would be a mistake. Markowitz (1959) derived the general formula for the standard deviation of a portfolio as follows:

$$\sigma_{\text{port}} = \sqrt{\sum \text{weight}^2 \sigma^2_i + \sum \text{weight}_i \text{weight}_j \text{Cov}_{ij}}$$

where

- $\sigma_{\text{port}}$ = the standard deviation of the portfolio
- $\text{weight}_i$ = the weights of an individual asset in the portfolio, where weights are determined by the proportion of value in the portfolio
- $\sigma^2_i$ = the variance of rates of return for asset $i$
- $\text{Cov}_{ij}$ = the covariance between the rates of return for assets $i$ and $j$, where $\text{Cov}_{ij} = r_{ij} \sigma_i \sigma_j$

This formula indicates that the standard deviation for a portfolio of assets is a function of the weighted average of the individual variances (where the weights are squared), plus the weighted covariances between all the assets in the portfolio. The very important point is that the standard deviation for a portfolio of assets encompasses not only the variances of the individual assets but also includes the covariances between all the pairs of individual assets in the portfolio. Further, it can be shown that, in a portfolio with a large number of securities, this formula reduces to the sum of the weighted covariances.

### Exhibit 7.8 Scatterplot of Monthly Returns for the Dow Jones Total Stock Market Index and the Barclays Capital Treasury Bond Index, 2010

In Exhibit 7.7, We can square each of these values and sum them as shown in Exhibit 7.9 to calculate the variance of each return series; again, we divide by $(n - 1)$ to avoid statistical bias.

$$\sigma_i^2 = \frac{1}{11}340.11 = 30.92$$

and

$$\sigma_j^2 = \frac{1}{11}16.29 = 1.48$$

**Variance:**

$\text{variance}_i = \frac{340.11}{11} = 30.92$

$\text{variance}_j = \frac{16.29}{11} = 1.48$

**Standard Deviation:**

$\text{Standard Deviation}_i = (30.92)^{1/2} = 5.56$

$\text{Standard Deviation}_j = (1.48)^{1/2} = 1.22$
The standard deviation for each index is the square root of the variance for each, as follows:

\[
\sigma_i = \sqrt{30.92} = 5.56 \\
\sigma_j = \sqrt{1.48} = 1.22
\]

As expected, the stock index series is more volatile than the Treasury bond series.

Thus, based on the covariance between the two indexes and the individual standard deviations, we can calculate the correlation coefficient between returns for common stocks and Treasury bonds during 2010:

\[
r_{ij} = \frac{\text{Cov}_{ij}}{\sigma_i \sigma_j} = \frac{-5.06}{(5.56)(1.22)} = \frac{-5.06}{6.78} = -0.746
\]

Obviously, this formula also implies that

\[
\text{Cov}_{ij} = r_{ij} \sigma_i \sigma_j = (-0.746)(5.56)(1.22) = -5.06
\]

As noted, a correlation of +1.0 indicates perfect positive correlation, and a value of -1.0 means that the returns moved in completely opposite directions. A value of zero means that the returns had no linear relationship, that is, they were uncorrelated statistically. That does not mean that they are independent. The value of $r_{ij} = -0.746$ is significantly different from zero. This significant negative correlation is not unusual for stocks versus bonds during a short time period such as one year.

### 7.2.5 Standard Deviation of a Portfolio

#### Portfolio Standard Deviation Formula

Now that we have discussed the concepts of covariance and correlation, we can consider the formula for computing the standard deviation of returns for a portfolio of assets, our measure of risk for a portfolio. In Exhibit 7.2, we showed that the expected rate of return of the portfolio was the weighted average of the expected returns for the individual assets in the portfolio; the weights were the percentage of value of the portfolio. One might assume it is possible to derive the standard deviation of the portfolio in the same manner, that is, by computing the weighted average of the standard deviations for the individual assets. This would be a mistake. Markowitz (1959) derived the general formula for the standard deviation of a portfolio as follows:

\[
\sigma_{\text{port}} = \sqrt{\sum_{i=1}^{n} w_i^2 \sigma_i^2 + \sum_{i=1}^{n} \sum_{j=i+1}^{n} w_i w_j \text{Cov}_{ij}}
\]

where

- $\sigma_{\text{port}}$ = the standard deviation of the portfolio
- $w_i$ = the weights of an individual asset in the portfolio, where weights are determined by the proportion of value in the portfolio
- $\sigma_i^2$ = the variance of rates of return for asset $i$
- $\text{Cov}_{ij}$ = the covariance between the rates of return for assets $i$ and $j$, where $\text{Cov}_{ij} = r_{ij} \sigma_i \sigma_j$

This formula indicates that the standard deviation for a portfolio of assets is a function of the weighted average of the individual variances (where the weights are squared), plus the weighted covariances between all the assets in the portfolio. The very important point is that the standard deviation for a portfolio of assets encompasses not only the variances of the individual assets but also includes the covariances between all the pairs of individual assets in the portfolio. Further, it can be shown that, in a portfolio with a large number of securities, this formula reduces to the sum of the weighted covariances.
**Impact of a New Security in a Portfolio** Although in most of the following discussion we will consider portfolios with only two assets (because it is possible to show the effect in two dimensions), we will also demonstrate the computations for a three-asset portfolio. Still, it is important at this point to consider what happens in a large portfolio with many assets. Specifically, what happens to the portfolio’s standard deviation when we add a new security to such a portfolio? As shown by the formula, we see two effects. The first is the asset’s own variance of returns, and the second is the covariance between the returns of this new asset and the returns of every other asset that is already in the portfolio. The relative weight of these numerous covariances is substantially greater than the asset’s unique variance; the more assets in the portfolio, the more this is true. This means that the important factor to consider when adding an investment to a portfolio that contains a number of other investments is _not_ the new security’s own variance but _the average covariance of this asset with all other investments in the portfolio._

**Portfolio Standard Deviation Calculation** Because of the assumptions used in developing the Markowitz portfolio model, any asset or portfolio of assets can be described by two characteristics: the expected rate of return and the expected standard deviation of returns. Therefore, the following demonstrations can be applied to two _individual_ assets, two _portfolios_ of assets, or two _asset classes_ with the indicated rate of return-standard deviation characteristics and correlation coefficients.

**Equal Risk and Return—Changing Correlations** Consider first the case in which both assets have the same expected return and expected standard deviation of return. As an example, let’s assume

\[
E(R_1) = 0.20, \ E(\sigma_1) = 0.10 \\
E(R_2) = 0.20, \ E(\sigma_2) = 0.10
\]

To show the effect of different covariances, we assume different levels of correlation between the two assets. We also assume that the two assets have equal weights in the portfolio \((w_1 = 0.50; \ w_2 = 0.50)\). Therefore, the only value that changes in each example is the correlation between the returns for the two assets.

Now consider the following five correlation coefficients and the covariances they yield. Since \(\text{Cov}_{ij} = r_{ij}\sigma_i\sigma_j\), the covariance will be equal to \(r_{1,2}(0.10)(0.10)\) because the standard deviation of both assets is 0.10.

a. For \(r_{1,2} = 1.00\), \(\text{Cov}_{1,2} = (1.00)(0.10)(0.10) = 0.01\)
b. For \(r_{1,2} = 0.50\), \(\text{Cov}_{1,2} = (0.50)(0.10)(0.10) = 0.005\)
c. For \(r_{1,2} = 0.00\), \(\text{Cov}_{1,2} = (0.00)(0.10)(0.10) = 0.000\)
d. For \(r_{1,2} = -0.50\), \(\text{Cov}_{1,2} = (-0.50)(0.10)(0.10) = -0.005\)
e. For \(r_{1,2} = -1.00\), \(\text{Cov}_{1,2} = (-1.00)(0.10)(0.10) = -0.01\)

Now let’s see what happens to the standard deviation of the portfolio under these five conditions.

When we apply the general portfolio formula from Equation 7.6 to a two-asset portfolio, it is

\[
\sigma_{\text{port}} = \sqrt{w_1^2\sigma_1^2 + w_2^2\sigma_2^2 + 2w_1w_2r_{1,2}\sigma_1\sigma_2}
\]

or

\[
\sigma_{\text{port}} = \sqrt{w_1^2\sigma_1^2 + w_2^2\sigma_2^2 + 2w_1w_2\text{Cov}_{1,2}}
\]
Thus, in Case a:

\[
\sigma_{\text{port}(a)} = \sqrt{(0.5)^2(0.10)^2 + (0.5)^2(0.10)^2 + 2(0.5)(0.5)(0.01)} \\
= \sqrt{(0.25)(0.01) + (0.25)(0.01) + 2(0.25)(0.01)} \\
= \sqrt{(0.0025) + (0.0025) + (0.0005)} \\
= \sqrt{0.01} = 0.10
\]

In this case, where the returns for the two assets are perfectly positively correlated, the standard deviation for the portfolio is, in fact, the weighted average of the individual standard deviations. The important point is that we get no real benefit from combining two assets that are perfectly correlated; they are like one asset already because their returns move together. Now consider Case b, where \( r_{1,2} \) equals 0.50.

\[
\sigma_{\text{port}(b)} = \sqrt{(0.5)^2(0.10)^2 + (0.5)^2(0.10)^2 + 2(0.5)(0.5)(0.005)} \\
= \sqrt{(0.0025) + (0.0025) + 2(0.25)(0.005)} \\
= \sqrt{0.0075} = 0.0866
\]

The only term that changed from Case a is the last term, \( \text{Cov}_{1,2} \), which changed from 0.01 to 0.005. As a result, the standard deviation of the portfolio declined by about 13 percent, from 0.10 to 0.0866. Note that the expected return of the portfolio did not change because it is simply the weighted average of the individual expected returns; it is equal to 0.20 in both cases.

You should be able to confirm through your own calculations that the standard deviations for Portfolios c and d are as follows:

c. 0.0707

d. 0.05

The final case, where the correlation between the two assets is –1.00, indicates the ultimate benefits of diversification.

\[
\sigma_{\text{port}(c)} = \sqrt{(0.5)^2(0.10)^2 + (0.5)^2(0.10)^2 + 2(0.5)(0.5)(-0.01)} \\
= \sqrt{(0.0050) + (-0.0050)} \\
= \sqrt{0} = 0
\]

Here, the negative covariance term exactly offsets the individual variance terms, leaving an overall standard deviation of the portfolio of zero. This would be a risk-free portfolio.

Exhibit 7.10 illustrates a graph of such a perfectly negative pattern. Perfect negative correlation gives a mean combined return for the two securities over time equal to the mean for each of them, so the returns for the portfolio show no variability. Any returns above and below the mean for each of the assets are completely offset by the return for the other asset, so there is no variability in total returns—that is, no risk—for the portfolio. Thus, a pair of completely negatively correlated assets provides the maximum benefits of diversification by completely eliminating variability—i.e., risk.

The graph in Exhibit 7.11 shows the difference in the risk–return posture for our five cases. As noted, the only effect of the change in correlation is the change in the standard deviation of this two-asset portfolio. Combining assets that are not perfectly correlated does not affect the expected return of the portfolio, but it does reduce the risk of the portfolio (as measured by its standard deviation). When we eventually reach the ultimate combination of perfect negative correlation, risk is eliminated.
We will use the previous set of correlation coefficients, but we must recalculate the covariances because this time the standard deviations of the assets are different. The results are shown in this table.

Because we are assuming the same weights in all cases (0.50 – 0.50), the expected return in every instance will be

$$E(R_{\text{port}}) = 0.50(0.10) + 0.50(0.20) = 0.15$$

The portfolio standard deviation for Case a will be

$$\sigma_{\text{port}(a)} = \sqrt{(0.5)^2(0.07)^2 + (0.5)^2(0.10)^2 + 2(0.5)(0.5)(0.0070)} = 0.085$$

Again, with perfect positive correlation, the portfolio standard deviation is the weighted average of the standard deviations of the individual assets:

$$(0.5)(0.07) + (0.5)(0.10) = 0.085$$

As you might envision, changing the weights with perfect positive correlation causes the portfolio standard deviation to change in a linear fashion. This will be an important point to remember when we discuss the capital asset pricing model (CAPM) in the next chapter.

For Cases b, c, d, and e, the portfolio standard deviations are as follows:

- **Case b**
  $$\sigma_{\text{port}(b)} = \sqrt{(0.5)^2(0.001225) + (0.5)^2(0.0025) + 2(0.5)(0.5)(0.0035)} = 0.07399$$

- **Case c**
  $$\sigma_{\text{port}(c)} = \sqrt{(0.5)^2(0.001225) + (0.5)^2(0.0025) + 2(0.5)(0.5)(0.00)} = 0.0610$$

- **Case d**
  $$\sigma_{\text{port}(d)} = \sqrt{(0.5)^2(0.001225) + (0.5)^2(0.0025) + 2(0.5)(0.5)(-0.0035)} = 0.0444$$

- **Case e**
  $$\sigma_{\text{port}(e)} = \sqrt{(0.5)^2(0.003725) + (0.5)^2(0.0070) + 2(0.5)(0.5)(0.0070)} = 0.015$$

In all the following examples, we will skip some steps because you are now aware that only the last term changes. You are encouraged to work out the individual steps to ensure that you understand the computational procedure.

### Combining Stocks with Different Returns and Risk

We have seen what happens when only the correlation coefficient (covariance) differs between the assets. We now consider two assets (or portfolios) with different expected rates of return and individual standard deviations. We will show what happens when we vary the correlations between them. We will assume two assets with the following characteristics.

---

3As noted, these could be two asset classes. For example, Asset 1 could be low risk–low return bonds and Asset 2 could be higher return–higher risk stocks.
Note that, in this example, with perfect negative correlation the portfolio standard deviation is not zero. This is because the different examples have equal weights, but the asset standard deviations are not equal.

Exhibit 7.12 shows the results for the two individual assets and the portfolio of the two assets assuming the correlation coefficients vary as set forth in Cases a through e. As before, the expected return does not change because the proportions are always set at 0.50 – 0.50, so all the portfolios lie along the horizontal line at the return, \( R = 0.15 \).

### Constant Correlation with Changing Weights

If we changed the weights of the two assets while holding the correlation coefficient constant, we would derive a set of combinations that trace an ellipse starting at Asset 2, going through the 0.50 – 0.50 point, and ending at Asset 1. We can demonstrate this with Case c, in which the correlation coefficient of zero eases the computations. We begin with 100 percent in Asset 2 (Case f) and change the weights as follows, ending with 100 percent in Asset 1 (Case l):

<table>
<thead>
<tr>

We already know the standard deviations (\( \sigma \)) for portfolios f and i (only one asset) and portfolio (i). In Cases g, h, j, and k, the standard deviations are

Because we are assuming the same weights in all cases (0.50 – 0.50), the expected return in every instance will be

\[
E(R_{\text{port}}) = 0.50(0.10) + 0.50(0.20) \\
= 0.15
\]

The portfolio standard deviation for Case a will be

\[
\sigma_{\text{port}(a)} = \sqrt{(0.5)^2(0.07)^2 + (0.5)^2(0.10)^2 + 2(0.5)(0.5)(0.0070)} \\
= \sqrt{0.007225} \\
= 0.085
\]

Again, with perfect positive correlation, the portfolio standard deviation is the weighted average of the standard deviations of the individual assets:

\[(0.5)(0.07) + (0.5)(0.10) = 0.085\]

As you might envision, changing the weights with perfect positive correlation causes the portfolio standard deviation to change in a linear fashion. This will be an important point to remember when we discuss the capital asset pricing model (CAPM) in the next chapter.

For Cases b, c, d, and e, the portfolio standard deviations are as follows:\(^4\):

\[
\sigma_{\text{port}(b)} = \sqrt{(0.001225) + (0.0025) + (0.5)(0.0035)} \\

\(^4\) In all the following examples, we will skip some steps because you are now aware that only the last term changes. You are encouraged to work out the individual steps to ensure that you understand the computational procedure.
Note that, in this example, with perfect negative correlation the portfolio standard deviation is not zero. This is because the different examples have equal weights, but the asset standard deviations are not equal.5

Exhibit 7.12 shows the results for the two individual assets and the portfolio of the two assets assuming the correlation coefficients vary as set forth in Cases a through e. As before, the expected return does not change because the proportions are always set at 0.50–0.50, so all the portfolios lie along the horizontal line at the return, \( R = 0.15 \).

**Constant Correlation with Changing Weights** If we changed the weights of the two assets while holding the correlation coefficient constant, we would derive a set of combinations that trace an ellipse starting at Asset 2, going through the 0.50–0.50 point, and ending at Asset 1. We can demonstrate this with Case c, in which the correlation coefficient of zero cases the computations. We begin with 100 percent in Asset 2 (Case f) and change the weights as follows, ending with 100 percent in Asset 1 (Case l):

<table>
<thead>
<tr>
<th>Case</th>
<th>( w_1 )</th>
<th>( w_2 )</th>
<th>( E(R) )</th>
</tr>
</thead>
<tbody>
<tr>

</tbody>
</table>

We already know the standard deviations (\( \sigma \)) for portfolios f and i (only one asset) and portfolio (i). In Cases g, h, j, and k, the standard deviations are\(^6\)

---

5The two appendixes to this chapter show proofs for equal weights with equal variances and solve for the appropriate weights to get zero standard deviation when standard deviations are not equal.

6 Again, you are encouraged to fill in the steps we skipped in the computations.
Appendix 7B, it is possible to solve for the specified set of weights that would give a portfolio with zero risk. In this case, it is \( w_1 = 0.412 \) and \( w_2 = 0.588 \), which implies an \( E(R) \) of 0.1588.

7.2.6 A Three-Asset Portfolio

A demonstration of what occurs with a three-asset portfolio is useful because it shows the dynamics of the portfolio process when assets are added. It also shows the rapid growth in the computations required, which is why we will stop at three!

In this example, we will combine three asset classes we have been discussing: stocks, bonds, and cash equivalents. We will assume the following characteristics:

<table>
<thead>
<tr>
<th>Asset Classes</th>
<th>( E(R) )</th>
<th>( E(\sigma) )</th>
<th>( w_i )</th>
</tr>
</thead>
<tbody>
<tr>
<td>Stocks (S)</td>
<td>0.12</td>
<td>0.20</td>
<td>0.60</td>
</tr>
<tr>
<td>Bonds (B)</td>
<td>0.08</td>
<td>0.10</td>
<td>0.30</td>
</tr>
<tr>
<td>Cash equivalent (C)</td>
<td>0.04</td>
<td>0.03</td>
<td>0.10</td>
</tr>
</tbody>
</table>

The correlations are \( r_{S,B} = 0.25; r_{S,C} = -0.08; r_{B,C} = 0.15 \).

Given the weights specified, the expected return of the portfolio is

\[
E(R_{port}) = (0.60)(0.12) + (0.30)(0.08) + (0.10)(0.04) = (0.072 + 0.024 + 0.004) = 0.100 = 10.00\% 
\]

The expected standard deviation of a three-asset portfolio is

\[
\sigma_{port} = \sqrt{(0.20)^2(0.07)^2 + (0.80)^2(0.10)^2 + 2(0.20)(0.80)(0.00)}
\]

\[
= \sqrt{(0.04)(0.0049) + (0.64)(0.01) + 0) 
\]

\[
= \sqrt{0.006596} 
\]

\[
= 0.0812 
\]

\[
\sigma_{port} = \sqrt{(0.40)^2(0.07)^2 + (0.60)^2(0.10)^2 + 2(0.40)(0.60)(0.00)} 
\]

\[
= \sqrt{0.004384} 
\]

\[
= 0.0662 
\]

\[
\sigma_{port} = \sqrt{(0.60)^2(0.07)^2 + (0.40)^2(0.10)^2 + 2(0.60)(0.40)(0.00)} 
\]

\[
= \sqrt{0.003364} 
\]

\[
= 0.0580 
\]

\[
\sigma_{port} = \sqrt{(0.80)^2(0.07)^2 + (0.20)^2(0.10)^2 + 2(0.80)(0.20)(0.00)} 
\]

\[
= \sqrt{0.003536} 
\]

\[
= 0.0595 
\]

The various weights with a constant correlation yield the following risk-return combinations.

<table>
<thead>
<tr>

</tbody>
</table>

A graph of these combinations appears in Exhibit 7.13. We could derive a complete curve by simply varying the weighting by smaller increments.

A notable result is that with low, zero, or negative correlations, it is possible to derive portfolios that have lower risk than either single asset. In our set of examples where \( r_{ij} = 0.00 \), this occurs in Cases h, i, j, and k. This ability to reduce risk is the essence of diversification.

As shown in Exhibit 7.13, assuming the normal risk-return relationship where assets with higher risk (larger standard deviation of returns) provide high rates of return, it is possible for a conservative investor to experience both lower risk and higher return by diversifying into a higher risk-higher return asset, assuming that the correlation between the two assets is fairly low. Exhibit 7.13 shows that, in the case where we used the correlation of zero (0.00), the low-risk investor at Point 1—who would receive a return of 10 percent and risk of 7 percent—could, by investing in portfolio j, increase his/her return to 14 percent and experience a decline in risk to 5.8 percent by investing (diversifying) 40 percent of the portfolio in riskier Asset 2. As noted, the benefits of diversification are critically dependent on the correlation between assets. The exhibit shows that there is even some benefit when the correlation is 0.50 rather than zero.

Exhibit 7.13 also shows that the curvature in the graph depends on the correlation between the two assets or portfolios. With \( r_{ij} = +1.00 \), the combinations lie along a straight line between the two assets. When \( r_{ij} = 0.50 \), the curve is to the right of the \( r_{ij} = 0.00 \) curve; when \( r_{ij} = -0.50 \), the curve is to the left. Finally, when \( r_{ij} = -1.00 \), the graph would be two straight lines that would touch at the vertical line (zero risk) with some combination. As shown in
From the characteristics specified, the standard deviation of this three-asset-class portfolio \( \sigma_{\text{port}} \) would be

\[
\sigma_{\text{port}}^2 = \frac{1}{2} \left( 0.6^2 \cdot 0.20^2 + 0.3^2 \cdot 0.10^2 + 0.1^2 \cdot 0.03^2 \right)
\]

\[
+ \frac{1}{2} \left( 0.6^2 \cdot 0.3^2 \cdot 0.15^2 \right) + \frac{1}{2} \left( 0.6^2 \cdot 0.1^2 \cdot 0.08^2 \right) + \frac{1}{2} \left( 0.3^2 \cdot 0.10^2 \cdot 0.15^2 \right)
\]

\[
= \frac{0.015309}{2} + \frac{0.0018}{2} + \frac{-0.0000576}{2} + \frac{0.000027}{2} = 0.0170784
\]

\[
\sigma_{\text{port}} = \sqrt{0.0170784} = 0.1306 = 13.06\%
\]

### 7.2.7 Estimation Issues

It is important to keep in mind that the results of this portfolio asset allocation depend on the accuracy of the statistical inputs. In the current instance, this means that for every asset (or asset class) being considered for inclusion in the portfolio, we must estimate its expected returns and standard deviation. We must also estimate the correlation coefficient among the entire set of assets. The number of correlation estimates can be significant—for example, for a portfolio of 100 securities, the number of correlation estimates is 4,950 (that is, 99 + 98 + 97 + …). The potential source of error that arises from these approximations is referred to as estimation risk.

We can reduce the number of correlation coefficients that must be estimated by assuming that stock returns can be described by the relationship of each stock to a market index—that is, a single index market model, as follows:

\[
R_i = a_i + b_i R_m + \varepsilon_i
\]

where:

- \( b_i \) is the slope coefficient that relates the returns for Security \( i \) to the returns for the aggregate stock market
- \( R_m \) is the returns for the aggregate stock market

If all the securities are similarly related to the market and a slope coefficient \( b_i \) is derived for each one, it can be shown that the correlation coefficient between two securities \( i \) and \( j \) is

\[
r_{ij} = b_i b_j \sigma_m^2 \sigma_i \sigma_j
\]

where:

- \( \sigma_m^2 \) is the variance of returns for the aggregate stock market

This reduces the number of estimates from 4,950 to 100—that is, once we have derived a slope estimate \( b_i \) for each security, we can compute the correlation estimates. Notably, this assumes that the single index market model provides a good estimate of security returns.

### 7.2.8 The Efficient Frontier

If we examined different two-asset combinations and derived the curves assuming all the possible weights, we would have a graph like that in Exhibit 7.14. The envelope curve that contains the best of all these possible combinations is referred to as the efficient frontier. Specifically, the efficient frontier represents the set of portfolios that has the maximum rate of return for every given level of risk or the minimum risk for every level of return. An example of such a frontier is shown in Exhibit 7.15. Every portfolio that lies on the efficient frontier has

---

**Exhibit 7.13 Portfolio Risk-Return Plots for Different Weights When \( r_{ij} = \pm 1.00; \pm 0.50; 0.00; -0.50; -1.00 \)**

---

Appendix 7B, it is possible to solve for the specified set of weights that would give a portfolio with zero risk. In this case, it is \( w_1 = 0.412 \) and \( w_2 = 0.588 \), which implies an \( E(R) \) of 0.1588.

### 7.2.6 A Three-Asset Portfolio

A demonstration of what occurs with a three-asset portfolio is useful because it shows the dynamics of the portfolio process when assets are added. It also shows the rapid growth in the computations required, which is why we will stop at three!

In this example, we will combine three asset classes we have been discussing: stocks, bonds, and cash equivalents. We will assume the following characteristics:

<table>
<thead>
<tr>
<th>Asset Classes</th>
<th>( E(R_i) )</th>
<th>( E(\sigma_i) )</th>
<th>( w_i )</th>
</tr>
</thead>
<tbody>
<tr>
<td>Stocks (S)</td>
<td>0.12</td>
<td>0.20</td>
<td>0.60</td>
</tr>
<tr>
<td>Bonds (B)</td>
<td>0.08</td>
<td>0.10</td>
<td>0.30</td>
</tr>
<tr>
<td>Cash equivalent (C)</td>
<td>0.04</td>
<td>0.03</td>
<td>0.10</td>
</tr>
</tbody>
</table>

The correlations are

\[
r_{S,B} = 0.25; r_{S,C} = -0.08; r_{B,C} = 0.15
\]

Given the weights specified, the \( E(R_{\text{port}}) \) is

\[
E(R_{\text{port}}) = (0.60)(0.12) + (0.30)(0.08) + (0.10)(0.04)
\]

\[
= 0.072 + 0.024 + 0.004 = 0.100 = 10.00\%
\]

When we apply the generalized formula from Equation 7.6 to the expected standard deviation of a three-asset portfolio, it is

\[
\sigma_{\text{port}}^2 = \left( w_S^2 \sigma_S^2 + w_B^2 \sigma_B^2 + w_C^2 \sigma_C^2 \right)
\]

\[
+ \left( 2w_S w_B \sigma_S \sigma_B + 2w_S w_C \sigma_S \sigma_C + 2w_B w_C \sigma_B \sigma_C \right)
\]

\[
= \left( w_S \sigma_S^2 + w_B \sigma_B^2 + w_C \sigma_C^2 \right)
\]

\[
+ \left( 2w_S w_B \sigma_S \sigma_B + 2w_S w_C \sigma_S \sigma_C + 2w_B w_C \sigma_B \sigma_C \right)
\]

\[
\sigma_{\text{port}} = \sqrt{\sigma_{\text{port}}^2}
\]

---

\( ^{\text{The asset allocation articles regularly contained in The Wall Street Journal generally refer to these three asset classes.}} \)
From the characteristics specified, the standard deviation of this three-asset-class portfolio \( \sigma_{\text{port}} \) would be
\[
\sigma_{\text{port}} = \left[ (0.6)^2 (0.20)^2 + (0.3)^2 (0.10)^2 + (0.1)^2 (0.03)^2 \right] \\
+ \left[ 2(0.6)(0.3)(0.20)(0.10)(0.25) \right] \\
+ \left[ 2(0.6)(0.1)(0.20)(0.03)(-0.08) \right] \\
= 0.0170784 \\
= (0.0170784)^{1/2} = 0.1306 = 13.06\%
\]

If we examined different two-asset combinations and derived the curves assuming all the possible weights, we would have a graph like that in Exhibit 7.14. The envelope curve that contains the best of all these possible combinations is referred to as the efficient frontier. Specifically, the efficient frontier represents the set of portfolios that has the maximum rate of return for every given level of risk or the minimum risk for every level of return. An example of such a frontier is shown in Exhibit 7.15. Every portfolio that lies on the efficient frontier has
7.2.9 The Efficient Frontier and Investor Utility

The curve in Exhibit 7.15 shows that the slope of the efficient frontier curve decreases steadily as we move upward. This implies that adding equal increments of risk as we move up the efficient frontier gives diminishing increments of expected return. To evaluate this situation, we calculate the slope of the efficient frontier as follows:

$$\Delta \frac{E(R_{\text{port}})}{\Delta \sigma_{\text{port}}}$$

An individual investor’s utility curves specify the trade-offs he or she is willing to make between expected return and risk. In conjunction with the efficient frontier, these utility curves determine which particular portfolio on the efficient frontier best suits an individual investor. Two investors will choose the same portfolio from the efficient set only if their utility curves are identical.

Exhibit 7.16 shows two sets of utility curves along with an efficient frontier of investments. The curves labeled $U_1, U_2, \text{ and } U_3$ are for a strongly risk-averse investor. These utility curves are quite steep, indicating that the investor will not tolerate much additional risk to obtain additional returns. The investor is equally disposed toward any $E(R), E(\sigma)$ combinations along the specific utility curve $U_1$.

The curves labeled $(U_3', U_2', U_1')$ characterize a less risk-averse investor. Such an investor is willing to tolerate a bit more risk to get a higher expected return.

The optimal portfolio is the efficient portfolio that has the highest utility for a given investor. It lies at the point of tangency between the efficient frontier and the $U_1$ curve with the highest possible utility. A conservative investor’s highest utility is at Point X in Exhibit 7.16, where the $U_2$ curve just touches the efficient frontier. A less risk-averse investor’s highest utility occurs at Point Y, which represents a portfolio on the efficient frontier with higher expected returns and higher risk than the portfolio at X.

Either a higher rate of return for equal risk or lower risk for an equal rate of return than some portfolio beneath the frontier. Thus, we would say that Portfolio A in Exhibit 7.15 dominates Portfolio C because it has an equal rate of return but substantially less risk. Similarly, Portfolio B dominates Portfolio C because it has equal risk but a higher expected rate of return. Because of the benefits of diversification among imperfectly correlated assets, we would expect the efficient frontier to be made up of portfolios of investments rather than individual securities. Two possible exceptions arise at the end points, which represent the asset with the highest return and the asset with the lowest risk.

As an investor, you will target a point along the efficient frontier based on your utility function, which reflects your attitude toward risk. No portfolio on the efficient frontier can dominate any other portfolio on the efficient frontier. All of these portfolios have different return and risk measures, with expected rates of return that increase with higher risk.
7.2.9 The Efficient Frontier and Investor Utility

The curve in Exhibit 7.15 shows that the slope of the efficient frontier curve decreases steadily as we move upward. This implies that adding equal increments of risk as we move up the efficient frontier gives diminishing increments of expected return. To evaluate this situation, we calculate the slope of the efficient frontier as follows:

\[
\frac{\Delta E(R_{\text{port}})}{\Delta E(\sigma_{\text{port}})}
\]

An individual investor’s utility curves specify the trade-offs he or she is willing to make between expected return and risk. In conjunction with the efficient frontier, these utility curves determine which particular portfolio on the efficient frontier best suits an individual investor. Two investors will choose the same portfolio from the efficient set only if their utility curves are identical.

Exhibit 7.16 shows two sets of utility curves along with an efficient frontier of investments. The curves labeled \(U_1, U_2,\) and \(U_3\) are for a strongly risk-averse investor. These utility curves are quite steep, indicating that the investor will not tolerate much additional risk to obtain additional returns. The investor is equally disposed toward any \(E(R), E(\sigma)\) combinations along the specific utility curve \(U_1\).

The curves labeled \((U_3, U_2, U_1)\) characterize a less risk-averse investor. Such an investor is willing to tolerate a bit more risk to get a higher expected return.

The optimal portfolio is the efficient portfolio that has the highest utility for a given investor. It lies at the point of tangency between the efficient frontier and the \(U_1\) curve with the highest possible utility. A conservative investor’s highest utility is at Point X in Exhibit 7.16, where the \(U_2\) curve just touches the efficient frontier. A less risk-averse investor’s highest utility occurs at Point Y, which represents a portfolio on the efficient frontier with higher expected returns and higher risk than the portfolio at X.

c. 0.0
d. +1.0

**SUMMARY**

- The basic Markowitz portfolio model derives the expected rate of return for a portfolio of assets and a measure of expected risk, which is the standard deviation of expected rates of return. Markowitz showed that the expected rate of return of a portfolio is the weighted average of the expected return for the individual investments in the portfolio. The standard deviation of a portfolio is a function not only of the standard deviations for the individual investments but also of the covariance between the rates of return for all the pairs of assets in the portfolio. In a large portfolio, these covariances are the important factors.
- Different weights or amounts of a portfolio held in various assets yield a curve of potential combinations. Correlation coefficients among assets are the critical factor to consider when selecting investments. Investors can maintain their rate of return while reducing the risk level of their portfolio by combining assets or portfolios that have low-positive or negative correlation.
- Assuming numerous assets and a multitude of combination curves, the efficient frontier is the envelope curve that encompasses all of the best combinations. It defines the set of portfolios that has the highest expected return for each given level of risk or the minimum risk for each given level of return. From this set of dominant portfolios, investors select the one that lies at the point of tangency between the efficient frontier and their highest utility curve. Because risk–return utility functions differ, the point of tangency and, therefore, the portfolio choice will differ among investors.

At this point, you understand that an optimum portfolio is a combination of investments, each having desirable individual risk–return characteristics that also fit together based on their correlations. This deeper understanding of portfolio theory should lead you to reflect back on our earlier discussion of global investing. Because many foreign stock and bond investments provide superior rates of return compared with U.S. securities and have low correlations with portfolios of U.S. stocks and bonds (as shown in Chapter 3), including these foreign securities in your portfolio will help you to reduce the overall risk of your portfolio while possibly increasing your rate of return.

14. An investor is considering adding another investment to a portfolio. To achieve the maximum diversification benefits, the investor should add, if possible, an investment that has which of the following correlation coefficients with the other investments in the portfolio?
   a. −1.0
   b. −0.5
   c. 0.0
   d. +1.0

PROBLEMS

1. Considering the world economic outlook for the coming year and estimates of sales and earning for the pharmaceutical industry, you expect the rate of return for Lauren Labs common stock to range between −20 percent and +40 percent with the following probabilities.

Compute the following.
- Average monthly rate of return $\bar{R}_i$ for each stock
- Standard deviation of returns for each stock
- Covariance between the rates of return
- The correlation coefficient between the rates of return

What level of correlation did you expect? How did your expectations compare with the computed correlation? Would these two stocks be good choices for diversification? Why or why not?

4. You are considering two assets with the following characteristics.

\[
\begin{align*}
E(R_1) &= 0.15 \\
E(\sigma_1) &= 0.10 \\
w_1 &= 0.5 \\
E(R_2) &= 0.20 \\
E(\sigma_2) &= 0.20 \\
w_2 &= 0.5 \\
\end{align*}
\]

Compute the mean and standard deviation of two portfolios if $r_{1,2} = 0.40$ and $-0.60$, respectively. Plot the two portfolios on a risk-return graph and briefly explain the results.

5. Given:

\[
\begin{align*}
E(R_1) &= 0.10 \\
E(R_2) &= 0.15 \\
E(\sigma_1) &= 0.03 \\
E(\sigma_2) &= 0.05 \\

Calculate the expected returns and expected standard deviations of a two-stock portfolio in which Stock 1 has a weight of 60 percent under the following conditions.

- $r_{1,2} = 1.00$
- $r_{1,2} = 0.75$
- $r_{1,2} = 0.25$
- $r_{1,2} = 0.00$
- $r_{1,2} = -0.25$
- $r_{1,2} = -0.75$
- $r_{1,2} = -1.00$
APPENDIX 7

A. Proof That Minimum Portfolio Variance Occurs with Equal Weights
When Securities Have Equal Variance

When $\sigma_1 = \sigma_2$, we have:

$$\sigma_{\text{port}}^2 = w_1^2 (\sigma_1)^2 + (1 - w_1)^2 (\sigma_1)^2 - 2w_1 (1 - w_1) r_1;$$

$$= (\sigma_1)^2 \left[ w_1^2 + (1 - 2w_1 + 2w_1^2) r_1^2 \right].$$

For this to be a minimum,

$$\frac{\partial (\sigma_{\text{port}}^2)}{\partial w_1} = 0 = (\sigma_1)^2 \frac{4w_1 - 2 + 2r_1^2 - 4w_1r_1^2}{2}.$$

Assuming $(\sigma_1)^2 > 0$,

$$4w_1 - 2 + 2r_1^2 - 4w_1r_1^2 = 0$$

$$4w_1(1 - r_1^2) = 2 - 2r_1^2$$

$$w_1 = \frac{1}{2} \text{ regardless of } r_{1,2},$$

Thus, if $\sigma_1 = \sigma_2$, $\sigma_{\text{port}}^2$ will always be minimized by choosing $w_1 = w_2 = \frac{1}{2}$, regardless of the value of $r_{1,2}$, except when $r_{1,2} = +1$ (in which case $\sigma_{\text{port}}^2 = \sigma_1^2 = \sigma_2^2$).

This can be verified by checking the second-order condition

$$\frac{\partial^2 (\sigma_{\text{port}}^2)}{\partial w_1^2} > 0.$$

Problem 1.
The following information applies to Questions 1a and 1b. The general equation for the weight of the first security to achieve minimum variance (in a two-stock portfolio) is given by

$$w_1 = \frac{(\sigma_2)^2 - r_{1,2} (\sigma_1 \sigma_2)}{(\sigma_2)^2 - (\sigma_1 \sigma_2) - (\sigma_1)^2}.$$

1a. Show that $w_1 = 0.5$ when $\sigma_1 = \sigma_2$.

1b. What is the weight of Security 1 that gives minimum portfolio variance when $r_{1,2} = 0.5$, $\sigma_1 = 0.04$, and $\sigma_2 = 0.06$?

B. Derivation of Weights That Will Give Zero Variance When Correlation Equals $-1.00$

$$\sigma_{\text{port}}^2 = w_1^2 (\sigma_1)^2 + (1 - w_1)^2 (\sigma_2)^2 + 2w_1 (1 - w_1) r_{1,2} (\sigma_1 \sigma_2)$$

$$= (\sigma_1)^2 \left[ w_1^2 + (1 - 2w_1 + 2w_1^2) r_{1,2}^2 \right].$$

$$\frac{\partial (\sigma_{\text{port}}^2)}{\partial w_1} = 0 = (\sigma_1)^2 \frac{4w_1 - 2 + 2r_{1,2}^2 - 4w_1r_{1,2}^2}{2}.$$

8. The standard deviation of Shamrock Corp. stock is 19 percent. The standard deviation of Cara Co. stock is 14 percent. The covariance between these two stocks is 100. What is the correlation between Shamrock and Cara stock?

THOMSON REUTERS

Use the Thomson One—Business School Edition Online Database to answer the following questions.

1. Collect daily price data for the past 30 trading days and compute the daily percentage price returns for each: Avon Products, Inc. (AVP), Best Buy Inc. (BBY), and Cisco Systems (CSCO).
2. Compute the mean daily return for each stock and the standard deviation of daily returns.
3. Compute the covariance and correlations between the three possible pairs.
4. Assuming equal weight between each pair of stocks, compute the mean daily return and the standard deviation of each of the three portfolios.
5. Create a risk–return scatterplot and enter the average daily return (vertical axis) and standard deviation (horizontal axis) for the three individual stocks and the three portfolios. Briefly discuss the results based on the material in this chapter.
### A. Proof That Minimum Portfolio Variance Occurs with Equal Weights When Securities Have Equal Variance

When \( \sigma_1 = \sigma_2 \), we have:

\[
\sigma_{\text{port}}^2 = w_1^2 (\sigma_1)^2 + (1 - w_1)^2 (\sigma_1)^2 - 2w_1 (1 - w_1) r_{1,2} (\sigma_1)^2
\]

\[
= (\sigma_1)^2 [w_1^2 + 1 - 2w_1 + w_1^2 + 2w_1 r_{1,2} - 2w_1^2 r_{1,2}]
\]

\[
= (\sigma_1)^2 [2w_1^2 + 1 - 2w_1 + 2w_1 r_{1,2} - 2w_1^2 r_{1,2}]
\]

For this to be a minimum,

\[
\frac{\partial (\sigma_{\text{port}}^2)}{\partial w_1} = 0 = (\sigma_1)^2 [4w_1 + 2 + 2r_{1,2} 	imes 4w_1 r_{1,2}]
\]

Assuming \( (\sigma_1)^2 > 0 \),

\[
4w_1 - 2 + 2r_{1,2} - 4w_1 r_{1,2} = 0
\]

\[
4w_1 (1 - r_{1,2}) - 2(1 - r_{1,2}) = 0
\]

from which

\[
w_1 \frac{2(1 - r_{1,2})}{4(1 - r_{1,2})} = \frac{1}{2}
\]

regardless of \( r_{1,2} \). Thus, if \( \sigma_1 = \sigma_2 \), \( \sigma_{\text{port}}^2 \) will always be minimized by choosing \( w_1 = w_2 = 1/2 \), regardless of the value of \( r_{1,2} \), except when \( r_{1,2} = +1 \) (in which case \( \sigma_{\text{port}} = \sigma_1 = \sigma_2 \)). This can be verified by checking the second-order condition

\[
\frac{\partial (\sigma_{\text{port}}^2)}{\partial w_1^2} > 0
\]

### Problem

1. The following information applies to Questions 1a and 1b. The general equation for the weight of the first security to achieve minimum variance (in a two-stock portfolio) is given by

\[
w_1 = \frac{(\sigma_2)^2 - r_{1,2} (\sigma_1)(\sigma_2)}{(\sigma_1)^2 + (\sigma_2)^2 - 2r_{1,2} (\sigma_1)(\sigma_2)}
\]

1a. Show that \( w_1 = 0.5 \) when \( \sigma_1 = \sigma_2 \).

1b. What is the weight of Security 1 that gives minimum portfolio variance when \( r_{1,2} = 0.5 \), \( \sigma_1 = 0.04 \), and \( \sigma_2 = 0.06 \)?

### B. Derivation of Weights That Will Give Zero Variance When Correlation Equals −1.00

\[
\sigma_{\text{port}}^2 = w_1^2 (\sigma_1)^2 + (1 - w_1)^2 (\sigma_2)^2 + 2w_1 (1 - w_1) r_{1,2} (\sigma_1)(\sigma_2)
\]

\[
= w_1^2 (\sigma_1)^2 + (\sigma_2)^2 - 2w_1 (\sigma_2)^2 - w_1^2 (\sigma_2)^2 + 2w_1 r_{1,2} (\sigma_1)(\sigma_2) - 2w_1^2 r_{1,2} (\sigma_1)(\sigma_2)
\]
If $r_{1,2} = 1$, this can be rearranged and expressed as
\[
\sigma_{\text{port}}^2 = w_1^2 [(\sigma_1)^2 + 2(\sigma_1)(\sigma_2) + (\sigma_2)^2] - 2w_1(\sigma_2)^2 + (\sigma_1)(\sigma_2) + (\sigma_2)^2
\]
\[
= w_1^2[(\sigma_1) + (\sigma_2)]^2 - 2w_1(\sigma_2)[(\sigma_1) - (\sigma_2)] + (\sigma_2)^2
\]
\[
= \{w_1[(\sigma_1) + (\sigma_2)] - (\sigma_2)\}^2
\]
We want to find the weight, $w_1$, which will reduce $(\sigma_{\text{port}}^2)$ to zero; therefore,
\[
w_1[(\sigma_1) + (\sigma_2)] - (\sigma_2) = 0
\]
which yields
\[
w_1 = \frac{(\sigma_2)}{(\sigma_1) + (\sigma_2)}, \quad \text{and} \quad w_2 = 1 - w_1 = \frac{(\sigma_1)}{(\sigma_1) + (\sigma_2)}
\]

**Problem**

1. Given two assets with the following characteristics:
   \[
   E(R_1) = 0.12 \quad \sigma_1 = 0.04
   \]
   \[
   E(R_2) = 0.16 \quad \sigma_2 = 0.06
   \]
   Assume that $r_{1,2} = -1.00$. What is the weight that would yield a zero variance for the portfolio?
8.1.1 Background for Capital Market Theory

With any theory, it is necessary to articulate a set of assumptions that specify how the world is expected to act. In this section, we consider the main assumptions that underlie the development of capital market theory.

Assumptions of Capital Market Theory

Because capital market theory builds on the Markowitz portfolio model, it requires the same assumptions, along with some additional ones:

1. All investors are Markowitz-efficient in that they seek to invest in tangent points on the efficient frontier. The exact location of this tangent point and, therefore, the specific portfolio selected will depend on the individual investor’s risk-return utility function.

2. Investors can borrow or lend any amount of money at the risk-free rate of return ($RFR$).

3. All investors have homogeneous expectations; that is, they estimate identical probability distributions for future rates of return.

4. All investors have the same one-period time horizon, such as one month or one year. The model will be developed for a single hypothetical period, and its results could be affected by a different assumption since it requires investors to derive risk measures and risk-free assets that are consistent with their investment horizons.

5. All investments are infinitely divisible, so it is possible to buy or sell fractional shares of any asset or portfolio. This assumption allows us to discuss investment alternatives as continuous curves.

6. There are no taxes or transaction costs involved in buying or selling assets. This is a reasonable assumption in many instances. Neither pension funds nor charitable foundations have to pay taxes, and the transaction costs for most financial institutions are negligible on most financial instruments.

7. There is no inflation or any change in interest rates, or inflation is fully anticipated. This is a reasonable initial assumption, and it can be modified.

8. Capital markets are in equilibrium. This means that we begin with all investments properly priced in line with their risk levels.

Some of these assumptions may seem unrealistic, but keep in mind two things. First, as mentioned, relaxing them would have only a minor effect on the model and would not change its main implications or conclusions. Second, a theory should never be judged on the basis of its assumptions but rather on how well it explains and helps us predict behavior in the real world. If this theory and the model it implies help us explain the rates of return on a wide variety of risky assets, it is useful, even if some of its assumptions are unrealistic.

Development of Capital Market Theory

The major factor that allowed Markowitz portfolio theory to develop into capital market theory is the concept of a risk-free asset, that is, an asset with zero variance. As we will show, such an asset would have zero correlation with all other risky assets and would provide the risk-free rate of return ($RFR$). This assumption of a risk-free asset allows us to derive a generalized theory of capital asset pricing under conditions of uncertainty from the portfolio theory. This achievement is generally attributed to William Sharpe (1964), who received a Nobel Prize for it, but Lintner (1965) and Mossin (1966) derived similar theories independently. Consequently, you may see references to the Sharpe-Lintner-Mossin capital asset pricing model.

2. Investors can borrow or lend any amount of money at the risk-free rate of return (RFR). (Clearly, it is always possible to lend money at the nominal risk-free rate by buying risk-free securities such as government T-bills. It is not always possible to borrow at this level.)

3. All investors have homogeneous expectations; that is, they estimate identical probability distributions for future rates of return.

4. All investors have the same one-period time horizon, such as one month or one year. Consequently, you may see references to the Sharpe-Lintner-Mossin capital asset pricing model.

8.1.2 Developing the Capital Market Line
We have defined a risky asset as one from which future returns are uncertain, and we have measured this uncertainty by the standard deviation of expected returns. Because the expected return on a risk-free asset is entirely certain, the standard deviation of its expected return is
The Risk-Return Combination

With these results, we can develop the risk-return relationship between $E(R_{port})$ and $\sigma_{port}$ by using a few algebraic manipulations:

$$E(R_{port}) = \left( w_{RF} \right) (R_{FR}) + \left( 1 - w_{RF} \right) E(R_M) + \frac{R_{FR} - R_{FR}}{C138} = R_{FR} + \left( 1 - w_{RF} \right) \frac{E(R_M) - R_{FR}}{C138}$$

so that

$$E(R_{port}) = R_{FR} + \left( 1 - w_{RF} \right) \frac{\sigma_M}{C20/C21}$$

Equation 8.1 is the primary result of capital market theory. It can be interpreted as follows: Investors who allocate their money between a riskless security and the risky Portfolio M can expect a return equal to the risk-free rate plus compensation for the number of risk units ($\sigma_{port}$) they accept.

This outcome is consistent with the concept underlying all of investment theory that investors perform two functions in the capital markets for which they can expect to be rewarded. First, they allow someone else to use their money, for which they receive the risk-free rate of interest. Second, they bear the risk that the returns they have been promised in exchange for their invested capital will not be repaid. The term, $\frac{E(R_M) - R_{FR}}{C138}$, is the expected compensation per unit of risk taken, which is more commonly referred to as the investor's expected risk premium per unit of risk.

The Capital Market Line

The risk-return relationship shown in Equation 8.1 holds for every combination of the risk-free asset with any collection of risky assets. However, investors would obviously like to maximize their expected compensation for bearing risk (i.e., they would like to maximize the risk premium they receive). Let us now assume that Portfolio M is the single collection of risky assets that happens to maximize this risk premium. With this assumption, Portfolio M is called the market portfolio and, by definition, it contains all risky assets held anywhere in the marketplace and receives the highest level of expected return (in excess of the risk-free rate) per unit of risk for any available portfolio of risky assets. Under these conditions, Equation 8.1 is called the capital market line (CML).

Exhibit 8.1 shows the various possibilities when a risk-free asset is combined with alternative risky combinations of assets along the Markowitz efficient frontier. Each of the straight lines depicted represents mixtures of a risky portfolio with the riskless asset. For instance, the risk-free asset could be combined in various weights with Portfolio A, as shown by the straight line $RFR - A$. Any combination on this line would dominate portfolio possibilities that fall below it because it would have a higher expected return for the same level of risk. Similarly, any combination of the risk-free asset and Portfolio A is dominated by some mixture of the risk-free asset and Portfolio B.

You can continue to draw lines from $RFR$ to the efficient frontier with increasingly higher slopes until you reach the point of tangency at Portfolio M. The set of portfolio possibilities along Line $RFR - M$—which is the CML—dominates all other feasible combinations that investors could form. For example, Point C could be established by investing half of your assets in the riskless security (i.e., lending at $RFR$) and the other half in Portfolio M. Notice in Exhibit 8.1 that there is no way to invest your money and achieve a higher expected return for the same level of risk ($\sigma_c$). In this sense, the CML represents a new efficient frontier that combines the Markowitz efficient frontier of risky assets with the ability to invest in the risk-free security. The slope of the CML is $\frac{E(R_M) - R_{FR}}{C138} = \sigma_M$, which is the maximum risk premium compensation that investors can expect for each unit of risk they bear.

Covariance with a Risk-Free Asset

Recall that the covariance between two sets of returns is

$$\text{Cov}_{ij} = \sum_{i=1}^{n} \frac{(R_i - E(R_i))(R_j - E(R_j))}{n}$$

Assume for the moment that asset $i$ in this formula is the risk-free asset. Because the returns for the risk-free asset are certain ($\sigma_{RF} = 0$), $R_i = E(R_i)$ during all periods. Thus, $R_i - E(R_i)$ will equal zero, and the product of this expression with any other expression will equal zero. Consequently, the covariance of the risk-free asset with any risky asset or portfolio of assets will always equal zero. Similarly, the correlation between any risky asset $i$, and the risk-free asset, RF, would be zero because it is equal to

$$r_{RF,i} = \text{Cov}_{RF,i}/\sigma_{RF}\sigma_i$$

Combining a Risk-Free Asset with a Risky Portfolio

What happens to the expected rate of return and the standard deviation of returns when you combine a risk-free asset with a portfolio of risky assets such as those that exist on the Markowitz efficient frontier?

Expected Return

Like the expected return for a portfolio of two risky assets, the expected rate of return for a portfolio that includes a risk-free asset with a collection of risky assets (call it Portfolio M) is the weighted average of the two returns:

$$E(R_{port}) = w_{RF}(R_{FR}) + (1 - w_{RF})E(R_M)$$

where:

$w_{RF} =$ the proportion of the portfolio invested in the risk-free asset

$E(R_M) =$ the expected rate of return on risky Portfolio M

Standard Deviation

Recall from Chapter 7 that the expected variance for a two-asset portfolio is

$$\sigma_{port}^2 = w_1^2 \sigma_1^2 + w_2^2 \sigma_2^2 + 2w_1w_2\rho_{1,2}\sigma_1\sigma_2$$

Substituting the risk-free asset for Security 1, and the risky asset Portfolio M for Security 2, this formula would become

$$\sigma_{port}^2 = w_{RF}^2 \sigma_{RF}^2 + (1 - w_{RF})^2 \sigma_M^2 + 2w_{RF}(1 - w_{RF})r_{RF,M}\sigma_{RF}\sigma_M$$

We know that the variance of the risk-free asset is zero, that is, $\sigma_{RF}^2 = 0$. Because the correlation between the risk-free asset and any risky asset, M, is also zero, the factor $r_{RF,M}$ in the preceding equation also equals zero. Therefore, any component of the variance formula that has either of these terms will equal zero. When you make these adjustments, the formula becomes

$$\sigma_{port}^2 = (1 - w_{RF})^2 \sigma_M^2$$

The standard deviation is

$$\sigma_{port} = \sqrt{(1 - w_{RF})^2 \sigma_M^2}$$

$$= (1 - w_{RF})\sigma_M$$

Therefore, the standard deviation of a portfolio that combines the risk-free asset with risky assets is the linear proportion of the standard deviation of the risky asset portfolio.
The Risk-Return Combination With these results, we can develop the risk-return relationship between $E(R_{\text{port}})$ and $\sigma_{\text{port}}$ by using a few algebraic manipulations:

$$E(R_{\text{port}}) = (w_{\text{RF}})(R_{\text{FR}}) + (1 - w_{\text{RF}})E(R_{\text{M}}) + \{R_{\text{FR}} - R_{\text{FR}}\}$$

$$= R_{\text{FR}} - (1 - w_{\text{RF}})R_{\text{FR}} + (1 - w_{\text{RF}})E(R_{\text{M}})$$

$$= R_{\text{FR}} + (1 - w_{\text{RF}})\{E(R_{\text{M}}) - R_{\text{FR}}\}$$

$$= R_{\text{FR}} + (1 - w_{\text{RF}})\{\sigma_{\text{M}}/\sigma_{\text{M}}\}\{E(R_{\text{M}}) - R_{\text{FR}}\}$$

so that

$$8.1 \quad E(R_{\text{port}}) = R_{\text{FR}} + \sigma_{\text{port}} \frac{E(R_{\text{M}}) - R_{\text{FR}}}{\sigma_{\text{M}}}$$

Equation 8.1 is the primary result of capital market theory. It can be interpreted as follows: Investors who allocate their money between a riskless security and the risky Portfolio M can expect a return equal to the risk-free rate plus compensation for the number of risk units ($\sigma_{\text{port}}$) they accept.

This outcome is consistent with the concept underlying all of investment theory that investors perform two functions in the capital markets for which they can expect to be rewarded. First, they allow someone else to use their money, for which they receive the risk-free rate of interest. Second, they bear the risk that the returns they have been promised in exchange for their invested capital will not be repaid. The term, $[E(R_{\text{M}}) - R_{\text{FR}}]/\sigma_{\text{M}}$, is the expected compensation per unit of risk taken, which is more commonly referred to as the investor’s expected risk premium per unit of risk.

The Capital Market Line The risk-return relationship shown in Equation 8.1 holds for every combination of the risk-free asset with any collection of risky assets. However, investors would obviously like to maximize their expected compensation for bearing risk (i.e., they would like to maximize the risk premium they receive). Let us now assume that Portfolio M is the single collection of risky assets that happens to maximize this risk premium. With this assumption, Portfolio M is called the market portfolio and, by definition, it contains all risky assets held anywhere in the marketplace and receives the highest level of expected return (in excess of the risk-free rate) per unit of risk for any available portfolio of risky assets. Under these conditions, Equation 8.1 is called the capital market line (CML).

Exhibit 8.1 shows the various possibilities when a risk-free asset is combined with alternative risky combinations of assets along the Markowitz efficient frontier. Each of the straight lines depicted represents mixtures of a risky portfolio with the riskless asset. For instance, the risk-free asset could be combined in various weights with Portfolio A, as shown by the straight line $R_{\text{FR}} - A$. Any combination on this line would dominate portfolio possibilities that fall below it because it would have a higher expected return for the same level of risk. Similarly, any combination of the risk-free asset and Portfolio A is dominated by some mixture of the risk-free asset and Portfolio B.

You can continue to draw lines from $R_{\text{FR}}$ to the efficient frontier with increasingly higher slopes until you reach the point of tangency at Portfolio M. The set of portfolio possibilities along Line $R_{\text{FR}} - M$—which is the CML—dominates all other feasible combinations that investors could form. For example, Point C could be established by investing half of your assets in the riskless security (i.e., lending at $R_{\text{FR}}$) and the other half in Portfolio M. Notice in Exhibit 8.1 that there is no way to invest your money and achieve a higher expected return for the same level of risk ($\sigma_{\text{port}}$). In this sense, the CML represents a new efficient frontier that combines the Markowitz efficient frontier of risky assets with the ability to invest in the risk-free security. The slope of the CML is $[E(R_{\text{M}}) - R_{\text{FR}}]/\sigma_{\text{M}}$, which is the maximum risk premium compensation that investors can expect for each unit of risk they bear.
Therefore, both return and risk increase in a linear fashion along the CML. This is shown in Exhibit 8.2. Our discussion of portfolio theory stated that, when two assets are perfectly correlated, the set of portfolio possibilities falls along a straight line. Therefore, because the CML is a straight line, it implies that all the portfolios on the CML are perfectly positively correlated. This occurs because all portfolios on the CML combine the risky asset Portfolio M and the risk-free asset. You either invest part of your money in the risk-free asset (i.e., you lend at the RFR) and the rest in the risky asset portfolio. In either case, all the variability comes from the risky asset M portfolio. The only difference between the alternative portfolios on the CML is the magnitude of that variability, which is caused by the proportion of the risky asset portfolio held in the total portfolio.

8.1.3 Risk, Diversification, and the Market Portfolio

The investment prescription that emerges from capital market theory is clear-cut: Investors should only invest their funds in two types of assets—the risk-free security and risky asset Portfolio M—with the weights of these two holdings determined by the investors’ tolerance for risk. Because of the special place that the market Portfolio M holds for all investors, it must contain all risky assets for which there is any value in the marketplace. This includes not just U.S. common stocks, but also non-U.S. stocks, U.S. and non-U.S. bonds, real estate, private equity, options and futures contracts, art, antiques, and so on. Further, these assets should be represented in Portfolio M in proportion to their relative market values.

Since the market portfolio contains all risky assets, it is a completely diversified portfolio, which means that all risk unique to individual assets in the portfolio is diversified away. Unique risk—which is often called unsystematic risk—of any single asset is offset by the unique variability of all of the other holdings in the portfolio. This implies that only systematic risk, defined as the variability in all risky assets caused by macroeconomic variables, remains in Portfolio M. Systematic risk can be measured by the standard deviation of returns to the market portfolio, and it changes over time whenever there are changes in the underlying economic forces that affect the valuation of all risky assets, such as variability of

Risk-Return Possibilities with Leverage An investor may want to attain a higher expected return than is available at Point M in exchange for accepting higher risk. One alternative would be to invest in one of the risky asset portfolios on the Markowitz frontier beyond Point M such as the portfolio at Point D. A second alternative is to add leverage to the portfolio by borrowing money at the risk-free rate and investing the proceeds in the risky asset portfolio at Point M; this is depicted as Point E. What effect would this have on the return and risk for your portfolio?

If you borrow an amount equal to 50 percent of your original wealth at the risk-free rate, \( w_{RFR} \) will not be a positive fraction but, rather, a negative 50 percent (\( w_{RFR} = -0.50 \)). The effect on the expected return for your portfolio is:

\[
E(R_{port}) = w_{RFR}(RFR) + (1 - w_{RFR})E(R_M) \\
= -0.50(RFR) + [1 - (-0.50)]E(R_M) \\
= -0.50(RFR) + 1.50E(R_M)
\]

The return will increase in a linear fashion along the CML because the gross return increases by 50 percent, but you must pay interest at the RFR on the money borrowed. If \( RFR = 0.06 \) and \( E(R_M) = 0.12 \), the return on your leveraged portfolio would be:

\[
E(R_{port}) = -0.50(0.06) + 1.50(0.12) \\
= -0.03 + 0.18 \\
= 0.15
\]

The effect on the standard deviation of the leveraged portfolio is similar.

\[
s_{port} = (1 - w_{RFR})s_M \\
= [1 - (-0.50)]s_M = 1.50s_M
\]

where:

\( s_M = \) the standard deviation of Portfolio M
Therefore, both return and risk increase in a linear fashion along the CML. This is shown in Exhibit 8.2.

Our discussion of portfolio theory stated that, when two assets are perfectly correlated, the set of portfolio possibilities falls along a straight line. Therefore, because the CML is a straight line, it implies that all the portfolios on the CML are perfectly positively correlated. This occurs because all portfolios on the CML combine the risky asset Portfolio M and the risk-free asset. You either invest part of your money in the risk-free asset (i.e., you lend at the RFR) and the rest in the risky asset Portfolio M, or you borrow at the risk-free rate and invest these funds in the risky asset portfolio. In either case, all the variability comes from the risky asset M portfolio. The only difference between the alternative portfolios on the CML is the magnitude of that variability, which is caused by the proportion of the risky asset portfolio held in the total portfolio.

### 8.1.3 Risk, Diversification, and the Market Portfolio

The investment prescription that emerges from capital market theory is clear-cut: Investors should only invest their funds in two types of assets—the risk-free security and risky asset Portfolio M—with the weights of these two holdings determined by the investors' tolerance for risk. Because of the special place that the market Portfolio M holds for all investors, it must contain all risky assets for which there is any value in the marketplace. This includes not just U.S. common stocks, but also non-U.S. stocks, U.S. and non-U.S. bonds, real estate, private equity, options and futures contracts, art, antiques, and so on. Further, these assets should be represented in Portfolio M in proportion to their relative market values.

Since the market portfolio contains all risky assets, it is a completely diversified portfolio, which means that all risk unique to individual assets in the portfolio is diversified away. Unique risk—which is often called unsystematic risk—of any single asset is offset by the unique variability of all of the other holdings in the portfolio. This implies that only systematic risk, defined as the variability in all risky assets caused by macroeconomic variables, remains in Portfolio M. Systematic risk can be measured by the standard deviation of returns to the market portfolio, and it changes over time whenever there are changes in the underlying economic forces that affect the valuation of all risky assets, such as variability of
money supply growth, interest rate volatility, and variability in industrial production or corporate earnings.1

**How to Measure Diversification** We have seen that all portfolios on the CML are perfectly positively correlated, so all portfolios on the CML are perfectly correlated with the completely diversified market Portfolio M. Lorie (1975) notes that a completely diversified portfolio would have a correlation with the market portfolio of +1.00. This is logical because complete diversification means the elimination of all the unsystematic or unique risk. Once this occurs, only systematic risk is left, which cannot be diversified away. Therefore, completely diversified portfolios would correlate perfectly with the market portfolio, which has only systematic risk.

**Diversification and the Elimination of Unsystematic Risk** As discussed in Chapter 7, the purpose of diversification is to reduce the standard deviation of the total portfolio. This assumes imperfect correlations among securities. Ideally, as you add securities, the average covariance for the portfolio declines. How many securities must be included to arrive at a completely diversified portfolio? For the answer, you must observe what happens as you increase the sample size of the portfolio by adding securities that have some positive correlation. The typical correlation between U.S. securities ranges from 0.20 to 0.60.

One set of studies examined the average standard deviation for numerous portfolios of randomly selected stocks of different sample sizes. Evans and Archer (1968) and Tole (1982) computed the standard deviation for portfolios of increasing size up to 20 stocks. The results indicated that the major benefits of diversification were achieved rather quickly, with about 90 percent of the maximum benefit of diversification derived from portfolios of 12 to 18 stocks. Exhibit 8.3 shows a stylized depiction of this effect.

Two subsequent studies have modified this finding. Statman (1987) considered the trade-off between the diversification benefits and additional transaction costs involved with increasing the size of a portfolio. He concluded that a well-diversified portfolio must contain at least

1For analyses of changes in the standard deviation (volatility) of returns for stocks and bonds in the United States, see Schwert (1989); Ineichen (2000); Reilly, Wright, and Chan (2000); and Ang, Hodrick, Xing, and Zhang (2006).
The variance of returns for a risky asset can similarly be described as

\[ \text{Var}(R_{it}) = \text{Var}(a_i + b_i R_M + \epsilon) = \text{Var}(a_i) + \text{Var}(b_i R_M) + \text{Var}(\epsilon) = 0 + \text{Var}(b_i R_M) + \text{Var}(\epsilon) \]

Note that \( \text{Var}(b_i R_M) \) is the variance of return for an asset related to the variance of the market return, or the asset’s systematic variance or risk. Also, \( \text{Var}(\epsilon) \) is the residual variance of return for the individual asset that is not related to the market portfolio. This residual variance is what we have referred to as the unsystematic or unique risk because it arises from the unique features of the asset. Therefore:

\[ \text{Var}(R_{it}) = \text{Systematic Variance} + \text{Unsystematic Variance} \]

We know that a completely diversified portfolio has had all of its unsystematic variance eliminated. Therefore, the unsystematic variance of an asset is not relevant to investors, because they can eliminate it when holding an asset as part of a broad-based portfolio. As a consequence, investors should not expect to receive compensation for bearing this unsystematic risk. Only the systematic variance is relevant because it cannot be diversified away.

8.1.4 Investing with the CML: An Example

After doing considerable research on current capital market conditions, you have estimated the investment characteristics for six different combinations of risky assets. Exhibit 8.4 lists your expected return and standard deviation forecasts for these portfolios. You have also established that each of these portfolios is completely diversified so that its volatility estimate represents systematic risk only. The risk-free rate at the time of your analysis is 4 percent.

Based on your forecasts for \( E(R) \) and \( \sigma \) alone, none of these portfolios clearly dominates the others since higher levels of expected return always come at the cost of higher levels of risk. Which portfolio offers the best trade-off between risk and return? The last column in Exhibit 8.4 calculates the ratio of the expected risk premium (\( E(R) - RFR \)) to volatility (\( \sigma \)) for each portfolio. As explained earlier, this ratio is the amount of compensation that investors can expect for each unit of risk they assume in a particular portfolio. For example, Portfolio 2 offers investors 0.429 (= \( \frac{7 - 4}{7} \)) units of compensation per unit of risk while the comparable ratio for Portfolio 6 is lower at 0.393 (= \( \frac{15 - 4}{28} \)), despite promising a much higher overall return.

By this measure, Portfolio 3 offers investors the best combination of risk and return. No other feasible collection of risky assets in this comparison can match the 0.500 units of expected risk premium per unit of risk. Consequently, Portfolio 3 should be considered as the market portfolio. Capital market theory would recommend that you only consider two

alternatives when investing your funds: (1) lending or borrowing in the riskless security at 4 percent, and (2) buying Portfolio 3.

Suppose now that given your risk tolerance you are willing to assume a standard deviation of 8.5 percent. How should you go about investing your money, according to the CML? First, using Equation 8.1, the return you can expect is:

\[ 4\% + (8.5\%) \times (0.500) = 8.25\% \]

As we have seen, there is no way for you to obtain a higher expected return under the current conditions without assuming more risk. Second, the investment strategy necessary to achieve this return can be found by solving:

\[ 8.25\% = w_{RF}(4\%) + (1 - w_{RF})(9\%) \]

or

\[ w_{RF} = \frac{9\% - 8.25\%}{9\% - 4\%} = 0.15. \]

This means that you would need to invest 15 percent of your funds in the riskless asset and the remaining 85 percent in Portfolio 3. Finally, notice that the expected risk premium per unit of risk for this position is 0.500 (\( \frac{8.25\% - 4\%}{8.5\%} \)), the same as Portfolio 3. In fact, all points along the CML will have the same risk-return trade-off as the market portfolio since this ratio is the slope of the CML.

As a last extension, consider what would happen if you were willing to take on a risk level of \( \sigma = 15\% \). From Exhibit 8.4, you could realize an expected return of 11 percent if you placed 100 percent of funds in Portfolio 4. However, you can do better than this by following the investment prescription of the CML. Specifically, for a risk level of 15 percent, you can obtain an expected return of:

\[ 4\% + (15\%) \times (0.500) = 11.5\% \]

This goal is greater than the expected return offered by a 100 percent investment in the market portfolio (i.e., 9 percent), so you will have to use leverage to achieve it. Specifically, solving for the investment weights along the CML leaves

\[ w_{RF} = \frac{9\% - 11.5\%}{9\% - 4\%} = -0.50 \]

and

\[ (1 - w_{RF}) = 1.50. \]

Thus, for each dollar you currently have to invest, you will need to borrow an additional 50 cents and place all of these funds in Portfolio 3.

The capital asset pricing model (CAPM) extends capital market theory in a way that allows investors to evaluate the risk-return trade-off for both diversified portfolios and individual securities. To do this, the CAPM redefines the relevant measure of risk from total volatility to just the nondiversifiable portion of that total volatility (i.e., systematic risk). This new risk measure is called the beta coefficient, and it calculates the level of a security’s systematic risk compared to that of the market portfolio. Using beta as the relevant measure of risk, the

alternatives when investing your funds: (1) lending or borrowing in the riskless security at 4 percent, and (2) buying Portfolio 3.

Suppose now that given your risk tolerance you are willing to assume a standard deviation of 8.5 percent. How should you go about investing your money, according to the CML? First, using Equation 8.1, the return you can expect is:

\[ 4\% + (8.5\%)(0.500) = 8.25\% \]

As we have seen, there is no way for you to obtain a higher expected return under the current conditions without assuming more risk. Second, the investment strategy necessary to achieve this return can be found by solving:

\[ 8.25\% = w_{RF}(4\%) + (1 - w_{RF})(9\%) \]

or \( w_{RF} = (9 - 8.25)/(9 - 4) = 0.15 \). This means that you would need to invest 15 percent of your funds in the riskless asset and the remaining 85 percent in Portfolio 3. Finally, notice that the expected risk premium per unit of risk for this position is 0.500 (= [8.25 - 4]/8.5), the same as Portfolio 3. In fact, all points along the CML will have the same risk-return trade-off as the market portfolio since this ratio is the slope of the CML.

As a last extension, consider what would happen if you were willing to take on a risk level of \( \sigma = 15 \) percent. From Exhibit 8.4, you could realize an expected return of 11 percent if you placed 100 percent of funds in Portfolio 4. However, you can do better than this by following the investment prescription of the CML. Specifically, for a risk level of 15 percent, you can obtain an expected return of:

\[ 4\% + (15\%)(0.500) = 11.5\% \]

This goal is greater than the expected return offered by a 100 percent investment in the market portfolio (i.e., 9 percent), so you will have to use leverage to achieve it. Specifically, solving for the investment weights along the CML leaves \( w_{RF} = (9 - 11.5)/(9 - 4) = -0.50 \) and \( (1 - w_{RF}) = 1.50 \). Thus, for each dollar you currently have to invest, you will need to borrow an additional 50 cents and place all of these funds in Portfolio 3.

### 8.2 The Capital Asset Pricing Model

Capital market theory represented a major step forward in how investors should think about the investment process. The formula for the CML (Equation 8.1) offers a precise way of calculating the return that investors can expect for (1) providing their financial capital (\( R_{RF} \)), and (2) bearing \( \sigma_{\text{port}} \) units of risk ((\( E(R_{M}) - R_{RF} \))/\( \sigma_{\text{port}} \)). This last term is especially significant because it expresses the expected risk premium prevailing in the marketplace.

Unfortunately, capital market theory is an incomplete explanation for the relationship that exists between risk and return. To understand why, recall that the CML defined the risk an investor bears by the total volatility (\( \sigma \)) of the investment. However, since investors cannot expect to be compensated for any portion of risk that they could have diversified away (i.e., unsystematic risk), the CML must be based on the assumption that investors only hold fully diversified portfolios, for which total risk and systematic risk are the same thing. The limitation is thus that the CML cannot provide an explanation for the risk-return trade-off for individual risky assets because the standard deviation for these securities will contain a substantial amount of unique risk.

The capital asset pricing model (CAPM) extends capital market theory in a way that allows investors to evaluate the risk-return trade-off for both diversified portfolios and individual securities. To do this, the CAPM redefines the relevant measure of risk from total volatility to just the nondiversifiable portion of that total volatility (i.e., systematic risk). This new risk measure is called the beta coefficient, and it calculates the level of a security’s systematic risk compared to that of the market portfolio. Using beta as the relevant measure of risk, the
8.2.2 The Security Market Line

The CAPM can also be illustrated in graphical form as the security market line (SML). This is shown in Exhibit 8.5. Like the CML, the SML shows the trade-off between risk and expected return as a straight line intersecting the vertical axis (i.e., zero-risk point) at the risk-free rate. However, there are two important differences between the CML and the SML. First, the CML measures risk by the standard deviation (i.e., total risk) of the investment while the SML considers only the systematic component of an investment’s volatility. Second, as a consequence of the first point, the CML can be applied only to portfolio holdings that are already fully diversified, whereas the SML can be applied to any individual asset or collection of assets.

Determining the Expected Rate of Return for a Risky Asset

To demonstrate how you would compute expected or required rates of return with the CAPM, consider the following example stocks, assuming you have already computed betas:

<table>
<thead>
<tr>
<th>Stock</th>
<th>Beta</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>0.70</td>
</tr>
<tr>
<td>B</td>
<td>1.00</td>
</tr>
<tr>
<td>C</td>
<td>1.15</td>
</tr>
<tr>
<td>D</td>
<td>1.40</td>
</tr>
<tr>
<td>E</td>
<td>-0.30</td>
</tr>
</tbody>
</table>

Assume that we expect the economy’s RFR to be 5 percent (0.05) and the expected return on the market portfolio (E(R_M)) to be 9 percent (0.09). This implies a market risk premium of 4 percent (0.04). With these inputs, the SML would yield the following required rates of return for these five stocks:

\[
E(R_i) = RFR + \beta_i \left[ \frac{E(R_M) - RFR}{\sigma_M} \right]
\]

For Stock A:

\[
E(R_A) = 0.05 + 0.70 \left( \frac{0.09 - 0.05}{\sigma_M} \right) = 0.078 = 7.80\%
\]

For Stock B:

\[
E(R_B) = 0.05 + 1.00 \left( \frac{0.09 - 0.05}{\sigma_M} \right) = 0.09 = 9.00\%
\]

8.2.1 A Conceptual Development of the CAPM

As noted earlier, Sharpe (1964), along with Lintner (1965) and Mossin (1966), developed the CAPM in a formal way. In addition to the assumptions listed before, the CAPM requires others, such as that asset returns come from a Normal probability distribution. Rather than a mathematical derivation of the CAPM, we will present a conceptual development of the model, emphasizing its role in the natural progression that began with the Markowitz portfolio theory.

Recall that the CML expressed the risk-return trade-off for fully diversified portfolios as follows:

\[
E(R_{port}) = RFR + \sigma_{port} \left[ \frac{E(R_M) - RFR}{\sigma_M} \right]
\]

When trying to extend this expression to allow for the evaluation of any individual risky asset i, the logical temptation is to simply replace the standard deviation of the portfolio (\(\sigma_{port}\)) with that of the single security (\(\sigma_i\)). However, this would overstate the relevant level of risk in the i\(^{th}\) security because it does not take into account how much of that volatility the investor could diversify away by combining that asset with other holdings. One way to address this concern is to “shrink” the level of \(\sigma_i\) to include only the portion of risk in Security i that is systematically related to the risk in the market portfolio. This can be done by multiplying \(\sigma_i\) by the correlation coefficient between the returns to Security i and the market portfolio (\(r_{im}\)). Inserting this product into the CML and adapting the notation for the i\(^{th}\) individual asset leaves:

\[
E(R_i) = RFR + (\sigma_i r_{im}) \left[ \frac{E(R_M) - RFR}{\sigma_M} \right]
\]

This expression can be rearranged as:

\[
E(R_i) = RFR + (\sigma_i r_{im}) \left[ \frac{E(R_M) - RFR}{\sigma_M} \right]
\]

or:

\[
E(R_i) = RFR + \beta_i [E(R_M) - RFR]
\]

Equation 8.4 is the CAPM. The CAPM redefines risk in terms of a security’s beta (\(\beta_i\)), which captures the nondiversifiable portion of that stock’s risk relative to the market as a whole. Because of this, beta can be thought of as indexing the asset’s systematic risk to that of the market portfolio. This leads to a very convenient interpretation: A stock with a beta of 1.20 has a level of systematic risk that is 20 percent greater than the average for the entire market, while a stock with a beta of 0.70 is 30 percent less risky than the market. By definition, the market portfolio itself will always have a beta of 1.00.

Indexing the systematic risk of an individual security to the market has another nice feature as well. From Equation 8.4, it is clear that the CAPM once again expresses the expected return for an investment as the sum of the risk-free rate and the expected risk premium. However, rather than calculate a different risk premium for every separate security that exists, the CAPM states that only the overall market risk premium (\(E(R_M) - RFR\)) matters and that this quantity can then be adapted to any risky asset by scaling it up or down according to that asset’s riskiness relative to the market (\(\beta_i\)). As we will see, this substantially reduces the number of calculations that investors must make when evaluating potential investments for their portfolios.
Stock A has lower risk than the aggregate market, so you should not expect its return to be as high as the return on the market portfolio. You should expect Stock A to return 7.80 percent. Stock B has systematic risk equal to the market’s (beta = 1.00), so its required rate of return should likewise be equal to the expected market return (9 percent). Stocks C and D have systematic risk greater than the market’s, so they should provide returns consistent with their risk. Finally, Stock E has a negative beta (which is quite rare in practice), so its required rate of return, if such a stock could be found, would be below the RFR of 5 percent.

In equilibrium, all assets and all portfolios of assets should plot on the SML. That is, all assets should be priced so that their estimated rates of return, which are the actual holding period rates of return that you anticipate, are consistent with their levels of systematic risk. Any security with an estimated rate of return that plots above the SML would be considered undervalued because it implies that you forecast receiving a rate of return on the security that is above its required rate of return based on its systematic risk. In contrast, assets with estimated rates of return that plot below the SML would be considered overvalued. This position relative to the SML implies that your estimated rate of return is below what you should require based on the asset’s systematic risk.

In an efficient market, you would not expect any assets to plot off the SML because, in equilibrium, all stocks should provide holding period returns that are equal to their required rates of return. Alternatively, a market that is not completely efficient may misprice certain assets because not everyone will be aware of all the relevant information. As discussed in Chapter 6, a superior investor has the ability to derive value estimates for assets that consistently outperform the consensus market evaluation. As a result, such an investor will earn better rates of return than the average investor on a risk-adjusted basis.

### Exhibit 8.5 The Security Market Line

The CAPM can also be illustrated in graphical form as the security market line (SML). This is shown in Exhibit 8.5. Like the CML, the SML shows the trade-off between risk and expected return as a straight line intersecting the vertical axis (i.e., zero-risk point) at the risk-free rate. However, there are two important differences between the CML and the SML. First, the CML measures risk by the standard deviation (i.e., total risk) of the investment while the SML considers only the systematic component of an investment’s volatility. Second, as a consequence of the first point, the CML can be applied only to portfolio holdings that are already fully diversified, whereas the SML can be applied to any individual asset or collection of assets.

**Determining the Expected Rate of Return for a Risky Asset** To demonstrate how you would compute expected or required rates of return with the CAPM, consider the following example stocks, assuming you have already computed betas:

<table>
<thead>
<tr>
<th>Stock</th>
<th>Beta</th>
</tr>
</thead>
<tbody>
<tr>

Assume that we expect the economy’s RFR to be 5 percent (0.05) and the expected return on the market portfolio (E(Rm)) to be 9 percent (0.09). This implies a market risk premium of 4 percent (0.04). With these inputs, the SML would yield the following required rates of return for these five stocks:

\[
E(R_A) = RFR + \beta_A [E(R_m) - RFR] \\
E(R_B) = 0.05 + 0.70(0.09 - 0.05) \\
= 0.078 = 7.80\% \\
E(R_C) = 0.05 + 1.15(0.09 - 0.05) \\
= 0.09 = 9.00\% \\
E(R_D) = 0.05 + 1.40(0.09 - 0.05) \\
= 0.10 = 10.00\% \\
E(R_E) = 0.05 + (-0.30)(0.09 - 0.05) \\
= 0.01 = 1.00\% \\
\]
Stock A has lower risk than the aggregate market, so you should not expect its return to be as high as the return on the market portfolio. You should expect Stock A to return 7.80 percent. Stock B has systematic risk equal to the market’s (beta = 1.00), so its required rate of return should likewise be equal to the expected market return (9 percent). Stocks C and D have systematic risk greater than the market’s, so they should provide returns consistent with their risk. Finally, Stock E has a negative beta (which is quite rare in practice), so its required rate of return, if such a stock could be found, would be below the RFR of 5 percent.

In equilibrium, all assets and all portfolios of assets should plot on the SML. That is, all assets should be priced so that their estimated rates of return, which are the actual holding period rates of return that you anticipate, are consistent with their levels of systematic risk. Any security with an estimated rate of return that plots above the SML would be considered undervalued because it implies that you forecast receiving a rate of return on the security that is above its required rate of return based on its systematic risk. In contrast, assets with estimated rates of return that plot below the SML would be considered overvalued. This position relative to the SML implies that your estimated rate of return is below what you should require based on the asset’s systematic risk.

In an efficient market, you would not expect any assets to plot off the SML because, in equilibrium, all stocks should provide holding period returns that are equal to their required rates of return. Alternatively, a market that is not completely efficient may misprice certain assets because not everyone will be aware of all the relevant information. As discussed in Chapter 6, a superior investor has the ability to derive value estimates for assets that consistently outperform the consensus market evaluation. As a result, such an investor will earn better rates of return than the average investor on a risk-adjusted basis.

**Identifying Undervalued and Overvalued Assets** Now that we understand how to compute the rate of return one should expect or require for a specific risky asset using the SML, we can compare this required rate of return to the asset’s estimated rate of return over a specific investment horizon to determine whether it would be an appropriate investment. To make this comparison, you need an independent estimate of the return outlook for the security based on either fundamental or technical analysis techniques, which will be discussed in subsequent chapters.

Assume that analysts at a major brokerage firm have been following the five stocks in the preceding example. Based on extensive fundamental analysis, they provide you with forecasted price and dividend information for the next year, as shown in Exhibit 8.6. Given these projections, you can compute an estimated rate of return for each stock by summing the expected capital gain \([P_{t+1} - P_1]/P_1\) and the expected dividend yield \(D_{t+1}/P_t\). For example, the analysts’ estimated future return for Stock A is 8.00 percent \(= (26 - 25)/25 + 1/25\).

Exhibit 8.7 summarizes the relationship between the required rate of return for each stock based on its systematic risk as computed earlier, and its estimated rate of return. This difference between estimated return and expected return is sometimes referred to as a stock’s expected alpha or its excess return. This alpha can be positive (the stock is undervalued) or negative (the stock is overvalued). If the alpha is zero (or nearly zero), the stock is on the SML and is properly valued in line with its systematic risk.
If you trusted these analysts to forecast estimated returns, you would take no action regarding Stock A, but you would buy Stocks C and E and sell Stocks B and D. You might even sell short Stocks B and D if you favored such aggressive tactics.

Calculating Systematic Risk

There are two ways that a stock's beta can be calculated in practice. First, given our conceptual discussion of the CAPM, a beta coefficient for Security \( i \) can be calculated directly from the following formula:

\[
\beta_i = \frac{\sigma_{i} \sigma_{M}}{\sigma_{M}^2} \exp \left( \frac{r_{im}}{\sigma_{M}^2} \right) = \text{Cov}(R_i, R_M) / \sigma_M^2
\]

where, in addition to the terms defined earlier, \( \sigma_M^2 \) is the return variance for the market portfolio and \( \text{Cov}(R_i, R_M) \) is the covariance between returns to the Security \( i \) and the market.

Alternatively, security betas can also be estimated as the slope coefficient in a regression equation between the returns to the security \( R_i \) over time and the returns \( R_M \) to the market portfolio:

\[
R_i = a_i + \beta_i (R_M) + \epsilon_i
\]

where \( a_i \) is the intercept of the regression and \( \epsilon_i \) is the random error term that accounts for Security \( i \)'s unsystematic risk. Equation 8.6 is known as the security's characteristic line with the market portfolio.

Equations 8.5 and 8.6 will produce the same estimate of \( \beta_i \) for any given sample of security and market portfolio returns. However, the regression-based method in Equation 8.6 is often preferred because it is a formal estimation process, meaning that the statistical reliability of the estimate can be assessed (i.e., a \( t \)-statistic on the \( \beta_i \) estimate can be evaluated).

The Impact of the Time Interval

In practice, the number of observations and the time interval used in the calculation of beta vary widely. For example, Morningstar derives characteristic lines for common stocks using monthly returns for the most recent five-year period (60 observations). Reuters Analytics calculates stock betas using daily returns over the prior two years (504 observations). Bloomberg uses two years of weekly returns (104 observations) in its basic calculations, although its system allows the user to select daily, weekly, monthly, quarterly, or annual returns over other time horizons. Because there is no theoretically correct time interval for this estimation, we must make a trade-off between enough observations to eliminate the impact of random rates of return and an excessive length of time, such as 15 or 20 years, over which the subject company may have changed dramatically. Remember that what you really want is the expected systematic risk for the potential investment. In this process, you are analyzing historical data to help you derive a reasonable estimate of the asset's future level of systematic risk.

Reilly and Wright (1988) analyzed the differential effects of return computation, market index, and the time interval and showed that the major cause of the differences in beta was the use of monthly versus weekly return intervals. Also, the shorter weekly interval caused a larger beta for large firms and a smaller beta for small firms. Handa, Kothari, and Wasley (1989) showed that the reason for this result was that an asset's covariance with the market and the market's return variance did not change proportionally with the return interval.

The Effect of the Market Proxy

Another significant decision when computing an asset's characteristic line is which indicator series to use as a proxy for the market portfolio of all risky assets. Many investigators use the Standard & Poor's 500 Composite Index as a proxy for the market portfolio because the stocks in this index encompass a large proportion of the total market value of U.S. stocks and it is a value-weighted series, which is consistent with the theoretical market series. Still, this series is dominated by large-cap U.S. stocks, most of them

Plotting these estimated rates of return and stock betas on the SML gives Exhibit 8.8. Stock A is almost exactly on the line, so it is considered properly valued because its estimated rate of return is almost equal to its required rate of return. Stocks B and D are considered overvalued because their estimated rates of return during the coming period are substantially less than what an investor should expect for the risk involved. As a result, they plot below the SML. In contrast, Stocks C and E are expected to provide rates of return greater than we would require based on their systematic risk. Therefore, both stocks plot above the SML, indicating that they are undervalued.

### Exhibit 8.8 Plot of Estimated Returns on SML Graph
If you trusted these analysts to forecast estimated returns, you would take no action regarding Stock A, but you would buy Stocks C and E and sell Stocks B and D. You might even sell short Stocks B and D if you favored such aggressive tactics.

**Calculating Systematic Risk** There are two ways that a stock’s beta can be calculated in practice. First, given our conceptual discussion of the CAPM, a beta coefficient for Security i can be calculated directly from the following formula:

\[
\beta_i = \frac{\text{Cov}(R_i, R_M)}{\sigma_M^2}
\]

where, in addition to the terms defined earlier, \(\sigma_M^2\) is the return variance for the market portfolio and \(\text{Cov}(R_i, R_M)\) is the covariance between returns to the Security i and the market.

Alternatively, security betas can also be estimated as the slope coefficient in a regression equation between the returns to the security \(R_i\) over time and the returns \(R_M\) to the market portfolio:

\[
R_i = \alpha_i + \beta_i R_M + \epsilon_i
\]

where \(\alpha_i\) is the intercept of the regression and \(\epsilon_i\) is the random error term that accounts for Security i's unsystematic risk. Equation 8.6 is known as the security’s characteristic line with the market portfolio.

Equations 8.5 and 8.6 will produce the same estimate of \(\beta_i\) for any given sample of security and market portfolio returns. However, the regression-based method in Equation 8.6 is often preferred because it is a formal estimation process, meaning that the statistical reliability of the estimate can be assessed (i.e., a t-statistic on the \(\beta_i\) estimate can be evaluated).

**The Impact of the Time Interval** In practice, the number of observations and the time interval used in the calculation of beta vary widely. For example, Morningstar derives characteristic lines for common stocks using monthly returns for the most recent five-year period (60 observations). Correlation Coeff. (JPM, SPX) = \frac{27.73}{5.09 \times 6.39} = 0.85
Correlation Coeff. (JPM, MXWO) = \frac{27.80}{5.38 \times 6.39} = 0.81

How does this analysis change if we use a different market proxy? Exhibit 8.9 also lists calculations for the JPM beta using a global equity index as a market portfolio. Two things are notable when this substitution is made. First, the volatility of the MSCI World Index (28.92) was somewhat larger than the S&P 500 over this period. Second, the covariance between JPM and MXWO (27.80) is virtually the same, although the overall correlation coefficient between the two is lower (0.81) than between JPM and SPX. Taken together, the higher volatility of the World Index has the greatest effect so the beta coefficient between JPM and MXWO is 0.96, which is lower than when the S&P 500 was used as the market proxy. In fact, notice that the interpretation of the nature of JPM’s relative systematic risk changes with this new index. Rather than being 7 percent more risky than the domestic equity market, JPM is now seen as being 4 percent less risky than the global index.

Beyond demonstrating the computations involved in the process, the important point illustrated in this example is that the proper selection of a proxy for the market portfolio is of vital importance when measuring risk. Reilly and Akhtar (1995) showed that beta differences of this magnitude are to be expected when comparing the stock of any company to both U.S. and world equity indexes. Further, even more extreme differences are possible when stock betas are calculated relative to market proxies that contain other asset classes, such as fixed-income securities or real estate.

---

2Substantial discussion surrounds the market proxy used and its impact on the empirical results and usefulness of the CAPM. This concern is discussed further and demonstrated in the subsequent section on computing an asset’s characteristic line. The effect of the market proxy is also considered when we discuss the arbitrage pricing theory (APT) in Chapter 9 and in Chapter 25 when we discuss the evaluation of portfolio performance.

3The returns used in this example are based solely on monthly price changes for JPM and two indexes (S&P 500 and MSCI World Equity); they do not include dividends. This is done for simplicity, but it is also based on Sharpe and Cooper’s (1972a) finding that betas derived from returns with and without dividends have a correlation coefficient of 0.99.

Industry Characteristic Lines

Characteristic lines can also be calculated for entire portfolios of stocks, such as market or sector indexes. Exhibit 8.12 summarizes a set of computations over the December 2009–November 2010 period for nine different industry segments comprising the overall stock market: Materials, Health Care, Consumer Staples, Consumer Discretionary, Energy, Financials, Industrials, Technology, and Utilities. Each of these industry segments is represented by a different index of companies that operate primarily in that area. For instance, leading firms such as Monsanto (Materials), Procter & Gamble (Consumer Staples), Amazon.com (Consumer Discretionary), and Apple (Technology) are divided into separate portfolios. JPMorgan, from the previous example, is included in the Financials industry index.

Notice that each of these industry indexes is highly correlated with the designated overall market portfolio (i.e., the Standard & Poor’s 500). The correlation coefficients range from 0.70 to 0.98, with seven of the nine industries having coefficients in excess of 0.90. This indicates that these industry indexes are well-diversified portfolios that have eliminated most of their unsystematic risk. On the other hand, the beta coefficients (i.e., the level of systematic risk relative to the market) for these industries vary widely. Some industries, such as Health Care (0.58) and Consumer Staples (0.60), are about 40 percent less risky than the overall market, and so investors should expect a lower level of compensation from companies in these areas. By contrast, Consumer Discretionary (1.18) and Technology (1.20) stocks are, on average, about 20 percent riskier than the market, meaning that the CAPM would predict an expected risk premium that is 20 percent larger than average.

8.3 RELAXING THE ASSUMPTIONS

Earlier in the chapter, we listed several assumptions related to the CAPM. In this section, we discuss the impact on the capital market line (CML) and the security market line (SML) when we relax several of these assumptions.

8.3.1 Differential Borrowing and Lending Rates

One of the first assumptions of the CAPM was that investors could borrow and lend any amount of money at the risk-free rate. It is reasonable to assume that investors can lend unlimited amounts at the risk-free rate by buying government securities (e.g., T-bills). In contrast, it is quite unlikely that investors can borrow unlimited amounts at the T-bill rate. For example, when T-bills are yielding 4 percent, most individuals would have to pay about 6 or 7 percent to borrow at a bank.

Exhibit 8.10 Characteristic Line and Scatterplot of JPMorgan Chase (JPM) with the S&P 500 Index (SPX): December 2009–November 2010

Exhibit 8.11 Characteristic Line and Scatterplot of JPMorgan Chase (JPM) with the MSCI World Index (MXWO): December 2009–November 2010
Because of this differential, there will be two different lines going to the Markowitz efficient frontier, as shown in Exhibit 8.13. The segment \( RFR - F \) indicates the investment opportunities available when an investor combines risk-free assets (i.e., lending at the \( RFR \)) and Portfolio F on the Markowitz efficient frontier. It is not possible to extend this line any farther if you cannot borrow at this risk-free rate to acquire further units of Portfolio F. If you can borrow at \( Rb \), the point of tangency from this rate would be on the curve at Portfolio K. This indicates that you could borrow at \( Rb \) and use the proceeds to invest in Portfolio K to extend the CML along the line segment K – G.

Therefore, the CML is made up of \( RFR - F \) – K – G; that is, a line segment \( RFR - F \), a curve segment \( F - K \), and another line segment \( K - G \). As noted by Brennan (1969), this implies that you can either lend or borrow, but the borrowing portfolios are not as profitable as when it was assumed that you could borrow at the \( RFR \).

In this instance, your net return is less and the slope of the borrowing line \( K - G \) is below that for \( RFR - F \).

Because of this differential, there will be two different lines going to the Markowitz efficient frontier, as shown in Exhibit 8.13. The segment $RFR–F$ indicates the investment opportunities available when an investor combines risk-free assets (i.e., lending at the $RFR$) and Portfolio F on the Markowitz efficient frontier. It is not possible to extend this line any farther if you cannot borrow at this risk-free rate to acquire further units of Portfolio F. If you can borrow at $R_b$, the point of tangency from this rate would be on the curve at Portfolio K. This indicates that you could borrow at $R_b$ and use the proceeds to invest in Portfolio K to extend the CML along the line segment K–G. Therefore, the CML is made up of $RFR–F$–K–G; that is, a line segment ($RFR–F$), a curve segment (F–K), and another line segment (K–G). As noted by Brennan (1969), this implies that you can either lend or borrow, but the borrowing portfolios are not as profitable as when it was assumed that you could borrow at the $RFR$. In this instance, your net return is less and the slope of the borrowing line (K–G) is below that for $RFR–F$.

### 8.3.2 Zero-Beta Model

If the market portfolio (M) is mean-variance efficient (i.e., it has the lowest risk for a given level of return among the attainable set of portfolios), an alternative model, derived by Black (1972), does not require a risk-free asset. Within the set of feasible alternative portfolios, several exist where the returns are completely uncorrelated with the market portfolio; the beta of these portfolios with the market portfolio is zero. Among the several zero-beta portfolios, you would select the one with minimum variance. Although this portfolio does not have any systematic risk, it may have some unsystematic risk. The availability of this zero-beta portfolio will not affect the CML, but it will allow construction of a linear SML, as shown in Exhibit 8.14. The combinations of this zero-beta portfolio and the market portfolio will be a linear relationship in return and risk because the covariance between the zero-beta portfolio ($R_b$) and the market portfolio is similar to what it was with the risk-free asset. Assuming the return for the zero-beta portfolio is greater than that for a risk-free asset, the slope of the line through...
8.3.4 Heterogeneous Expectations and Planning Periods

If all investors had different expectations about risk and return, each would have a unique CML or SML, and the composite graph would be a group of lines with a breadth determined by the divergence of expectations. If all investors had similar information and background, the width of the group would be reasonably narrow. Chiarella, Dieci, and He (2010) develop an extension of the CAPM where investors are grouped by similar beliefs.

The impact of planning periods is similar. Recall that the CAPM is a one-period model, corresponding to the planning period for the individual investor. Thus, if you are using a one-year planning period, your CML and SML could differ from someone with a one-month planning period.

8.3.5 Taxes

The expected returns in the CAPM are pretax returns. In fact, the actual returns for most investors are affected as follows:

\[
E(R_i) = \frac{P_e - P_b}{P_b} \times (1 - T_{cg}) + \text{Div} \times (1 - T_i)
\]

where:

\[
E(R_i) = \text{after-tax rate of return} \\
P_e = \text{ending price} \\
P_b = \text{beginning price} \\
T_{cg} = \text{tax on capital gain or loss} \\
\text{Div} = \text{dividend paid during period} \\
T_i = \text{tax on ordinary income}
\]

Several studies have tested this model with its higher intercept and flatter slope and had conflicting results. Specifically, Gibbons (1982) and Shanken (1985b) rejected the model, while Stambaugh (1982) supported the zero-beta CAPM.

8.3.3 Transaction Costs

The CAPM assumes that there are no transaction costs, so investors will buy or sell mispriced securities until they plot on the SML. If there are transaction costs, investors will not correct all mispricing because in some instances the cost of buying and selling the mispriced security will exceed any potential excess return. Therefore, securities will plot very close to the SML, but not exactly on it. Thus, the SML will be a band, as shown in Exhibit 8.15, rather than a single line. Obviously, the width of the band is a function of the amount of the transaction costs. In a world with a large proportion of trading by institutions at pennies per share and with discount brokers available for individual investors, the band should be quite narrow.

Dimson (1979) considered how transaction costs affect the extent of diversification by investors. Earlier in the chapter, we discussed the relationship between the number of stocks in a portfolio and the variance of the portfolio. Initially, the variance declined rapidly, approaching about 90 percent of complete diversification with around 20 securities. An important question is: How many securities must be added to derive the last 10 percent? Because of transaction costs, Brennan and Subramanyam (1996) show that at some point the additional cost of diversification would exceed its benefit, especially when considering the costs of monitoring and analyzing the added securities. Degennaro and Robotti (2007) demonstrate that transaction costs can reduce the slope of the CML.
8.3.4 Heterogeneous Expectations and Planning Periods
If all investors had different expectations about risk and return, each would have a unique CML or SML, and the composite graph would be a group of lines with a breadth determined by the divergence of expectations. If all investors had similar information and background, the width of the group would be reasonably narrow. Chiarella, Dieci, and He (2010) develop an extension of the CAPM where investors are grouped by similar beliefs.

The impact of planning periods is similar. Recall that the CAPM is a one-period model, corresponding to the planning period for the individual investor. Thus, if you are using a one-year planning period, your CML and SML could differ from someone with a one-month planning period.

8.3.5 Taxes
The expected returns in the CAPM are pretax returns. In fact, the actual returns for most investors are affected as follows:

\[ E(R_i(\text{AT})) = \frac{(P_e - P_b) \times (1 - T_{cg}) + (\text{Div}) \times (1 - T_i)}{P_b} \]

where:

- \( R_i(\text{AT}) \) = after-tax rate of return
- \( P_e \) = ending price
- \( P_b \) = beginning price
- \( T_{cg} \) = tax on capital gain or loss
- \( \text{Div} \) = dividend paid during period
- \( T_i \) = tax on ordinary income
Clearly, tax rates differ between individuals and institutions. For institutions that do not pay taxes, the original pretax model is correctly specified—that is, $T_g$ and $T_i$ are zero. As noted by Black and Scholes (1979) and Litzenberger and Ramaswamy (1979), because investors have heavy tax burdens, this could cause major differences in the CML and SML among investors. Elton, Gruber, and Rentzler (1983); Miller and Scholes (1982); and Christie (1990) have examined the effect of the differential taxes on dividends versus capital gains, but the evidence is inconclusive.

### 8.4 Additional Empirical Tests of the CAPM

When testing the CAPM, there are two major questions. First, *How stable is the measure of systematic risk (beta)?* Because beta is our principal risk measure, it is important to know whether past betas can be used as estimates of future betas. Second, *Is there a positive linear relationship as hypothesized between beta and the rate of return on risky assets?* That is, how well do returns conform to the SML? Some specific questions might include:

- Does the intercept approximate the prevailing RFR?
- Was the slope of the line positive and was it consistent with the slope implied by the prevailing risk premium $(E(R_m) - RFR)$?

#### 8.4.1 Stability of Beta

Numerous studies have examined the stability of beta and generally concluded that the risk measure was *not* stable for individual stocks, but was stable for portfolios of stocks. Further, the larger the portfolio (e.g., over 50 stocks) and the longer the period (over 26 weeks), the more stable the beta estimate. Also, the betas tended to regress toward the mean. Specifically, high-beta portfolios tended to decline over time toward 1.00, whereas low-beta portfolios tended to increase over time toward unity.

Carpenter and Upton (1981) considered the influence of the trading volume on beta stability and contended that predictions were slightly better using the volume-adjusted betas. Ilbotson, Kaplan, and Peterson (1997) showed that the beta for low-volume securities was biased downward.

#### 8.4.2 Relationship between Systematic Risk and Return

The ultimate question regarding the CAPM is whether it is useful in explaining the return on risky assets. Specifically, is there a positive linear relationship between the systematic risk and the rates of return on these risky assets? Sharpe and Cooper (1972b) found a positive relationship between return and risk, although it was not completely linear. Black, Jensen, and Scholes (1972) examined the risk and return for portfolios of stocks and found a positive linear relationship between monthly excess return and portfolio beta, although the intercept was higher than zero. Exhibit 8.16 contains charts from this study, which show that (1) most of the measured SMLs had a positive slope, (2) the slopes change between periods, (3) the intercepts are not zero, and (4) the intercepts change between periods.

**Effect of Skewness on the Relationship** Beyond the analysis of return and beta, several authors have considered the impact of skewness on expected returns. Skewness reflects the presence of too many large positive or negative observations in a distribution. A normal distribution is symmetric, which means that balance exists between positive and negative observations. In contrast, positive skewness indicates an abnormal number of large positive price changes.

Investigators contended that skewness helped explain why the CAPM appeared to under-price low-beta stocks (so investors received returns above expectations) and over-price
Bhandari (1988) found that financial leverage also helps explain the cross section of average returns after both beta and size are considered. This suggests a multivariate CAPM with three risk variables: beta, size, and financial leverage.

**Effect of Book-to-Market Value**

Fama and French (1992) evaluated the joint roles of market beta, size, \(E/P\), financial leverage, and the book-to-market equity ratio in the cross section of average returns on the NYSE, AMEX, and NASDAQ stocks. While some earlier studies found a significant positive relationship between returns and beta, this study finds that the relationship between beta and the average rate of return disappears during the period 1963 to 1990, even when beta is used alone to explain average returns. In contrast, univariate tests between average returns and size, leverage, \(E/P\), and book-to-market equity (\(BE/ME\)) indicate that all of these variables are significant and have the expected sign.

In the multivariate tests, the results showed that the negative relationship between size and average returns is robust to the inclusion of other variables. Further, the positive relation between book-to-market equity ratio (\(BE/ME\)) and average returns also persists when the other variables are included. Interestingly, when both of these variables are included, the \(BE/ME\) has the consistently stronger role in explaining average returns.

Fama and French concluded that size and book-to-market equity capture the cross-sectional variation in average stock returns associated with size, \(E/P\), book-to-market equity, and leverage. Moreover, of the two variables, \(BE/ME\) appears to subsume \(E/P\) and leverage. Following these results, Fama and French (1993) suggested the use of a three-factor CAPM model. This model was used by Fama and French (1996) to explain a number of the anomalies from prior studies.

**8.4.3 Summary of CAPM Risk-Return Empirical Results**

Most of the early evidence regarding the relationship between returns and systematic risk of portfolios supported the CAPM; there was evidence that the intercepts were generally higher than implied by the \(RFR\) that prevailed, which is either consistent with a zero-beta model or the existence of higher borrowing rates. To explain these unusual returns, additional variables were considered, including the third moment of the distribution (skewness). The results indicated that positive skewness and high betas were correlated. There is also extensive evidence that size, the \(P/E\) ratio, financial leverage, and the book-to-market value ratio have explanatory power regarding returns beyond beta. The Fama-French study concluded that the two dominant variables were size and the book-value to market-value ratio.

In contrast to Fama and French, who measure beta with monthly returns, Kothari, Shanken, and Sloan (1995) measured beta with annual returns and found substantial compensation for beta risk. They suggested that the results obtained by Fama and French may have been time period specific and might not be significant over a longer period. Pettengill, Dundaram, and Matthur (1995) noted that empirical studies typically use realized returns to test the CAPM model when theory specifies expected returns. When they adjusted for negative market excess returns, they found a consistent and significant relationship between beta and rates of return. When Jagannathan and Wang (1996) employed a conditional CAPM that allows for changes in betas and in the market risk premium, this model performed well in explaining the cross section of returns. Grundy and Malkiel (1996) also contend that beta is a very useful measure of risk during declining markets, which is when it is most important. Finally, when Reilly and Wright (2004) examined the risk-adjusted performance for 31 different asset classes utilizing betas computed using a very broad proxy for the market portfolio, the risk-return relationship was significant and as expected by theory.

This three-factor model by Fama and French is discussed further and demonstrated in Chapter 9, which deals with multifactor models of risk and return.

High-beta stocks (so investors received returns lower than expected). Also, high-beta stocks have high-positive skewness, which implied that investors prefer stocks with high-positive skewness that provide an opportunity for very large returns. Kraus and Litzenberger (1976) tested a version of the CAPM that included a skewness term and confirmed that investors are willing to pay for positive skewness. The importance of skewness was supported by Sears and Wei (1988) and Lim (1989).

**Effect of Size, \(P/E\), and Leverage** In Chapter 6, we discussed the size effect (the small-firm anomaly) and the \(P/E\) effect and showed that these variables have an inverse impact on returns after considering the CAPM. These results imply that size and \(P/E\) are additional risk factors that need to be considered along with beta. Specifically, expected returns are a positive function of beta, but investors also require higher returns from relatively small firms and for stocks with relatively low \(P/E\) ratios.
Throughout our presentation of the CAPM, we noted that the market portfolio included all the risky assets in the economy. Further, in equilibrium, assets would be included in the portfolio in proportion to their market value. Therefore, this market portfolio should contain not only U.S. stocks and bonds but also real estate, options, art, foreign stocks and bonds, and so on, with weights equal to their relative market value.

Although this concept is reasonable in theory, it is difficult to implement when testing or using the CAPM. The easy part is getting an index series for U.S. and foreign stocks and bonds. Because of the difficulty in deriving series that are available monthly in a timely fashion for numerous other assets, most studies have been limited to using a stock or bond series alone. In fact, the vast majority of studies have chosen an index limited to just U.S. stocks, which constitutes less than 15 percent of a truly global risky asset portfolio. It is then assumed that the particular series used as a proxy for the market portfolio was highly correlated with the true market portfolio.

Most researchers recognize this potential problem but assume that the deficiency is not serious. Roll (1977a, 1978, 1980, 1981), however, concluded that the use of these indexes as a proxy for the market portfolio had very serious implications for tests of the CAPM and especially for using the model when evaluating portfolio performance. He referred to this problem as a benchmark error because the practice is to compare the performance of a portfolio manager to the return of an unmanaged portfolio of equal risk—that is, the market portfolio adjusted for risk would be the benchmark. Roll’s point is that, if the benchmark is incorrectly specified, you cannot measure the performance of a portfolio manager properly. A misspecified market portfolio can have two effects. First, the beta computed for investor portfolios would be wrong because the market portfolio used to compute the portfolio’s systematic risk is inappropriate. Second, the SML derived would be wrong because it goes through the improperly specified M portfolio.

Exhibit 8.17 illustrates this second problem by showing that the intercept and slope of the SML will differ if (1) there is an error in selecting a proper risk-free asset and (2) if the market portfolio selected is not the correct mean-variance efficient portfolio. Obviously, it is very possible that under these conditions, a portfolio judged to be superior relative to the first SML (i.e., the portfolio plotted above the measured SML) could be inferior relative to the true SML (i.e., the portfolio would plot below the true SML).

Roll contends that a test of the CAPM requires an analysis of whether the proxy used to represent the market portfolio falls on the Markowitz efficient frontier and whether it is the true optimum market portfolio. Roll showed that if the proxy market portfolio (e.g., the S&P 500 index) is mean-variance efficient, it is mathematically possible to show a linear relationship between returns and betas derived with this portfolio.

A demonstration of the impact of the benchmark problem is provided in a study by Reilly and Akhtar (1995). Exhibit 8.18 shows the substantial difference in average beta for the 30 stocks in the DJIA during three alternative periods using two different proxies for the market portfolio: (1) the S&P 500 Index, and (2) the Brinson Partners Global Security Market Index (GSMI) that includes U.S. and non-U.S. stocks and bonds. The results are as expected because as we change from an all-U.S. stock index to a world stock and bond index (GSMI), we would expect the covariance with U.S. stocks to decline. The other component of beta is the variance for the market portfolio. As shown in Exhibit 8.18, although the covariance between the U.S. stocks and the GSMI is lower, the variance of the GSMI market portfolio is substantially lower (about 25 to 33 percent). As a result, the beta is substantially larger (about 27 to 48 percent larger) when the Brinson GSMI is used rather than the S&P 500 Index. Of course, the Brinson GSMI has a composition of assets that is substantially closer to the true M portfolio than the S&P 500 proxy that contains only U.S. stocks.

Bhandari (1988) found that financial leverage also helps explain the cross section of average returns after both beta and size are considered. This suggests a multivariate CAPM with three risk variables: beta, size, and financial leverage.

**Effect of Book-to-Market Value** Fama and French (1992) evaluated the joint roles of market beta, size, E/P, financial leverage, and the book-to-market equity ratio in the cross section of average returns on the NYSE, AMEX, and NASDAQ stocks. While some earlier studies found a significant positive relationship between returns and beta, this study finds that the relationship between beta and the average rate of return disappears during the period 1963 to 1990, even when beta is used alone to explain average returns. In contrast, univariate tests between average returns and size, leverage, E/P, and book-to-market equity (BE/ME) indicate that all of these variables are significant and have the expected sign.

In the multivariate tests, the results showed that the negative relationship between size and average returns is robust to the inclusion of other variables. Further, the positive relation between book-to-market equity ratio (BE/ME) and average returns also persists when the other variables are included. Interestingly, when both of these variables are included, the BE/ME has the consistently stronger role in explaining average returns.

Fama and French concluded that size and book-to-market equity capture the cross-sectional variation in average stock returns associated with size, E/P, book-to-market equity, and leverage. Moreover, of the two variables, BE/ME appears to subsume E/P and leverage. Following these results, Fama and French (1993) suggested the use of a three-factor CAPM model. This model was used by Fama and French (1996) to explain a number of the anomalies from prior studies.\(^a\)

### 8.4.3 Summary of CAPM Risk-Return Empirical Results

Most of the early evidence regarding the relationship between returns and systematic risk of portfolios supported the CAPM; there was evidence that the intercepts were generally higher than implied by the RFR that prevailed, which is either consistent with a zero-beta model or the existence of higher borrowing rates. To explain these unusual returns, additional variables were considered, including the third moment of the distribution (skewness). The results indicated that positive skewness and high betas were correlated. There is also extensive evidence that size, the P/E ratio, financial leverage, and the book-to-market value ratio have explanatory power regarding returns beyond beta. The Fama-French study concluded that the two dominant variables were size and the book-value to market-value ratio.

In contrast to Fama and French, who measure beta with monthly returns, Kothari, Shanken, and Sloan (1995) measured beta with annual returns and found substantial compensation for beta risk. They suggested that the results obtained by Fama and French may have been time period specific and might not be significant over a longer period. Pettengill, Dundaram, and Mathur (1995) noted that empirical studies typically use realized returns to test the CAPM model when theory specifies expected returns. When they adjusted for negative market excess returns, they found a consistent and significant relationship between beta and rates of return. When Jagannathan and Wang (1996) employed a conditional CAPM that allows for changes in betas and in the market risk premium, this model performed well in explaining the cross section of returns. Grundy and Malkiel (1996) also contend that beta is a very useful measure of risk during declining markets, which is when it is most important. Finally, when Reilly and Wright (2004) examined the risk-adjusted performance for 31 different asset classes utilizing betas computed using a very broad proxy for the market portfolio, the risk-return relationship was significant and as expected by theory.

\(^a\)This three-factor model by Fama and French is discussed further and demonstrated in Chapter 9, which deals with multifactor models of risk and return.
8.5 The Market Portfolio: Theory versus Practice

Throughout our presentation of the CAPM, we noted that the market portfolio included all the risky assets in the economy. Further, in equilibrium, assets would be included in the portfolio in proportion to their market value. Therefore, this market portfolio should contain not only U.S. stocks and bonds but also real estate, options, art, foreign stocks and bonds, and so on, with weights equal to their relative market value.

Although this concept is reasonable in theory, it is difficult to implement when testing or using the CAPM. The easy part is getting an index series for U.S. and foreign stocks and bonds. Because of the difficulty in deriving series that are available monthly in a timely fashion for numerous other assets, most studies have been limited to using a stock or bond series alone. In fact, the vast majority of studies have chosen an index limited to just U.S. stocks, which constitutes less than 15 percent of a truly global risky asset portfolio. It is then assumed that the particular series used as a proxy for the market portfolio was highly correlated with the true market portfolio.

Most researchers recognize this potential problem but assume that the deficiency is not serious. Roll (1977a, 1978, 1980, 1981), however, concluded that the use of these indexes as a proxy for the market portfolio had very serious implications for tests of the CAPM and especially for using the model when evaluating portfolio performance. He referred to this problem as a benchmark error because the practice is to compare the performance of a portfolio manager to the return of an unmanaged portfolio of equal risk—that is, the market portfolio adjusted for risk would be the benchmark. Roll’s point is that, if the benchmark is incorrectly specified, you cannot measure the performance of a portfolio manager properly. A misspecified market portfolio can have two effects. First, the beta computed for investor portfolios would be wrong because the market portfolio used to compute the portfolio’s systematic risk is inappropriate. Second, the SML derived would be wrong because it goes through the improperly specified M portfolio.

Exhibit 8.17 illustrates this second problem by showing that the intercept and slope of the SML will differ if (1) there is an error in selecting a proper risk-free asset and (2) if the market portfolio selected is not the correct mean-variance efficient portfolio. Obviously, it is very possible that under these conditions, a portfolio judged to be superior relative to the first SML (i.e., the portfolio plotted above the measured SML) could be inferior relative to the true SML (i.e., the portfolio would plot below the true SML).

Roll contends that a test of the CAPM requires an analysis of whether the proxy used to represent the market portfolio falls on the Markowitz efficient frontier and whether it is the true optimum market portfolio. Roll showed that if the proxy market portfolio (e.g., the S&P 500 index) is mean-variance efficient, it is mathematically possible to show a linear relationship between returns and betas derived with this portfolio.

A demonstration of the impact of the benchmark problem is provided in a study by Reilly and Akhtar (1995). Exhibit 8.18 shows the substantial difference in average beta for the 30 stocks in the DJIA during three alternative periods using two different proxies for the market portfolio: (1) the S&P 500 Index, and (2) the Brinson Partners Global Security Market Index (GSMI) that includes U.S. and non-U.S. stocks and bonds. The results are as expected because as we change from an all-U.S. stock index to a world stock and bond index (GSMI), we would expect the covariance with U.S. stocks to decline. The other component of beta is the variance for the market portfolio. As shown in Exhibit 8.18, although the covariance between the U.S. stocks and the GSMI is lower, the variance of the GSMI market portfolio is substantially lower (about 25 to 33 percent). As a result, the beta is substantially larger (about 27 to 48 percent larger) when the Brinson GSMI is used rather than the S&P 500 Index. Of course, the Brinson GSMI has a composition of assets that is substantially closer to the true M portfolio than the S&P 500 proxy that contains only U.S. stocks.
There also was a difference in the SMLs implied by each of the market proxies. Exhibit 8.19 contains the average RFR, the market returns, and the slope of the SML during three time periods for the two indexes. Clearly, the slopes differ dramatically for the alternative indexes and over time. Needless to say, the benchmark used does make a difference.

In summary, an incorrect market proxy will affect both the beta risk measure and the position and slope of the SML that is used to evaluate portfolio performance. In general, the errors will tend to overestimate the performance of portfolio managers because the proxy used for the market portfolio is probably not as efficient as the true market portfolio, so the slope of the SML will be underestimated. Also, the beta measure generally will be underestimated because the true market portfolio will have a lower variance than the typical market proxy because the true market portfolio is more diversified. However, recognize that benchmark problems do not invalidate the CAPM as a normative model of asset pricing; they only indicate a problem in measurement when attempting to test the theory and when using this model for evaluating portfolio performance.

**Summary**

Capital market theory expanded the concepts introduced by Markowitz portfolio theory by introducing the notion that investors could borrow or lend at the risk-free rate in addition to forming efficient portfolios of risky assets. This insight led to the development of the capital market line (CML), which can be viewed as a new efficient frontier that emanates from the risk-free rate and is tangent to the Markowitz efficient frontier. The point of tangency is called the market portfolio.

The CML’s main contribution is the relationship it specifies between the risk and expected return of a well-diversified portfolio. The CML makes it clear that the market portfolio is the single collection of risky assets that maximizes the ratio of expected risk premium to portfolio volatility. The investment prescription of the CML is that investors cannot do better, on average, than when they divide their investment funds between (1) the riskless asset and (2) the market portfolio.

The CML is a model of the risk–return trade-off that only applies to portfolios that have diversified away all unsystematic risk. The capital asset pricing model (CAPM) generalizes this relationship to individual securities as well as entire portfolios. To make this extension, the CAPM redefines the relevant measure of risk as beta, which is the systematic component of a security’s volatility relative to that of the market portfolio. Like the CML, the security market line (SML) shows that the relationship between risk and expected return is a straight line with a positive slope. The SML provides investors with a tool for judging whether securities are undervalued or overvalued given their level of systematic (beta) risk.

The CAPM has been subjected to extensive empirical testing with mixed findings. Early tests substantiated the positive relationship between returns and measures of systematic risk, although subsequent studies indicated that the single-beta model needed to be supplemented with additional dimensions of risk (e.g., skewness, firm size, P/E, book value/market value). Another challenge confronting the CAPM in practice is the benchmark error problem that results from improperly specifying a proxy for the market portfolio.

**QUESTIONS**

1. Draw a graph that shows what happens to the Markowitz efficient frontier when you combine a risk-free asset with alternative risky asset portfolios on the Markowitz efficient frontier. Explain why the line from the RFR that is tangent to the efficient frontier defines the dominant set of portfolio possibilities.

2. What changes would you expect in the standard deviation for a portfolio of between 4 and 10 stocks, between 10 and 20 stocks, and between 50 and 100 stocks?

3. The capital asset pricing model (CAPM) contends that there is systematic and unsystematic risk for an individual security. Which is the relevant risk variable and why is it relevant? Why is the other risk variable not relevant?

4. What are the similarities and differences between the CML and SML as models of the risk-return trade-off?

5. While the capital asset pricing model (CAPM) has been widely used to analyze securities and manage portfolios for the past 50 years, it has also been widely criticized as providing too simple a view of risk. Describe three problems in relation to the definition and estimation of the beta measure in the CAPM that would support this criticism.

6. You have been offered an opportunity to invest in one of the two fully diversified portfolios, Portfolio H and Portfolio L. While you know that the betas of these portfolios are identical, you only know that, on average, the stocks held in Portfolio H have a higher level of specific risk than those in Portfolio L. From what you know about the capital asset pricing model (CAPM), which portfolio should you invest in? Which portfolio should give you a higher expected return?

7. You have recently been appointed chief investment officer of a major charitable foundation. Its large endowment fund is currently invested in a broadly diversified portfolio of stocks (60 percent) and bonds (40 percent). The foundation’s board of trustees is a group of prominent individuals whose knowledge of modern investment theory and practice is superficial. You decide a discussion of basic investment principles would be helpful.

   a. Explain the concepts of specific risk, systematic risk, variance, covariance, standard deviation, and beta as they relate to investment management.

a. Explain the concepts of specific risk, systematic risk, variance, covariance, standard deviation, and beta as they relate to investment management.

You believe that the addition of other asset classes to the endowment portfolio would improve the portfolio by reducing risk and enhancing return. You are aware that depressed conditions in U.S. real estate markets are providing opportunities for property
acquisition at levels of expected return that are unusually high by historical standards. You believe that an investment in U.S. real estate would be both appropriate and timely, and have decided to recommend a 20 percent position be established with funds taken equally from stocks and bonds.

Preliminary discussions revealed that several trustees believe real estate is too risky to include in the portfolio. The board chairman, however, has scheduled a special meeting for further discussion of the matter and has asked you to provide background information that will clarify the risk issue.

   a. Draw and label a graph showing the security market line, and position Stocks X and Y relative to it.
   b. Compute the alphas both for Stock X and for Stock Y. Show your work.
   c. Assume that the risk-free rate increases to 7 percent, with the other data in the preceding matrix remaining unchanged. Select the stock providing the higher expected risk-adjusted return and justify your selection. Show your calculations.
8. As an equity analyst, you have developed the following return forecasts and risk estimates for two different stock mutual funds (Fund T and Fund U):

<table>
<thead>
<tr>
<th>Fund</th>

a. If the risk-free rate is 3.9 percent and the expected market risk premium (i.e., $E(R_M) - RFR$) is 6.1 percent, calculate the expected return for each mutual fund according to the CAPM.

b. Using the estimated expected returns from Part a along with your own return forecasts, demonstrate whether Fund T and Fund U are currently priced to fall directly on the security market line (SML), above the SML, or below the SML.

c. According to your analysis, are Funds T and U overvalued, undervalued, or properly valued?

9. Given the following results, indicate what will happen to the beta for Sophie Fashion Co., relative to the market proxy, compared to the beta relative to the true market portfolio:

c. If the current period return for the market is 12 percent and for Rader Tire it is 11 percent, are superior results being obtained for either index beta?
CHAPTER 9
Multifactor Models of Risk and Return

After you read this chapter, you should be able to answer the following questions:

1. What are the deficiencies of the capital asset pricing model (CAPM) as an explanation of the relationship between risk and expected asset returns?
2. What is the arbitrage pricing theory (APT) and how is it similar and different from the CAPM?
3. What are the strengths and weaknesses of the APT as a theory of how risk and expected return are related?
4. How can the APT be used in the security valuation process?
5. How do you test the APT by examining anomalies found with the CAPM and why do some authors contend that the APT model is untestable?
6. What are multifactor models and how are they related to the APT?
7. What are the steps necessary in developing a usable multifactor model?
8. What are the two primary approaches employed in defining common risk factors?
9. What are the main macroeconomic variables used in practice as risk factors?
10. What are the main security characteristic-oriented variables used in practice as risk factors?
11. How can multifactor models be used to identify the investment "bets" that an active portfolio manager is making relative to a benchmark?
12. How are multifactor models used to estimate the expected risk premium of a security or portfolio?

Chapter 7 and Chapter 8 introduced Markowitz portfolio theory and the capital asset pricing model (CAPM), which represent the foundation for understanding the connection between risk and expected return. This chapter considers several extensions of this framework. Specifically, whereas the CAPM designated a single risk factor to account for the volatility of an individual security or portfolio, in this chapter we develop the intuition and application of multifactor explanations of risk and return.

We begin with an explanation of the leading alternative to the CAPM— the arbitrage pricing theory (APT), which was developed by Stephen Ross. The chief difference between the CAPM and the APT is that the latter specifies several risk factors, thereby expanding the definition of systematic investment risk compared to that implied by the CAPM's single market portfolio.

After developing the conceptual basis for the APT in the next section and contrasting its major assumptions with those of the CAPM, we also examine the empirical evidence supporting the theory. One of the practical challenges that an investor faces when attempting to implement the APT is that the risk factors in the model are not defined in terms of their quantity (i.e., how many there are) or their identity (i.e., what they are).

We conclude the chapter by discussing how investors use multifactor models, which can be viewed as attempts to convert the APT into a working tool for security analysis.

THOMSON REUTERS

Use the Thomson One—Business School Edition Online Database to answer the following questions.

1. You want to evaluate the recent investment performance for two stocks—Walgreens and Exxon Mobil—relative to the S&P 500 index.
   a. Under the "Company Analysis" tab, look up the ticker symbols for Walgreens and Exxon Mobil.
   b. For each firm, as well as for the S&P 500 index, download daily price information for the past year using the menu options available under the "Prices" tab for each company.
   c. For each firm, calculate the set of daily returns that correspond to these daily price series.
   d. Using daily returns for the past year, calculate the beta coefficient for Walgreens and Exxon Mobil compared to the S&P 500 index. (Note: You can either build your own spreadsheet model to perform these calculations or use Excel's built-in functions for "Slope" or "Regression.""
   e. Based on your results in Part d, which stock appears to be the riskiest?
2. To evaluate how sensitive beta estimates are to the period over which returns are measured, you now want to repeat the analysis in the last problem using weekly data over the past year.
   a. For each firm, as well as for the S&P 500 index, download weekly price information for the past year using the menu options available in the Prices tab for each company.
   b. For each firm, calculate the set of weekly returns that correspond to these daily price series.
   c. Using weekly returns for the past year, calculate the beta for Walgreens and Exxon Mobil compared to the S&P 500 index.
   d. How do your beta estimates for Walgreens and Exxon Mobil differ when using daily versus weekly data in the estimation process? Does your conclusion change about which stock is the riskiest?
3. You would now like to evaluate the impact that the choice of index used for the market portfolio proxy has on the beta estimation process.
   a. Collect monthly price data for Walgreens and Exxon Mobil for the past five years and use this information to compute monthly returns over that period.
   b. Collect monthly price data for the S&P 500 index and MSCI World index (based in U.S. dollars) for the past five years and compute monthly returns for both series. (Note: You can access the information for a wide variety of different indexes under the main "Indices" tab.)
   c. Calculate betas for both stocks compared to the S&P 500 index.
   d. Calculate betas for both stocks compared to the MSCI World index.
   e. Compare the two beta estimates for each stock and explain why they would differ from one another.
A wide variety of factor models are currently in use. These models can be grouped broadly into those that use macroeconomic factor definitions and those that specify microeconomic factors. Examples are shown to illustrate each of the different approaches.

9.1 Arbitrage Pricing Theory

The last chapter highlighted many of the ways in which the CAPM has contributed to the investment management field. In many respects, the CAPM has been one of the most useful—and frequently used—financial economic theories ever developed. However, some of the empirical studies cited point out deficiencies in the model as an explanation of the link between risk and return. For example, tests of the CAPM indicated that the beta coefficients for individual securities were not stable but that portfolio betas generally were stable. There was mixed support for a positive linear relationship between rates of return and systematic risk for portfolios of stock, with some recent evidence indicating the need to consider additional risk variables or a need for different risk proxies. In addition, other papers criticized the tests of the model and its usefulness in portfolio evaluation because of a dependence on a market portfolio that is not currently available.

One major challenge to the CAPM was the set of results suggesting that it is possible to use knowledge of certain firm or security characteristics to develop profitable trading strategies, even after adjusting for investment risk as measured by beta. Banz (1981) showed that portfolios of stocks with low market capitalizations (i.e., “small” stocks) outperformed “large” stock portfolios on a risk-adjusted basis, and Basu (1977) documented that stocks with low price-earnings (P/E) ratios similarly outperformed high P/E stocks. More recent work by Fama and French (1992) also demonstrated that “value” stocks (i.e., those with high book value-to-market price ratios) tend to produce larger risk-adjusted returns than “growth” stocks (i.e., those with low book-to-market ratios). In an efficient market, these return differentials should not occur, meaning that either: (1) markets are not particularly efficient for extended periods of time (i.e., investors have been ignoring profitable investment opportunities for decades), or (2) market prices are efficient, but there is something wrong with the way the single-factor models such as the CAPM measure risk.

Given the implausibility of the first possibility, in the early 1970s financial economists began to consider the implications of the second. The academic community searched for an alternative asset pricing theory to the CAPM that was reasonably intuitive, required only limited assumptions, and allowed for multiple dimensions of investment risk. The result was the APT, which was developed by Ross (1976, 1977) in the mid-1970s and has three major assumptions:

1. Capital markets are perfectly competitive.
2. Investors always prefer more wealth to less wealth with certainty.
3. The stochastic process generating asset returns can be expressed as a linear function of a set of \( K \) risk factors (or indexes), and all unsystematic risk is diversified away.

Equally important, the following major assumptions—which were used in the development of the CAPM—are not required: (1) Investors possess quadratic utility functions, (2) normally distributed security returns, and (3) a market portfolio that contains all risky assets and is mean-variance efficient. Obviously, if a model is simpler and can also explain differential security prices, it will be considered a superior theory to the CAPM.

Prior to discussing the empirical tests of the APT, we provide a brief review of the basics of the model. The theory assumes that the stochastic process generating asset returns can be represented as a \( K \) factor model of the form:

\[
R_i = \text{E}(R_i) + b_{i1} \delta_1 + b_{i2} \delta_2 + \epsilon_i \quad \text{for} \quad i = 1 \text{ to } n
\]
A wide variety of factor models are currently in use. These models can be grouped broadly into those that use macroeconomic factor definitions and those that specify microeconomic factors. Examples are shown to illustrate each of the different approaches.

### 9.1 Arbitrage Pricing Theory

The last chapter highlighted many of the ways in which the CAPM has contributed to the investment management field. In many respects, the CAPM has been one of the most useful—and frequently used—financial economics theories ever developed. However, some of the empirical studies cited point out deficiencies in the model as an explanation of the link between risk and return. For example, tests of the CAPM indicated that the beta coefficients for individual securities were not stable but that portfolio betas generally were stable. In addition, other papers criticized the tests of the model and its usefulness in portfolio evaluation because of a dependence on a market portfolio that is not currently available.

One major challenge to the CAPM was the set of results suggesting that it is possible to use knowledge of certain firm or security characteristics to develop profitable trading strategies, even after adjusting for investment risk as measured by beta. Banz (1981) showed that portfolios of stocks with low market capitalizations (i.e., “small” stocks) outperformed “large” stock portfolios on a risk-adjusted basis, and Basu (1977) documented that stocks with low price-earnings (P/E) ratios similarly outperformed high P/E stocks. More recent work by Fama and French (1992) also demonstrated that “value” stocks (i.e., those with high book value-to-market price ratios) tend to produce larger risk-adjusted returns than “growth” stocks (i.e., those with low book-to-market ratios). Given the implausibility of the first possibility, in the early 1970s financial economists began to consider the implications of the second. The academic community searched for an alternative asset pricing theory to the CAPM that was reasonably intuitive, required only limited assumptions, and allowed for multiple dimensions of investment risk. The result was the APT, which was developed by Ross (1976, 1977) in the mid-1970s and has three major assumptions:

1. Capital markets are perfectly competitive.
2. Investors always prefer more wealth to less wealth with certainty.
3. The stochastic process generating asset returns can be expressed as a linear function of a set of K risk factors (or indexes), and all unsystematic risk is diversified away.

Equally important, the following major assumptions—which were used in the development of the CAPM—are not required: (1) Investors possess quadratic utility functions, (2) normally distributed security returns, and (3) a market portfolio that contains all risky assets and is mean-variance efficient. Obviously, if a model is simpler and can also explain differential security prices, it will be considered a superior theory to the CAPM.

Prior to discussing the empirical tests of the APT, we provide a brief review of the basics of the model. The theory assumes that the stochastic process generating asset returns can be represented as a K factor model of the form:

\[ R_i = E(R_i) + b_1 \delta_1 + b_2 \delta_2 + \cdots + b_K \delta_K + \varepsilon_i \text{ for } i = 1 \text{ to } n \]
where:

\[ R_i = \text{the actual return on asset } i \text{ during a specified time period, } i = 1, 2, 3, \ldots n \]

\[ E(R_i) = \text{the expected return for asset } i \text{ if all the risk factors have zero changes} \]

\[ b_j = \text{the reaction in asset } i's \text{ returns to movements in a common risk factor } j \]

\[ \delta_k = \text{a set of common factors or indexes with a zero mean that influences the} \]

\[ \text{returns on all assets} \]

\[ \epsilon_i = \text{a unique effect on asset } i's \text{ return (i.e., a random error term that, by assumption,} \]

\[ \text{is completely diversifiable in large portfolios and has a mean of zero)} \]

\[ n = \text{number of assets} \]

Two terms require elaboration: \( \delta \) and \( b_j \). As indicated, \( \delta \) terms are the multiple risk factors that are expected to impact the returns to all assets. Examples of these factors might include inflation, growth in gross domestic product (GDP), major political upheavals, or changes in interest rates. The APT contends that there are many such factors that affect returns, in contrast to the CAPM, where the only relevant risk to measure is the covariance of the asset with the market portfolio (i.e., the asset’s beta).

Given these common factors, the \( b_j \) terms determine how each asset reacts to the \( j \)th particular common factor. Although all assets may be affected by growth in GDP, the impact (i.e., reaction) to a factor will differ. For example, stocks of cyclical firms will have larger \( b_j \) terms for the “growth in GDP” factor than will noncyclical firms, such as grocery store chains. Likewise, all stocks are affected by changes in interest rates; however, some experience larger impacts. An interest-sensitive stock might have a \( b_j \) of 2.0 or more, whereas a stock that is relatively insensitive to interest rates has a \( b_j \) of 0.5. Note, however, that when we apply the theory, the factors are not identified. That is, when we discuss the empirical studies of the APT, the investigators will claim that they found three, four, or five factors that affect security returns, but they will give no indication of what these factors represent.

Similar to the CAPM model, the APT assumes that the unique effects (\( \epsilon \)) are independent and will be diversified away in a large portfolio. The APT requires that in equilibrium the return on a zero-investment, zero-systematic-risk portfolio is zero when the unique effects are fully diversified. This assumption (and some theoretical manipulation using linear algebra) implies that the expected return on any asset \( i \) (i.e., \( E(R) \)) can be expressed as:

\[ E(R_i) = \lambda_0 + \lambda_1 b_{11} + \lambda_2 b_{12} + \cdots + \lambda_k b_{1k} \quad \text{(APT)} \]

where:

\[ \lambda_0 = \text{the expected return on an asset with zero systematic risk} \]

\[ \lambda_j = \text{the risk premium related to the } j \text{th common risk factor} \]

\[ b_{ij} = \text{the pricing relationship between the risk premium and the asset; that is, how} \]

\[ \text{responsive asset } i \text{ is to the } j \text{th common factor. (These are called factor betas or} \]

\[ \text{factor loadings.)} \]

Equation 9.2 represents the fundamental result of the APT. It is useful to compare the form of the APT’s specification of the expected return-risk relationship with that of the CAPM from Chapter 8.

\[ E(R_i) = RFR + \beta_i [E(R_M) - RFR] \quad \text{(CAPM)} \]

Exhibit 9.1 contrasts the relevant features of the two models. The ultimate difference between these two theories lies in the way systematic investment risk is defined: a single, market-wide risk factor for the CAPM versus a few (or several) factors in the APT that capture the nuances of that market-wide risk. However, both theories specify linear models based on the common belief that investors are compensated for performing two functions: committing capital and bearing risk. Finally, notice that the equation for the APT suggests a relationship that is analogous to
the security market line associated with the CAPM. However, instead of a line connecting risk and expected return, the APT implies a security market plane with \((K + 1)\) dimensions—\(K\) risk factors and one additional dimension for the security’s expected return. Exhibit 9.2 illustrates this relationship for two risk factors (i.e., \(K = 2\)).

### 9.1.1 Using the APT

As noted earlier, the primary challenge with using the APT in security valuation is identifying the risk factors. The complexities of this issue are addressed later, so to illustrate how the
model works we will assume that there are two common factors: one related to unexpected changes in the level of inflation and another related to unanticipated changes in the real level of GDP. If the risk premium related to GDP sensitivity is 0.03 and a stock that is sensitive to GDP has a $b_j$ (where $j$ represents the GDP factor) of 1.5, this means that this factor would cause the stock’s expected return to increase by 4.5 percent ($= 1.5 \times 0.03$).

Consider the following example of two stocks and a two-factor model, with these risk factor definitions and sensitivities:

$\delta_1 =$ unanticipated changes in the rate of inflation. The risk premium related to this factor is 2 percent for every 1 percent change in the rate ($\lambda_1 = 0.02$).

$\delta_2 =$ unexpected changes in the growth rate of real GDP. The average risk premium related to this factor is 3 percent for every 1 percent change in the rate of growth ($\lambda_2 = 0.03$).

$\lambda_0 =$ the rate of return on a zero-systematic risk asset (i.e., zero-beta) is 4 percent ($\lambda_0 = 0.04$).

Assume also that there are two assets (x and y) that have the following sensitivities to these common risk factors:

$b_{x1} =$ the response of asset x to changes in the inflation factor is 0.50

$b_{x2} =$ the response of asset x to changes in the GDP factor is 1.50

$b_{y1} =$ the response of asset y to changes in the inflation factor is 2.00

$b_{y2} =$ the response of asset y to changes in the GDP factor is 1.75

These factor sensitivities can be interpreted in much the same way as beta in the CAPM; that is, the higher the level of $b_{ij}$, the greater the sensitivity of asset i to changes in the jth risk factor. Thus, asset y is a higher risk asset than asset x, and, therefore, its expected return should be greater. The overall expected return equation will be:

$$E(R_i) = \lambda_0 + \lambda_1 b_{i1} + \lambda_2 b_{i2}$$

$$= 0.04 + (0.02) b_{11} + (0.03) b_{12}$$

Therefore, for assets x and y:

$$E(R_x) = 0.04 + (0.02)(0.50) + (0.03)(1.50)$$

$$= 0.0950 = 9.50\%$$

and

$$E(R_y) = 0.04 + (0.02)(2.00) + (0.03)(1.75)$$

$$= 0.1325 = 13.25\%$$

The positions of the factor loadings and expected returns for these two assets are illustrated in Exhibit 9.2. If the prices of the two assets do not reflect these expected returns, we would expect investors to enter into arbitrage arrangements selling overpriced assets short and using the proceeds to purchase the underpriced assets until the relevant prices are corrected. Given these linear relationships, it should be possible to find an asset or a combination of assets with equal risk to the mispriced asset, yet providing a higher expected return.

### 9.1.2 Security Valuation with the APT: An Example

Suppose that three stocks (A, B, and C) and two common systematic risk factors (1 and 2) have the following relationship (for simplicity, it is assumed that the zero-beta return $|\lambda_0|$ equals zero):

$$E(R_A) = (0.80)\lambda_1 + (0.90)\lambda_2$$

$$E(R_B) = (-0.20)\lambda_1 + (1.30)\lambda_2$$

$$E(R_C) = (1.80)\lambda_1 + (0.50)\lambda_2$$
Net Exposure to Risk Factors:

Factor 1 Factor 2
Weighted exposure from Stock A: \((-1.0)(0.8)\) \((-1.0)(0.9)\)
Weighted exposure from Stock B: \((0.5)(-0.2)\) \((0.5)(1.3)\)
Weighted exposure from Stock C: \((0.5)(1.8)\) \((0.5)(0.5)\)

Net risk exposure:

Assuming prices in one year actually rise to the levels that you initially “knew” they would, your net profit from covering the short position and liquidating the two long holdings will be:

Net Profit:

\[2(35) - 2(37.20) + 37.80 - 35 + 38.50 - 35 = $1.90\]

Thus, from a portfolio in which you invested no net wealth and assumed no net risk, you have realized a positive profit. This is the essence of arbitrage investing and is an example of the “long-short” trading strategies often employed by hedge funds.

Finally, if everyone else in the market today begins to believe the way you do about the future price levels of A, B, and C—but do not revise their forecasts about the expected factor returns or factor betas for the individual stocks—then the current prices for the three stocks will be adjusted by arbitrage trading to:

\[P_A = \frac{37.20}{1.077} = 34.54\]
\[P_B = \frac{37.80}{1.057} = 35.76\]
\[P_C = \frac{38.50}{1.097} = 35.10\]

Thus, the price of Stock A will be bid down while the prices of Stocks B and C will be bid up until arbitrage trading in the current market is no longer profitable.

9.1.3 Empirical Tests of the APT

Although the APT is much newer than the CAPM, it has undergone considerable scrutiny. A brief overview of this literature is provided below. In discussing these empirical tests, remember the crucial earlier caveat that we do not know what the factors generated by the formal model actually represent. This becomes a major point in some discussions of test results.

Roll and Ross Study

Roll and Ross (1980) produced one of the first large-scale empirical tests of the APT. Their methodology followed a two-step procedure:

1. Estimate expected returns and factor coefficients from time-series data on individual asset returns.
2. Use these estimates to test the basic cross-sectional pricing conclusion implied by the APT. Specifically, are the expected returns for these assets consistent with the common factors derived in Step 1?

The authors tested the following pricing relationship:

\[H_0: \text{There exist nonzero constants } (\lambda_0, \lambda_1, \lambda_2) \text{ such that for any asset } i:\]
\[E(R_i) = \lambda_0 + \lambda_1 b_{i1} + \lambda_2 b_{i2} + \ldots + \lambda_k b_{ik}\]

The specific \(b\) coefficients were estimated using the statistical technique of factor analysis, which forms “portfolios” of the underlying assets (i.e., factors) based on the correlations in the underlying returns. Their database consisted of daily returns for the period from 1962 through 1972. Stocks were put into 42 portfolios of 30 stocks each (1,260 stocks) by alphabetical order.

If \(\lambda_1 = 4\%\) and \(\lambda_2 = 5\%\), then the returns expected by the market over the next year can be expressed:

\[E(R_A) = (0.80)(4\%) + (0.90)(5\%) = 7.7\%\]
\[E(R_B) = (-0.20)(4\%) + (1.30)(5\%) = 5.7\%\]
\[E(R_C) = (1.80)(4\%) + (0.50)(5\%) = 9.7\%\]

which, assuming that all three stocks are currently priced at $35 and do not pay a dividend, implies the following expected prices a year from now:

\[E(P_A) = 35(1.077) = 37.70\]
\[E(P_B) = 35(1.057) = 37.00\]
\[E(P_C) = 35(1.097) = 38.40\]

Now, suppose you believe that in one year the actual prices of stocks A, B, and C will be $37.20, $37.80, and $38.50. How can you take advantage of what you consider to be a market mispricing?

According to your forecasts, Stock A will not reach a price level in one year consistent with investor return expectations. Accordingly, you conclude that at a current price of $35 a share, Stock A is overvalued. Similarly, Stock B is undervalued and Stock C is (slightly) undervalued. Consequently, any investment strategy designed to take advantage of these discrepancies will, at the very least, need to consider purchasing Stocks B and C while short selling Stock A.

The idea of riskless arbitrage is to assemble a portfolio that: (1) requires no net wealth invested initially and (2) will bear no systematic or unsystematic risk, but (3) still earns a profit. Letting \(w_i\) represent the percentage investment in Security \(i\), the conditions that must be satisfied can be written formally as follows:

1. \(\sum w_i = 0\) [i.e., no net wealth invested]
2. \(\sum w_i b_{ij} = 0\) for all \(K\) factors [i.e., no systematic risk] and \(w_i\) is “small” for all \(i\) [i.e., unsystematic risk is fully diversified]
3. \(\sum w_i R_i > 0\) [i.e., the actual portfolio return is positive]

In this example, since Stock A is the only one that is overvalued, assume that it is the only one that actually is short sold. The proceeds from the short sale of Stock A can then be used to purchase the two undervalued securities, Stocks B and C. To illustrate this process, consider the following investment proportions:

\[w_A = -1.0\]
\[w_B = +0.5\]
\[w_C = +0.5\]

These investment weights imply the creation of a portfolio that is short two shares of Stock A for each one share of Stock B and one share of Stock C held long. Notice that this portfolio meets the net investment and risk mandates of an arbitrage-based trade:
Net Exposure to Risk Factors:

<table>
<thead>
<tr>
<th>Weighted exposure from Stock A:</th>
<th>Factor 1</th>
<th>Factor 2</th>
</tr>
</thead>
<tbody>
<tr>
<td>(-1.0)(0.8)</td>
<td>(-1.0)(0.9)</td>
<td></td>
</tr>
<tr>
<td>Weighted exposure from Stock B:</td>
<td>(0.5)(-0.2)</td>
<td>(0.5)(1.3)</td>
</tr>
<tr>
<td>Weighted exposure from Stock C:</td>
<td>(0.5)(1.8)</td>
<td>(0.5)(0.5)</td>
</tr>
<tr>
<td>Net risk exposure:</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>

Assuming prices in one year actually rise to the levels that you initially "knew" they would, your net profit from covering the short position and liquidating the two long holdings will be:

Net Profit:

\[
[2(35) - 2(37.20)] + [37.80 - 35] + [38.50 - 35] = $1.90
\]

Thus, from a portfolio in which you invested no net wealth and assumed no net risk, you have realized a positive profit. This is the essence of arbitrage investing and is an example of the "long-short" trading strategies often employed by hedge funds.

Finally, if everyone else in the market today begins to believe the way you do about the future price levels of A, B, and C—but do not revise their forecasts about the expected factor returns or factor betas for the individual stocks—then the current prices for the three stocks will be adjusted by arbitrage trading to:

\[
P_A = ($37.20) \div (1.077) = $34.54
\]

\[
P_B = ($37.80) \div (1.057) = $35.76
\]

\[
P_C = ($38.50) \div (1.097) = $35.10
\]

Thus, the price of Stock A will be bid down while the prices of Stocks B and C will be bid up until arbitrage trading in the current market is no longer profitable.

### 9.1.3 Empirical Tests of the APT

Although the APT is much newer than the CAPM, it has undergone considerable scrutiny. A brief overview of this literature is provided below. In discussing these empirical tests, remember the crucial earlier caveat that we do not know what the factors generated by the formal model actually represent. This becomes a major point in some discussions of test results.

**Roll and Ross Study** Roll and Ross (1980) produced one of the first large-scale empirical tests of the APT. Their methodology followed a two-step procedure:

1. Estimate expected returns and factor coefficients from time-series data on individual asset returns.
2. Use these estimates to test the basic cross-sectional pricing conclusion implied by the APT. Specifically, are the expected returns for these assets consistent with the common factors derived in Step 1?

The authors tested the following pricing relationship:

\[ H_0: \text{There exist nonzero constants } (\lambda_0, \lambda_1, \ldots, \lambda_k) \text{ such that for any asset } i:}\]

\[ [E(R_i) - \lambda_i] = \lambda_1 b_{i1} + \lambda_2 b_{i2} + \cdots + \lambda_k b_{ik} \]

The specific \( b_i \) coefficients were estimated using the statistical technique of factor analysis, which forms "portfolios" of the underlying assets (i.e., factors) based on the correlations in the underlying returns. Their database consisted of daily returns for the period from 1962 through 1972. Stocks were put into 42 portfolios of 30 stocks each (1,260 stocks) by alphabetical order.
The initial estimation of the factor model indicated that the maximum reasonable number of factors was five. The factors derived were applied to all 42 portfolios, allowing that the importance of the various factors might differ among portfolios (e.g., the first factor in Portfolio A might not be first in Portfolio B). Assuming a risk-free rate of 6 percent ($\lambda_0 = 0.06$), their analysis revealed the existence of at least three meaningful factors but probably not more than four. However, when they allowed the model to estimate the risk-free rate ($\lambda_0$), only two factors were consistently significant.

Roll and Ross also tested whether the three or four factors that affect Group A were the same as the factors that affect Group B. The analysis involved testing for cross-sectional consistency by examining whether the $\lambda_0$ terms for the 42 groups are similar. The results yielded no evidence that the intercept terms were different. The authors concluded that the evidence generally supported the APT but acknowledged that their tests were not conclusive.

**Extensions of the Roll-Ross Tests** Cho, Elton, and Gruber (1984) tested the APT by examining the number of factors in the return-generating process that were priced. The authors concluded that even when returns were generated by a two-factor model, two or three factors are required to explain the returns. These results support the APT model because it allows for the consideration of these additional factors, which is not possible with the classical CAPM.

Dhrymes, Friend, and Gultekin (1984) reexamined the methodology used in prior studies and found no relationship between the factor loadings for groups of 30 stocks and for a group of 240 stocks. Also, they could not identify the actual number of factors that characterize the return-generating process. When they applied the model to portfolios of different sizes, the number of factors changed. For example, for 15 securities, it is a two-factor model; for 30 securities, a three-factor model; for 45, a four-factor model; for 60, a six-factor model; and for 90, a nine-factor model.

Roll and Ross (1984) acknowledged that the number of risk factors differ with 30 stocks versus 240, but contended that the important consideration is whether the resulting estimates are consistent because it is not feasible to consider all of the stocks at once. When they tested for consistency, the APT was generally supported. They point out that the number of factors is a secondary issue compared to how well the model explains expected security returns compared to alternative models.

Dhrymes, Friend, Gultekin, and Gultekin (1985) repeated the prior tests for larger groups of securities. When they increased the number of securities in each group, both the number of factors that entered the model and the number of statistically significant (i.e., “priced”) factors increased, although most factors are not priced. In addition, they found that the unique or total standard deviation for a period was as good at predicting subsequent returns as the factor loadings. These results are not favorable to the empirical relevance of APT because they indicate extreme instability in the relationships.

Finally, Connor and Korajczyk (1993) argued that most tests for the number of priced risk factors are valid only for strict factor models in which diversifiable returns are uncorrelated across the set of stocks in the sample. They developed a test that identifies the number of factors in a model that does allow the unsystematic components of risk to be correlated across assets. Using this framework, they showed that between one and six priced factors exist for their sample of NYSE- and ASE-listed stocks. Harding (2008) also showed the connection between systematic and unsystematic risk factors.

**The APT and Stock Market Anomalies** An alternative set of tests of the APT considers how well the theory explains pricing anomalies that are not explained by a competing model (i.e., the CAPM). Two anomalies considered are the small-firm effect and the January effect.

**APT Tests of the Small-Firm Effect** Reinganum (1981) addressed the APT’s ability to account for the differences in average returns between small firms and large firms, which could not be
When it comes to putting theory into practice, one advantage of the CAPM framework is that the identity of the single risk factor (i.e., the excess return to the market portfolio) is well specified. The challenge in implementing the CAPM is to specify the market portfolio, which requires identifying the relevant investment universe. As we saw in the last chapter, this is not a trivial problem, as an improperly chosen proxy for the market portfolio (e.g., using the S&P 500 index to represent the market when evaluating a fixed-income portfolio) can lead to erroneous judgments. However, we also saw that once the returns to an acceptable surrogate for the market portfolio are identified (i.e., \( R_M \)), the process for estimating the parameters of the CAPM is straightforward.

In contrast to the CAPM, the primary practical problem associated with implementing the APT is that neither the identity nor the exact number of the underlying risk factors are developed by theory and therefore must be specified in an ad hoc manner. Said differently, before the APT can be used to value securities or measure investment performance, the investor must fill in a considerable amount of missing information about the fundamental relationship between risk and expected return.

As discussed earlier, the first attempts to implement a usable form of the APT relied on multivariate statistical techniques, such as principal components analysis and factor analysis, wherein many periods of realized returns for large number of securities are analyzed simultaneously in order to detect recognizable patterns of behavior. A consistent finding of these studies is that there appear to be as many as three or four "priced" (i.e., statistically significant) factors, although researchers were not able to establish that the same set of factors was generated by different subsets of their sample. Indeed, we also saw that the inability to identify the risk factors is a major limitation to the usefulness of the APT. Jones (2001) and Ludvigson and Ng (2007) provide some recent extensions along these lines.

A different approach to developing an empirical model that captures the essence of the APT relies on the direct specification of the form of the relationship to be estimated. That is, in a multifactor model, the investor chooses the exact number and identity of risk factors in the following equation:

\[
R_{it} = a_i + \sum_{j=1}^{K} b_{ij} F_{jt} + \epsilon_{it}
\]

where \( F_{jt} \) is the period \( t \) return to the \( j \)th designated risk factor and \( R_{it} \) can be measured as either a nominal or excess return to Security \( i \). The advantage of this approach is that the investor knows precisely how many and what things need to be estimated to fit the regression equation. The major disadvantage of a multifactor model is that it is developed with little theoretical guidance as to the true nature of the risk-return relationship. In this sense, developing a useful factor model is as much art form as theoretical exercise.

### 9.2.1 Multifactor Models in Practice

A wide variety of empirical factor specifications have been employed in practice. Each alternative model attempts to identify a set of economic influences that is simultaneously broad enough to capture the major nuances of investment risk but small enough to provide a workable solution to the investor. Two general approaches have been employed. First, risk factors can be viewed as macroeconomic in nature; that is, they attempt to capture variations in the underlying reasons an asset’s cash flows and investment returns might change over time (e.g., changes in inflation or real GDP growth in the example discussed earlier). On the other hand, risk factors can also be viewed at a microeconomic level by focusing on relevant characteristics of the securities themselves, such as the size of the firm in question or some of its financial ratios. A few examples representative of both of these approaches are discussed in the following sections.

**APT Tests of the January Effect**

Given the so-called January effect, where returns in January are significantly larger than in any other month, Gul liken and Gultekin (1987) tested the ability of the APT model to account for this anomaly. The APT model was estimated separately for each month, and risk premia were always significant in January but rarely priced in other months. They concluded that the APT model can explain the risk-return relation only in January, meaning that the APT model does not explain this anomaly any better than the CAPM.

Burmeister and McElroy (1988) estimated a linear factor model, the APT, and the CAPM. They found a significant January effect that was not captured by any of the models. When they moved beyond the January effect, however, they rejected the CAPM in favor of the APT. Kramer (1994) shows that an empirical form of the APT accounts for the January seasonal effect in average stock returns while the CAPM cannot.

**Is the APT Even Testable?**

Similar to Roll's critique of the CAPM, Shanken (1982) challenged whether it is possible for the APT to be empirically verified at all. He questioned whether the APT is more susceptible to testing than the CAPM, based on the usual empirical test that determines whether asset returns conform to a \( K \) factor model. One problem is that if stock returns are not explained by such a model, it is not considered a rejection of the model; however, if the factors do explain returns, it is considered support. Also, equivalent sets of securities may conform to different factor structures, meaning that the APT may yield different empirical implications regarding the expected returns for a given set of securities. Unfortunately, this implies that the theory cannot explain differential returns between securities because it cannot identify the relevant factor structure that explains the differential returns.

Dybvig and Ross (1985) replied by suggesting that the APT is testable as an equality rather than the "empirical APT" proposed by Shanken. Shanken (1985a) responded that what has emerged is a set of equilibrium APT pricing models that are testable but that arbitrage-based models are not testable as originally specified.

**Alternative Techniques for Testing the APT**

Jobson (1982) proposes that the APT be tested using a multivariate linear regression model. Brown and Weinstein (1983) propose an approach to estimating and testing asset pricing models using a bilinear paradigm. Geweke and Zhou (1996) produce an exact Bayesian framework and conclude that there is little reduction in pricing error from including additional factors beyond the first one. A number of subsequent papers have proposed new methodologies for testing the APT.\(^1\)

\(^1\)Among these papers are works by McCulloch and Rossi (1990), Onatski (2009), and Zhang (2009).
9.2 Multifactor Models and Risk Estimation

When it comes to putting theory into practice, one advantage of the CAPM framework is that the identity of the single risk factor (i.e., the excess return to the market portfolio) is well specified. The challenge in implementing the CAPM is to specify the market portfolio, which requires identifying the relevant investment universe. As we saw in the last chapter, this is not a trivial problem, as an improperly chosen proxy for the market portfolio (e.g., using the S&P 500 index to represent the market when evaluating a fixed-income portfolio) can lead to erroneous judgments. However, we also saw that once the returns to an acceptable surrogate for the market portfolio are identified (i.e., $R_M$), the process for estimating the parameters of the CAPM is straightforward.

In contrast to the CAPM, the primary practical problem associated with implementing the APT is that neither the identity nor the exact number of the underlying risk factors are developed by theory and therefore must be specified in an ad hoc manner. Said differently, before the APT can be used to value securities or measure investment performance, the investor must fill in a considerable amount of missing information about the fundamental relationship between risk and expected return.

As discussed earlier, the first attempts to implement a usable form of the APT relied on multivariate statistical techniques, such as principal components analysis and factor analysis, wherein many periods of realized returns for a large number of securities are analyzed simultaneously in order to detect recognizable patterns of behavior. A consistent finding of these studies is that there appear to be as many as three or four “priced” (i.e., statistically significant) factors, although researchers were not able to establish that the same set of factors was generated by different subsets of their sample. Indeed, we also saw that the inability to identify the risk factors is a major limitation to the usefulness of the APT. Jones (2001) and Ludvigson and Ng (2007) provide some recent extensions along these lines.

A different approach to developing an empirical model that captures the essence of the APT relies on the direct specification of the framework of the relationship to be estimated. That is, in a multifactor model, the investor chooses the exact number and identity of risk factors in the following equation:

$$R_i = a_i + \left[ b_{i1}F_{i1} + b_{i2}F_{i2} + \cdots + b_{ik}F_{ik} \right] + e_i$$

where $F_{jt}$ is the period $t$ return to the $j$th designated risk factor and $R_i$ can be measured as either a nominal or excess return to Security $i$. The advantage of this approach is that the investor knows precisely how many and what things need to be estimated to fit the regression equation. The major disadvantage of a multifactor model is that it is developed with little theoretical guidance as to the true nature of the risk-return relationship. In this sense, developing a useful factor model is as much art form as theoretical exercise.

9.2.1 Multifactor Models in Practice

A wide variety of empirical factor specifications have been employed in practice. Each alternative model attempts to identify a set of economic influences that is simultaneously broad enough to capture the major nuances of investment risk but small enough to provide a workable solution to the investor. Two general approaches have been employed. First, risk factors can be viewed as macroeconomic in nature; that is, they attempt to capture variations in the underlying reasons an asset’s cash flows and investment returns might change over time (e.g., changes in inflation or real GDP growth in the example discussed earlier). On the other hand, risk factors can also be viewed at a microeconomic level by focusing on relevant characteristics of the securities themselves, such as the size of the firm in question or some of its financial ratios. A few examples representative of both of these approaches are discussed in the following sections.
Macroeconomic-Based Risk Factor Models One particularly influential model was developed by Chen, Roll, and Ross (1986), who hypothesized that security returns are governed by a set of broad economic influences in the following fashion:

\[ R_t = a_t + [b_{11} R_{Mkt} + b_{12} MP_t + b_{13} DEI_t + b_{14} UI_t + b_{15} UPR_t + b_{16} UTS_t] + \varepsilon_t \]

where:

\( R_{Mkt} \) = the return on a value-weighted index of NYSE-listed stocks
\( MP \) = the monthly growth rate in U.S. industrial production
\( DEI \) = the change in inflation, measured by the U.S. consumer price index
\( UI \) = the difference between actual and expected levels of inflation
\( UPR \) = the unanticipated change in the bond credit spread (Baa yield – RFR)
\( UTS \) = the unanticipated term structure shift (long-term less short-term RFR)

In estimating this model, the authors used a series of monthly returns for a large collection of stocks over the period 1958–1984. Exhibit 9.3 shows the factor sensitivities (along with the associated t-statistics in parentheses) that they established. Notice two things about these findings. First, the economic significance of the designated risk factors changed dramatically over time. For instance, the inflation factors (DEI and UI) appear to only be relevant during the 1968–1977 period. Second, the parameter on the market portfolio proxy is never significant, suggesting that it contributes little to the explanation beyond the information contained in the other macroeconomic risk factors.

Burmeister, Roll, and Ross (1994) analyzed the predictive ability of a model based on a different set of macroeconomic factors. Specifically, they define the following five risk exposures: (1) confidence risk, based on unanticipated changes in the willingness of investors to take on investment risk; (2) time horizon risk, which is the unanticipated changes in investors’ desired time to receive payouts; (3) inflation risk, based on a combination of the unexpected components of short-term and long-term inflation rates; (4) business cycle risk, which represents unanticipated changes in the level of overall business activity; and (5) market-timing risk, defined as the part of the Standard & Poor’s 500 total return that is not explained by the other four macroeconomic factors. Using monthly data through the first quarter of 1992, the authors estimated risk premia (i.e., the market “price” of risk) for these factors:

They also compared the factor sensitivities for several different individual stocks and stock portfolios. Panel A and Panel B of Exhibit 9.4 show these factor beta estimates for a particular stock (Reebok International Ltd.) versus the S&P 500 index and for a portfolio of small-cap firms versus a portfolio of large-cap firms. Also included in these graphs is the security’s or portfolio’s exposure to

![Exhibit 9.4 Macroeconomic Risk Exposure Profiles](image)

the BIRR composite risk index, which is designed to indicate which position has the most overall systematic risk. These comparisons highlight how a multifactor model can help investors distinguish the nature of the risk they are assuming when they hold with a particular position. For instance, notice that Reebok has greater exposures to all sources of risk than the S&P 500, with the incremental difference in the business cycle exposure being particularly dramatic. Additionally, smaller firms are more exposed to business cycle and confidence risk than larger firms but less exposed to horizon risk.

**Microeconomic-Based Risk Factor Models** In contrast to macroeconomic-based explanations, it is also possible to specify risk in microeconomic terms using proxy variables that concentrate on certain characteristics of the underlying sample of securities. Typical of this characteristic-based approach to forming a multifactor model is the work of Fama and French (1993), who use the following functional form:

\[
(R_{it} - R_{FR}) = \alpha_i + b_{i1}(R_{Mkt} - R_{FR}) + b_{i2}\text{SMB}_t + b_{i3}\text{HML}_t + e_{it}
\]

where, in addition to the excess return on a stock market portfolio, two other risk factor proxies are defined:

- **SMB** (i.e., small minus big) is the return to a portfolio of small-capitalization stocks less the return to a portfolio of large-capitalization stocks.
- **HML** (i.e., high minus low) is the return to a portfolio of stocks with high ratios of book-to-market ratios less the return to a portfolio of low book-to-market ratio stocks.

In this specification, **SMB** is designed to capture elements of risk associated with firm size, while **HML** is intended to distinguish risk differentials associated with “growth” (i.e., low book-to-market ratio) and “value” (i.e., high book-to-market) firms. As we saw earlier, these are two dimensions of a security—or portfolio of securities—that have consistently been shown to matter when evaluating investment performance. Also, notice that without **SMB** and **HML** this model reduces to the excess returns form of the single-index market model.

Fama and French examined the behavior of a broad sample of stocks grouped into quintile portfolios by their price-to-earnings (**P/E**) ratios on a yearly basis over the period from July 1963 to December 1991. The results for both the single-index and multifactor versions of the model for the two extreme quintiles are shown in Exhibit 9.5 (**t**-statistics for the estimated coefficients are listed parenthetically). Notice that while the estimated beta from the single-factor model indicates that there are substantial differences between low and high **P/E** stocks.

Connor (1995) has analyzed the ability of the Barra model to explain the returns generated by a sample of U.S. stocks over the period from 1985 to 1993. He found that the industry indexes, taken collectively, provided about four times the explanatory power as any single characteristic-based factor, followed in importance by volatility, growth, dividend yield, and momentum. Overall, the

Carhart (1997) directly extends the Fama-French three-factor model by including a fourth common risk factor that accounts for the tendency for firms with positive (negative) past returns to produce positive (negative) future returns. He calls this additional risk dimension a price momentum factor and estimates it by taking the average return to a set of stocks with the best performance over the prior year minus the average return to stocks with the worst returns. In this fashion, Carhart municipalities the momentum factor—labeled here as MOM—in a fashion similar to SMB and HML. Formally, the model he proposes is:

\[
(R_d - R_{FR1}) = \alpha_i + b_1(R_{SMB} - R_{FR1}) + b_2SMB_i + b_3HML_i + b_4MOM_i + \epsilon_i
\]

He demonstrates that the typical factor sensitivity (i.e., factor beta) for the momentum variable is positive and its inclusion into the Fama-French model increases explanatory power by as much as 15 percent. Equation 9.6 is often referred to as the four-factor Fama-French model.

**Extensions of Characteristic-Based Risk Factor Models** Another type of security characteristic-based method for defining systematic risk exposures involves the use of index portfolios (e.g., S&P 500, Wilshire 5000) as common factors. Intuitively, if the indexes themselves are designed to emphasize certain investment characteristics, they can act as proxies for the underlying exposure. Examples include the Russell 1000 Growth Index, which emphasizes large-cap stocks with low book-to-market ratios, or the EAFE (Europe, Australia, and the Far East) Index that selects a variety of companies that are domiciled outside the United States. Typical of these index-based factor models is the work of Elton, Gruber, and Blake (1996), who rely on four indexes: the S&P 500, the Barclays Capital aggregate bond index, the Prudential Bache index of the difference between large- and small-cap stocks, and the Prudential Bache index of the difference between value and growth stocks. Penson and Schadt (1996) have developed an interesting variation on this approach, which, in addition to using stock and bond indexes as risk factors, also includes other “public information” variables, such as the shape of the yield curve and dividend payouts.

MSCI Barra, a leading risk forecasting and investment consulting firm, provides a final example of the microeconomic approach to building a multifactor model. The model they employ for analyzing U.S. equities includes as risk factors several characteristic-based variables and more than 50 industry indexes. Exhibit 9.6 provides a brief description of the characteristic-based factors representative of the Barra approach to decomposing investment risk. One useful application for this model is to understand where the investment “bets” in an actively managed portfolio are being placed relative to a performance benchmark. Exhibit 9.7 illustrates this for a small-cap-oriented mutual fund (POOL2) versus the S&P 500 Index (SAP500). As you would expect, there are dramatic differences between the fund and the benchmark in terms of the firm-size risk factors (i.e., size, SIZ; and size nonlinearity, SNL). However, it also appears that POOL2 holds companies with substantially different leverage (LEV) and momentum (MOM) exposures from the index.

2A more complete description of the Barra approach to analyzing investment risk can be found in Grinold and Kahn (1994).
9.2.2 Estimating Risk in a Multifactor Setting: Examples

Estimating Expected Returns for Individual Stocks

One direct way to employ a multifactor risk model is to use it to estimate the expected return for an individual stock position. In order to do this, the following steps must be taken: (1) a specific set of $K$ common risk factors (or their proxies) must be identified, (2) the risk premia ($F_j$) for the factors must be estimated, (3) the sensitivities ($b_{ij}$) of the $i$th stock to each of those $K$ factors must be estimated, and (4) the expected returns can be calculated by combining the results of the previous steps.

As an example, we will use both the three-factor and four-factor versions of the Fama-French model discussed earlier. This immediately solves the first step by designating proxies for the four common risk factors: the excess return on the market portfolio ($R_M - R_{FR}$), the return differential between small- and large-capitalization stocks ($SMB$), the return differential between high and low book-to-market stocks ($HML$), and the return differential between stocks with the highest and lowest past returns ($MOM$). The second step is often addressed in practice by using historical return data to calculate the average values for each of the risk factors. However, it is important to recognize that these averages can vary tremendously depending on the time period the investor selects. For the four factors just described, the first panel of Exhibit 9.8 lists the average annual factor risk premia over three different time frames: a 15-year period ending in December 2009, a 30-year period ending in December 2009, and an 83-year period ending in December 2009.

Notice that these data confirm that small stocks earned higher returns than large stocks, on average, and value stocks outperformed growth stocks (i.e., positive risk premia for the $SMB$ and $HML$ factors).

To illustrate the final steps involved in estimating expected stock returns, risk factor sensitivities were estimated by regression analysis for three different stocks using monthly return data over the period January 2005 – December 2009. The three stocks were Microsoft (MSFT), a multinational software developer; CSX Corporation (CSX), a railroad firm; and Xerox (XRX), a document-processing company. The estimated factor betas are listed in Panel B of Exhibit 9.8 for the three-factor model and in Panel C for the four-factor version of the equation.

These factor betas provide some interesting comparisons between the three stocks. First, the positive coefficients on the market factor indicate that all of these companies are positively correlated with general movements in the stock market. The coefficients on the $SMB$ factor confirm that MSFT and CSX produce returns consistent with large-cap stocks (i.e., negative $SMB$ exposures), while XRX acts like a small-cap or mid-cap stock. Further, CSX and XRX are more likely to be considered value stocks (i.e., positive $HML$ exposures), while MSFT can be considered a growth-oriented stock. Finally, MSFT and CSX exhibited positive price momentum (i.e., positive $MOM$ exposure in Panel C), while XRX was a negative momentum stock over this period.

Whichever specific factor risk estimates are used, the expected return for any stock in excess of the risk-free rate (i.e., the stock’s expected risk premium) can be calculated with either the three-factor or four-factor version of the formula:

$$E(R_i) - R_{FR} = b_{iM} \lambda_M + b_{iSMB} \lambda_{SMB} + b_{iHML} \lambda_{HML} + b_{iMOM} \lambda_{MOM}$$

In Panels B and C of Exhibit 9.8, these expected excess return calculations are summarized for all three stocks using two different factor risk premia estimates: (1) historical data from the 3 years ending in December 2009 and (2) data from the 10 years ending in December 2009.

Connor (1995) has analyzed the ability of the Barra model to explain the returns generated by a sample of U.S. stocks over the period from 1985 to 1993. He found that the industry indexes, taken collectively, provided about four times the explanatory power as any single characteristic-based factor, followed in importance by volatility, growth, dividend yield, and momentum. Overall, the...
model was able to explain slightly more return variability than the other models to which it was compared, in part because of the large number of factors it employs.

### 9.2.2 Estimating Risk in a Multifactor Setting: Examples

**Estimating Expected Returns for Individual Stocks** One direct way to employ a multifactor risk model is to use it to estimate the expected return for an individual stock position. In order to do this, the following steps must be taken: (1) a specific set of $K$ common risk factors (or their proxies) must be identified, (2) the risk premia ($F_i$) for the factors must be estimated, (3) the sensitivities ($b_{ij}$) of the $i$th stock to each of those $K$ factors must be estimated, and (4) the expected returns can be calculated by combining the results of the previous steps.

As an example, we will use both the three-factor and four-factor versions of the Fama-French model discussed earlier. This immediately solves the first step by designating proxies for the four common risk factors: the excess return on the market portfolio ($R_m - R_{FR}$), the return differential between small- and large-capitalization stocks ($SMB$), the return differential between high and low book-to-market stocks ($HML$), and the return differential between stocks with the highest and lowest past returns ($MOM$). The second step is often addressed in practice by using historical return data to calculate the average values for each of the risk factors. However, it is important to recognize that these averages can vary tremendously depending on the time period the investor selects. For the four factors just described, the first panel of Exhibit 9.8 lists the average annual factor risk premia over three different time frames: a 15-year period ending in December 2009, a 30-year period ending in December 2009, and an 83-year period ending in December 2009. Notice that these data confirm that small stocks earned higher returns than large stocks, on average, and value stocks outperformed growth stocks (i.e., positive risk premia for the SMB and HML factors).

To illustrate the final steps involved in estimating expected stock returns, risk factor sensitivities were estimated by regression analysis for three different stocks using monthly return data over the period January 2005–December 2009. The three stocks were Microsoft (MSFT), a multinational software developer; CSX Corporation (CSX), a railroad firm; and Xerox (XRX), a document-processing company. The estimated factor betas are listed in Panel B of Exhibit 9.8 for the three-factor model and in Panel C for the four-factor version of the equation.

These factor betas provide some interesting comparisons between the three stocks. First, the positive coefficients on the market factor indicate that all of these companies are positively correlated with general movements in the stock market. The coefficients on the SMB factor confirm that MSFT and CSX produce returns consistent with large-cap stocks (i.e., negative SMB exposures), while XRX acts like a small-cap or mid-cap stock. Further, CSX and XRX are more likely to be considered value stocks (i.e., positive HML exposures), while MSFT can be considered a growth-oriented stock. Finally, MSFT and CSX exhibited positive price momentum (i.e., positive MOM exposure in Panel C), while XRX was a negative momentum stock over this period.

Whichever specific factor risk estimates are used, the expected return for any stock in excess of the risk-free rate (i.e., the stock’s expected risk premium) can be calculated with either the three-factor or four-factor version of the formula:

\[ E(R_i) = \beta_{i,m} \lambda_m + \beta_{i,SMB} \lambda_{SMB} + \beta_{i,HML} \lambda_{HML} + \beta_{i,MOM} \lambda_{MOM} \]

In Panels B and C of Exhibit 9.8, these expected excess return calculations are summarized for all three stocks using two different factor risk premia estimates: (1) historical data from the

---

3 The data in these calculations are available from Professor Kenneth French’s Web site at http://mba.tuck.dartmouth.edu/pages/faculty/ken.french.
Morningstar Inc., an independent stock and mutual fund advisory service, classifies FCNTX's investment style into the "large-cap growth" category. This means that the typical equity holding of FCNTX is characterized as a large market capitalization firm whose P/E and book-to-market ratios exceed those of the average firm in the market. Exhibit 9.9 shows a sample page for FCNTX from Morningstar's public-access Web site and shows graphically where the fund fits into the investment "style box" as of the reporting date in 2010. Conversely, as shown in Exhibit 9.10, Morningstar plots TRMCX into the "mid-cap value" category, meaning that the portfolio generally emphasizes smaller companies than does FCNTX as well as those that fall closer to the middle of the value-growth spectrum. Thus, assuming that Morningstar's classification system is meaningful, the two funds should differ in the relative sensitivities to both the SMB and the HML factors.

Using monthly returns over July 2007 to June 2010, the risk parameters for both funds were estimated relative to three different specifications: (1) a single-factor model using the Standard & Poor's 500 Index as proxy for the market portfolio, (2) a single-factor model using a broader composite index of the U.S. stock market as a market proxy, and (3) the Fama-French three-factor model using the U.S. market composite. The results of these estimations are summarized in Exhibit 9.11.

From both versions of the one-factor market model, it is apparent that FCNTX and TRMCX differ substantially in their systematic risk. In particular, the beta coefficients for TRMCX indicate higher than average market risk (i.e., greater than 1.00), regardless of how the market portfolio is proxied. Additionally, notice that during July 2007–June 2010, the beta estimates for the two funds are higher when the market portfolio is defined by the S&P 500 rather than the U.S. Composite Index (e.g., 1.09 versus 1.03 for TRMCX). This suggests that S&P 500 was the less volatile of the two market indicators over this time period.

The multifactor model gives a much better sense of how FCNTX’s and TRMCX’s risk exposures actually differ from each other. First, notice that including the SMB and HML factors seems to affect the systematic market exposures of the two funds. For instance, the beta relative to the U.S. Composite Index for FCNTX is 0.84 in the single-index model, but increases substantially to 0.95 when estimated as part of the broader three-factor model. This means that some of the risk that the market beta is measuring in the single-factor model is better attributed to the size or value-growth risk factors.

A second implication of the multifactor equation is how the funds should react to the HML variable. Consistent with its Morningstar style category, FCNTX is tilted toward holding growth-oriented stocks. The fund’s HML sensitivity of \(-0.30\) is statistically significant, which shows that FCNTX’s returns move inversely to a risk factor that, by its construction, is implicitly long in value stocks and short in growth stocks. (Recall that a low book-to-market ratio, like a high P/E ratio, is a characteristic of a growth-oriented stock.) On the other hand, the HML coefficient for TRMCX is positive (i.e., 0.19) and also statistically reliable, which is expected for a fund that tends to mainly hold value stocks. Notice in Figure 9.10 that Morningstar places its "fund centroid" at the extreme right edge of the mid-cap value cell in the style box.

Finally, the Morningstar classification system also implies that FCNTX and TRMCX should differ in their sensitivity to the SMB risk factor. This does seem to be the case: FCNTX has a SMB sensitivity of \(-0.13\), suggesting a tilt toward stocks that have larger market capitalizations, while TRMCX, with a SMB sensitivity of 0.34, tends to hold a portfolio that emphasizes smaller stocks. However, the estimated size risk factor of TRMCX is statistically significant, which suggests that the portfolio may contain even smaller firms than its name implies. Nevertheless, the respective style classifications for these two mutual funds appear to be appropriate.

1995–2009 period, and (2) a set of hypothetical forecasts. For example, the expected risk premium estimates for MSFT using the historical risk factor data are:

Three-Factor: \(E(R) - RFR = (0.966)(7.23) + (-0.018)(2.00) + (-0.388)(4.41)\)

\[= 5.24\%\]

Four-Factor: \(E(R) - RFR = (1.001)(7.23) + (-0.012)(2.00) + (-0.341)(4.41) + (0.073)(4.91)\)

\[= 6.07\%\]

Notice three things about the forecasts in Exhibit 9.8. First, for any factor model and set of risk factor forecasts, the comparative excess return estimates across the stocks appear to be reasonable. Second, the forecasted expected stock returns generated by the hypothetical factor estimates are uniformly lower than those produced by using historical data. Finally, the three-factor and four-factor models produce fairly comparable forecasts for MSFT and CSX, but not for XRX, where ignoring the larger (and negative) MOM exposure matters more.

**Comparing Mutual Fund Risk Exposures** To get a better sense of how risk factor sensitivity is estimated at the portfolio level, consider the returns produced by two popular mutual funds: Fidelity’s Contrafund (FCNTX) and T. Rowe Price’s Mid-Cap Value Fund (TRMCX).
Morningstar Inc., an independent stock and mutual fund advisory service, classifies FCNTX’s investment style into the “large-cap growth” category. This means that the typical equity holding of FCNTX is characterized as a large market capitalization firm whose P/E and book-to-market ratios exceed those of the average firm in the market. Exhibit 9.9 shows a sample page for FCNTX from Morningstar’s public-access Web site and shows graphically where the fund fits into the investment “style box” as of the reporting date in 2010. Conversely, as shown in Exhibit 9.10, Morningstar plots TRMCX into the “mid-cap value” category, meaning that the portfolio generally emphasizes smaller companies than does FCNTX as well as those that fall closer to the middle of the value-growth spectrum. Thus, assuming that Morningstar’s classification system is meaningful, the two funds should differ in the relative sensitivities to both the SMB and the HML factors.

Using monthly returns over July 2007 to June 2010, the risk parameters for both funds were estimated relative to three different specifications: (1) a single-factor model using the Standard & Poor’s 500 Index as proxy for the market portfolio, (2) a single-factor model using a broader composite index of the U.S. stock market as a market proxy, and (3) the Fama-French three-factor model using the U.S. market composite. The results of these estimations are summarized in Exhibit 9.11.

From both versions of the one-factor market model, it is apparent that FCNTX and TRMCX differ substantially in their systematic risk. In particular, the beta coefficients for TRMCX indicate higher than average market risk (i.e., greater than 1.00), regardless of how the market portfolio is proxied. Additionally, notice that during July 2007–June 2010, the beta estimates for the two funds are higher when the market portfolio is defined by the S&P 500 rather than the U.S. Composite Index (e.g., 1.09 versus 1.03 for TRMCX). This suggests that S&P 500 was the less volatile of the two market indicators over this time period.

The multifactor model gives a much better sense of how FCNTX’s and TRMCX’s risk exposures actually differ from each other. First, notice that including the SMB and HML factors seems to affect the systematic market exposures of the two funds. For instance, the beta relative to the U.S. Composite Index for FCNTX is 0.84 in the single-index model, but increases substantially to 0.95 when estimated as part of the broader three-factor model. This means that some of the risk that the market beta is measuring in the single-factor model is better attributed to the size or value-growth risk factors.

A second implication of the multifactor equation is how the funds should react to the HML variable. Consistent with its Morningstar style category, FCNTX is tilted toward holding growth-oriented stocks. The fund’s HML sensitivity of −0.30 is statistically significant, which shows that FCNTX’s returns move inversely to a risk factor that, by its construction, is implicitly long in value stocks and short in growth stocks. (Recall that a low book-to-market ratio, like a high P/E ratio, is a characteristic of a growth-oriented stock.) On the other hand, the HML coefficient for TRMCX is positive (i.e., 0.19) and also statistically reliable, which is as expected for a fund that tends to mainly hold value stocks. Notice in Figure 9.10 that Morningstar places its “fund centroid” at the extreme right edge of the mid-cap value cell in the style box.

Finally, the Morningstar classification system also implies that FCNTX and TRMCX should differ in their sensitivity to the SMB risk factor. This does seem to be the case: FCNTX has a SMB sensitivity of −0.13, suggesting a tilt toward stocks that have larger market capitalizations, while TRMCX, with a SMB sensitivity of 0.34, tends to hold a portfolio that emphasizes smaller stocks. However, the estimated size risk factor of TRMCX is statistically significant, which suggests that the portfolio may contain even smaller firms than its name implies. Nevertheless, the respective style classifications for these two mutual funds appear to be appropriate.

Although the CAPM is an appealing explanation for the way in which investment risk and expected return are related, empirical anomalies have caused financial economists to seek other answers. Ross devised an alternative asset pricing model—the APT—that makes fewer assumptions than the CAPM and does not specifically require the designation of a market portfolio. Instead, the APT posits that expected security returns are related in a linear fashion to multiple common risk factors. Unfortunately, the theory does not specify how many factors exist or what their identities might be. The results from the empirical tests of the APT have thus far been mixed.

Given that the common risk factors are not identified, the APT is difficult to put into practice in a theoretically rigorous fashion. Multifactor models of risk and return attempt to bridge this gap by selecting a set of variables that are thought to capture the essence of the systematic risk exposures that exist in the capital market. One general approach has been to use macroeconomic variables—such as unexpected inflation, changes in consumer confidence, unanticipated shifts in the yield curve, or unexpected changes in real GDP—as surrogates for the types of exposures that will have an impact on all securities. Once selected, historical data are often employed to determine the risk premium (i.e., market "price") for each common factor.

A second approach to implementing a multifactor model has focused on the characteristics of the securities themselves. Typical of this sort of microeconomic approach is the work of Fama and French, who posit that three risk factors should be employed: the excess returns to a broad market index, the return difference between portfolios of small- and large-cap stocks, and the return difference between portfolios of value- and growth-oriented stocks. One advantage of this specification is that it accounts directly for some of the anomalies that plague the CAPM. Another advantage is the flexibility to modify the equation in response to changing market conditions. For instance, the Fama-French model has been expanded to include a factor accounting for stock return momentum.

It is probably safe to assume that both the CAPM and APT will continue to be used to value capital assets. Coincident with their use will be further empirical tests of both theories, the ultimate goal being to determine which theory does the best job of explaining current returns and predicting future returns.

Although the CAPM is an appealing explanation for the way in which investment risk and expected return are related, empirical anomalies have caused financial economists to seek other answers. Ross devised an alternative asset pricing model—the APT—that makes fewer assumptions than the CAPM and does not specifically require the designation of a market portfolio. Unfortunately, the theory does not specify how many factors exist or what their identities might be. The results from the empirical tests of the APT have thus far been mixed.

For instance, the Fama-French model has been expanded to include a factor accounting for stock return momentum.

It is probably safe to assume that both the CAPM and APT will continue to be used to value capital assets. Coincident with their use will be further empirical tests of both theories, the ultimate goal being to determine which theory does the best job of explaining current returns and predicting future returns.
ones. Subsequent work in this area will seek to identify the set of factors that best captures the relevant dimension of investment risk as well as explore the intertemporal dynamics of the models (e.g., factor betas and risk premia that change over time).

**QUESTIONS**

1. Both the capital asset pricing model and the arbitrage pricing theory rely on the proposition that a no-risk, no-wealth investment should earn, on average, no return. Explain why this should be the case, and describe similarities and differences between the CAPM and the APT. Also, explain how these theories can help establish investment performance.

2. You are the lead manager of a large mutual fund. You have become aware that several equity analysts who have recently joined your management team are interested in understanding the differences between the capital asset pricing model (CAPM) and arbitrage pricing theory (APT). In particular, they are interested in how these two asset pricing models can help them perform better security analysis.
   a. Explain what the CAPM and APT attempt to model. What are the main differences between these two asset pricing models?
   b. Under what circumstances would the APT be preferred over the CAPM as a tool for selecting stocks for the fund portfolio?

3. The *small-firm effect* refers to the observed tendency for stock prices to behave in a manner that is contrary to normal expectations. Discuss this effect and its implications for the CAPM and APT. What are your conclusions about the stock market and the role of risk?

4. Some studies related to the efficient market hypothesis generated results that implied additional factors beyond beta should be considered to explain expected returns. What are these other variables and why should they be considered?

5. Suppose you are considering the purchase of shares in the XYZ mutual fund. As part of your investment analysis, you regress XYZ’s monthly returns for the past five years against the three factors specified in the Fama and French models. This procedure generates the following coefficient estimates: market factor = 1.2, SMB factor = −0.3, HML factor = 1.4. Explain what each of these coefficient values means. What types of stocks is XYZ likely to be holding?

6. It is widely believed that changes in certain macroeconomic variables may directly affect performance of an equity portfolio. As the chief investment officer of a hedge fund employing a global macro-oriented investment strategy, you often consider how various macroeconomic events might impact your security selection decisions and portfolio performance. Briefly explain how each of the following economic factors would affect...
7. Describe the intuition underlying: (a) the macroeconomic approach to identifying risk factors, and (b) the microeconomic (i.e., characteristic-based) approach to identifying risk factors. Is it conceptually and practically possible for these two approaches to lead to the same estimate of expected return for any given security?

8. How can multifactor models be used to help investors understand the relative risk exposures in their portfolios relative to a benchmark portfolio? Support your answer with examples using both macroeconomic and microeconomic approaches to factor identification.

9. Consider the following questions related to empirical tests of the APT:
   a. Briefly discuss one study that does not support the APT. Briefly discuss a study that does support the APT. Which position seems more plausible?
   b. Briefly discuss why Shanken contends that the APT is not testable. What is the contrary view to Shanken’s position?

10. Jeffrey Bruner, CFA, uses the capital asset pricing model (CAPM) to help identify mispriced securities. A consultant suggests Bruner use the arbitrage pricing theory (APT) instead. In comparing the CAPM and the APT, the consultant made the following arguments:
   a. Both the CAPM and the APT require a mean-variance efficient market portfolio.
   b. Neither the CAPM nor the APT assumes normally distributed security returns.
   c. The CAPM assumes that one specific factor explains security returns, but the APT does not.

   State whether each of the consultant’s arguments is correct or incorrect. Indicate, for each incorrect argument, why the argument is incorrect.

PROBLEMS

1. Consider the following data for two risk factors (1 and 2) and two securities (J and L):

<table>
<thead>
<tr>
<th>Security</th>
<th>( \lambda_0 )</th>
<th>( b_{11} )</th>
<th>( \lambda_1 )</th>
<th>( b_{12} )</th>
<th>( \lambda_2 )</th>
<th>( b_{22} )</th>
</tr>
</thead>
<tbody>
<tr>
<td>J</td>
<td>0.05</td>
<td>0.80</td>
<td>0.02</td>
<td>1.40</td>
<td>0.04</td>
<td>1.60</td>
</tr>
<tr>
<td>L</td>
<td>2.60</td>
<td>2.60</td>
<td>15.4%</td>
<td>13.1%</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

a. Compute the expected returns for both securities.
b. Suppose that Security J is currently priced at $22.50 while the price of Security L is $15.00. Further, it is expected that both securities will pay a dividend of $0.75 during the coming year. What is the expected price of each security one year from now?

2. Exhibit 9.8 demonstrated how the Fama-French three-factor and four-factor models could be used to estimate the expected excess returns for three stocks (MSFT, CSX, and XRX). Specifically, using return data from 2005–2009, the following equations were estimated:

**Three-Factor Model:**

- **MSFT:** \[ E(R) - RFR = (0.966)(\lambda_M) + (-0.018)(\lambda_{SMB}) + (-0.388)(\lambda_{HML}) \]
- **CSX:** \[ E(R) - RFR = (1.042)(\lambda_M) + (-0.043)(\lambda_{SMB}) + (0.370)(\lambda_{HML}) \]
- **XRX:** \[ E(R) - RFR = (1.178)(\lambda_M) + (0.526)(\lambda_{SMB}) + (0.517)(\lambda_{HML}) \]

**Four-Factor Model:**

- **MSFT:** \[ E(R) - RFR = (1.001)(\lambda_M) + (-0.012)(\lambda_{SMB}) + (-0.341)(\lambda_{HML}) + (0.073)(\lambda_{MOM}) \]
- **CSX:** \[ E(R) - RFR = (1.122)(\lambda_M) + (-0.031)(\lambda_{SMB}) + (0.478)(\lambda_{HML}) + (0.166)(\lambda_{MOM}) \]
- **XRX:** \[ E(R) - RFR = (1.041)(\lambda_M) + (0.505)(\lambda_{SMB}) + (0.335)(\lambda_{HML}) + (-0.283)(\lambda_{MOM}) \]

Using the estimated factor risk premia of \( \lambda_M = 7.23\% \), \( \lambda_{SMB} = 2.00\% \), \( \lambda_{HML} = 4.41\% \) and \( \lambda_{MOM} = 4.91\% \), it was then shown that the expected excess returns for the three stocks were 5.24\%, 9.08\%, and 11.86\% (three-factor model) or 6.07\%, 10.98\%, and 8.63\% (four-factor model), respectively.
c. Suppose now that the risk premium for Factor 1 that you calculated in Part a suddenly increases by 0.25% (i.e., from $x\%$ to $(x + 0.25\%)$, where $x$ is the value established in Part a. What are the new expected returns for Stocks D and E?

d. If the increase in the Factor 1 risk premium in Part c does not cause you to change your opinion about what the stock prices will be in one year, what adjustment will be necessary in the current (i.e., today’s) prices?

5. Suppose that three stocks (A, B, and C) and two common risk factors (1 and 2) have the following relationship:

\[
\begin{align*}
E(R_A) &= (1.1)\lambda_1 + (0.8)\lambda_2 \\
E(R_B) &= (0.7)\lambda_1 + (0.6)\lambda_2 \\
E(R_C) &= (0.3)\lambda_1 + (0.4)\lambda_2
\end{align*}
\]

a. If $\lambda_1 = 4\%$ and $\lambda_2 = 2\%$, what are the prices expected next year for each of the stocks? Assume that all three stocks currently sell for $30 and will not pay a dividend in the next year.

b. Suppose that you know that next year the prices for Stocks A, B, and C will actually be $31.50, $35.00, and $30.50. Create and demonstrate a riskless, arbitrage investment to take advantage of these mispriced securities. What is the profit from your investment? You may assume that you can use the proceeds from any necessary short sale.

Problems 6 and 7 refer to the data contained in Exhibit 9.12, which lists 30 monthly excess returns to two different actively managed stock portfolios (A and B) and three different common risk factors (1, 2, and 3). (Note: You may find it useful to use a computer spreadsheet program such as Microsoft Excel to calculate your answers.)

6. a. Compute the average monthly return and monthly standard deviation for each portfolio and all three risk factors. Also state these values on an annualized basis. (Hint: Monthly returns can be annualized by multiplying them by 12, while monthly standard deviations can be annualized by multiplying them by the square root of 12.)

b. Based on the return and standard deviation calculations for the two portfolios from Part a, is it clear whether one portfolio outperformed the other over this time period?

c. Calculate the correlation coefficients between each pair of the common risk factors (i.e., 1 & 2, 1 & 3, and 2 & 3).

d. In theory, what should be the value of the correlation coefficient between the common risk factors? Explain why.

e. How close do the estimates from Part b come to satisfying this theoretical condition? What conceptual problem(s) is created by a deviation of the estimated factor correlation coefficients from their theoretical levels?

7. a. Using regression analysis, calculate the factor betas of each stock associated with each of the common risk factors. Which of these coefficients are statistically significant?

b. How well does the factor model explain the variation in portfolio returns? On what basis can you make an evaluation of this nature?

c. Suppose you are now told that the three factors in Exhibit 9.12 represent the risk exposures in the Fama-French characteristic-based model (i.e., excess market, SMB, and HML). Based on your regression results, which one of these factors is the most likely to be the market factor? Explain why.

d. Suppose it is further revealed that Factor 3 is the HML factor. Which of the two portfolios is most likely to be a growth-oriented fund and which is a value-oriented fund? Explain why.
c. Suppose now that the risk premium for Factor 1 that you calculated in Part a suddenly increases by 0.25% (i.e., from x% to (x + 0.25)%), where x is the value established in Part a. What are the new expected returns for Stocks D and E?
d. If the increase in the Factor 1 risk premium in Part c does not cause you to change your opinion about what the stock prices will be in one year, what adjustment will be necessary in the current (i.e., today’s) prices?

5. Suppose that three stocks (A, B, and C) and two common risk factors (1 and 2) have the following relationship:

\[
E(R_A) = (1.1)\lambda_1 + (0.8)\lambda_2 \\
E(R_B) = (0.7)\lambda_1 + (0.6)\lambda_2 \\
E(R_C) = (0.3)\lambda_1 + (0.4)\lambda_2 
\]

a. If \( \lambda_1 = 4\% \) and \( \lambda_2 = 2\% \), what are the prices expected next year for each of the stocks? Assume that all three stocks currently sell for \$30 and will not pay a dividend in the next year.
b. Suppose that you know that next year the prices for Stocks A, B, and C will actually be \$31.50, \$35.00, and \$30.50. Create and demonstrate a riskless, arbitrage investment to take advantage of these mispriced securities. What is the profit from your investment? Evaluate the potential success of this strategy by taking the difference in returns between the value and growth indexes you analyzed above. What is the average return and return standard deviation for the return differential series?

e. Plot the return differential series you calculated in Part d, using the return differential on the vertical axis and time on the horizontal axis. What do you conclude about the viability of the “long value, short growth” investment strategy?

2. You would also like to evaluate the historical relationship between small-cap-oriented and large-cap-oriented stocks that form the basis for the SMB risk factor in the Fama-French multifactor model. The proxies you choose are the Russell 2000 index and the Russell 1000 index, respectively.

a. Under the “Indices” tab, download weekly price information for the most recent five-year period available for each index.

b. For each index, calculate the set of weekly returns that correspond to these weekly price series.

c. Calculate the average weekly return and the return standard deviation for each index series. Which equity investment style (i.e., small cap vs. large cap) appears to have been the most successful over this sample period?

In Parts 1 and 2, you learned the purpose of investing and the importance of an appropriate asset allocation decision. You also learned about the numerous investment instruments available on a global basis and the background regarding the institutional characteristics of the capital markets. In addition, you are now aware of the major developments in investment theory as they relate to efficient capital markets, portfolio theory, capital asset pricing, and multifactor valuation models. Therefore, at this point you are in a position to consider the theory and practice of estimating the value of various securities, which is the heart of investing and leads to the construction of a portfolio that is consistent with your risk-return objectives. You will recall that the investment decision is based on a comparison of an asset’s intrinsic value and its market price.

The major source of information regarding a stock or bond is the corporation’s financial statements. Chapter 10 considers what financial statements are available and what information they provide, followed by a discussion of the financial ratios used to answer several important questions about a firm’s liquidity, its operating performance, its risk profile, and its growth potential.

Chapter 11 considers the basic principles of valuation and applies those principles to the valuation of bonds, preferred stock, and common stock. Because it is recognized that the valuation of common stock is the most challenging task, we present two general approaches to equity valuation (discounted cash flow models and relative valuation ratios) and several techniques for each of these approaches. We conclude Chapter 11 by reviewing the basic factors that influence the two critical variables that determine the intrinsic value of an asset irrespective of the valuation model: (1) the required rate of return for an investment, and (2) the estimated growth rate of earnings, dividends, and cash flows for the investment.

When you master these two chapters, you will have the tools and the theoretical understanding to apply the valuation models to the range of entities included in the top-down approach—the aggregate market, alternative industries, and individual companies and stocks. These specific valuations are the topics considered in Part 4.

CHAPTER 10
Analysis of Financial Statements

After you read this chapter, you should be able to answer the following questions:

- What are the major financial statements provided by firms, and what specific information does each of them contain?
- Why do we use financial ratios to examine the performance of a firm, and why is it important to examine performance relative to the economy and to a firm’s industry?
- What are the major categories for financial ratios, and what questions are answered by the ratios in these categories?
- What specific ratios help determine a firm’s internal liquidity, operating performance, risk profile, and growth potential?
- How can DuPont analysis help evaluate a firm’s past and future return on equity?
- What is a quality balance sheet or income statement?
- Why should you engage in financial statement analysis if markets are efficient and forward-looking?
- What major financial ratios are used by analysts in the following areas: stock valuation, estimating and evaluating systematic risk, predicting the credit ratings on bonds, and estimating the probability of bankruptcy?

You have probably already noted that this is a fairly long chapter with several financial statements and numerous financial ratios. The reason for this extensive discussion of how to analyze financial statements is because our ultimate goal (as noted earlier) is to construct a portfolio of investments that will provide rates of return that are consistent with the risk of the portfolio. In turn, to determine the expected rates of return on different assets, we must estimate the future value of each asset since a major component of the rate of return is the change in value for the asset over time. Therefore, the crux of investments is valuation. Although we consider various valuation models for common stocks in the next chapter, you are already aware that the value of any earning asset is the present value of the expected cash flows generated by the asset. Therefore, as noted in previous chapters, to estimate the value of an asset we must derive an estimate of the discount rate for the asset (the required rate of return) and its expected cash flows. The main sources of the information needed to make these two estimates are the firm’s financial statements. To derive an estimate of the required rate of return, we need to understand the business and financial risk of the firm. To estimate future cash flows, we must understand the composition of historical cash flows and what factors will contribute to the short-run and long-run growth of these cash flows. Financial statements, business and financial risk, and the analysis of the composition as well as the growth of cash flow are all topics of this chapter. In other
words, a primary purpose of this chapter is to help you understand how to estimate the relevant variables in alternative valuation models.

Financial statements are also the main source of information when deciding whether to lend money to a firm (invest in its bonds) or to buy warrants or options on a firm’s stock. In this chapter, we first introduce a corporation’s major financial statements and discuss why and how financial ratios are useful. We also provide example ratios that reflect internal liquidity, operating performance, risk analysis, and growth analysis. In addition, we address four major areas in investments where financial ratios have been effectively employed.

Our example in this chapter is Walgreen Co., the largest retail drugstore chain in the United States. It operates in all 50 states and Puerto Rico. Pharmacy prescription sales generate over 65 percent of total sales. The firm leads its industry (retail drugstores) in sales, profit, and store growth. The firm’s goal is to be America’s most convenient and technologically advanced health-care retailer. It takes great pride in its steady sales and earnings growth that have been reflected in outstanding stock performance—for example, dividends have increased in each of the past 35 years and, since 1980, the stock has been split two-for-one seven times.

10.1 Major Financial Statements

Financial statements are intended to provide information on the resources available to management, how these resources were financed, and what the firm accomplished with them. Corporate shareholder annual and quarterly reports include three required financial statements: the balance sheet, the income statement, and the statement of cash flows. In addition, reports that must be filed with the Securities and Exchange Commission (SEC) (e.g., the 10-K and 10-Q reports) carry detailed information about the firm, such as information on loan agreements and data on product line and subsidiary performance. Information from the basic financial statements can be used to calculate financial ratios and to analyze the operations of the firm to determine what factors influence a firm’s earnings, cash flows, and risk characteristics.

10.1.1 Generally Accepted Accounting Principles

Among the input used to construct the financial statements are generally accepted accounting principles (GAAP), which are formulated by the Financial Accounting Standards Board (FASB). The FASB recognizes that it would be improper for all companies to use identical and restrictive accounting principles. Some flexibility and choice are needed because industries and firms within industries differ in their operating environments. Therefore, the FASB allows companies some flexibility to choose among appropriate GAAP. This flexibility allows the firm’s managers to choose accounting standards that best reflect company practice. On the negative side, this flexibility can allow firms to appear healthier than they really are. Given this possibility, the financial analyst must rigorously analyze the available financial information to separate those firms that appear attractive from those that actually are in good financial shape.

Fortunately, the FASB requires that financial statements include footnotes that indicate which accounting principles were used by the firm. Because accounting principles frequently differ among firms, the footnote information assists the financial analyst in adjusting the financial statements of companies so that the analyst can better compare “apples with apples.”

1The Enron fiasco clearly makes this point. For a general discussion on this topic, see Byrnes and Henry (2001), Henry (2001), and McNamee (2002).
10.1.2 Balance Sheet
The balance sheet shows what resources (assets) the firm controls and how it has financed these assets. Specifically, it indicates the current and fixed assets available to the firm at a point in time (the end of the fiscal year or the end of a quarter). In most cases, the firm owns these assets, but some firms lease assets on a long-term basis. How the firm has financed the acquisition of these assets is indicated by its mixture of current liabilities (accounts payable or short-term borrowing), long-term liabilities (fixed debt and leases), and owners’ equity (preferred stock, common stock, and retained earnings).

The consolidated balance sheet for Walgreens in Exhibit 10.1 represents the stock of assets and its financing mix as of Walgreen Co.’s fiscal years ended August 31, 2006–2010.

10.1.3 Income Statement
The income statement contains information on the operating performance of the firm during some period of time (a quarter or a year). In contrast to the balance sheet, which is at a fixed point in time, the income statement indicates the flow of sales, expenses, and earnings during a period of time. The consolidated income statement for Walgreens for the years ended August 31, 2006–2010 appears in Exhibit 10.2. For Walgreens, the net income reported is very “clean” because the firm generally has no nonrecurring or unusual income or expense items.

10.1.4 Statement of Cash Flows
Our earlier discussion on valuation indicates that cash flows are a critical input that firms are required to provide. The statement of cash flows integrates the effects on the firm’s cash flow of income flows (based on the most recent year’s income statement) and changes on the balance sheet (based on the two most recent annual balance sheets). Analysts use these cash flow values to estimate the value of a firm and to evaluate the risk and return of the firm’s bonds and stock.

The statement of cash flows has three sections: cash flows from operating activities, cash flows from investing activities, and cash flows from financing activities. The total cash flows from the three sections is the net change in the cash position of the firm that should equal the difference in the cash balance between the ending and beginning balance sheets. The statements of cash flows for Walgreens for the years ended August 31, 2008, 2009, and 2010 appear in Exhibit 10.3.

Cash Flows from Operating Activities This section of the statement lists the sources and uses of cash that arise from the normal operations of a firm. The net cash flow from operations is computed as the net income reported on the income statement including changes in net working capital items (i.e., receivables, inventories, and so on) plus adjustments for noncash revenues and expenses (such as depreciation), or:

10.1 Cash Flows from Operating Activities = Net Income + Noncash Revenue and Expenses + Changes in Net Working Capital Items

Consistent with our previous discussion, the cash account is not included in the calculations of cash flow from operations. Notably, Walgreens has been able to generate consistently large cash flows from operations even after accounting for consistent substantial increases in accounts receivable and inventory required by the firm’s growth. There was a small decline in this value in 2010 from 2009 due to inventory changes.

Cash Flows from Investing Activities A firm makes investments in both its own noncurrent and fixed assets and the equity of other firms (which may be subsidiaries or joint ventures of the parent firm; they are listed in the “investment” account of the balance sheet). Increases and
Dividend payments are a significant financing cash outflow. For Walgreens and for many firms, the repurchase of shares was a major financing outflow in 2010. The total cash flows from operating, investing, and financing activities are the net increase or decrease in the firm's cash. In the case of Walgreens during 2010, it is shown that although the firm had strong cash flow from operations, it experienced a larger cash outflow for investments due to asset acquisitions and an outflow from financing caused by heavy share repurchases plus a paydown in its long-term debt. The overall effect was a decline in the firm's cash balance. Notably, the statement of cash flows provides cash flow detail that is lacking in the balance sheet and income statement.

10.1.5 Measures of Cash Flow

There are several cash flow measures an analyst can use to determine the underlying health of the corporation. You should become familiar with these alternative measures.

Traditional Cash Flow

The "traditional" measure of cash flow equals net income plus depreciation expense and the change in deferred taxes. But as we have just seen, it is also necessary to adjust for changes in operating (current) assets and liabilities that either use or provide cash. These changes can add to or subtract from the cash flow estimated from the traditional measure of cash flow: net income plus noncash expenses.

The table below compares the cash flow from operations figures (Exhibit 10.3) to the traditional cash flow figures for Walgreens from 2008 to 2010.

decreases in these noncurrent accounts are considered investment activities. The cash flow from investing activities is the change in gross plant and equipment plus the change in the investment account. The changes are positive if they represent a source of funds (e.g., sale of some plant and/or equipment); otherwise they are negative. The dollar changes in these accounts are computed using the firm’s two most recent balance sheets. Most firms (including Walgreens) experience negative cash flows from investments due to significant capital expenditures.

Cash Flows from Financing Activities

Cash inflows are created by increasing notes payable and long-term liability and equity accounts, such as bond and stock issues. Financing uses (outflows) include decreases in such accounts (that is, paying down liability accounts or the
repurchase of common shares). Dividend payments are a significant financing cash outflow. For Walgreens and for many firms, the repurchase of shares was a major financing outflow in 2010.

The total cash flows from operating, investing, and financing activities are the net increase or decrease in the firm’s cash. In the case of Walgreens during 2010, it is shown that although the firm had strong cash flow from operations, it experienced a larger cash outflow for investments due to asset acquisitions and an outflow from financing caused by heavy share repurchases plus a paydown in its long-term debt. The overall effect was a decline in the firm’s cash balance. Notably, the statement of cash flows provides cash flow detail that is lacking in the balance sheet and income statement.

For firms involved in leveraged buyouts, this free cash flow number is critical because the new owners typically want to use the firm’s free cash flow as funds available for retiring outstanding debt. It is not unusual for a firm’s free cash flow to be a negative value. For Walgreens, the free cash flow value has been positive but not large because of significant capital expenditures related to store growth. Notably, this free cash flow value or a variation of it will be used in the subsequent cash flow valuation models.

EBITDA

The widely-used EBITDA (earnings before interest, taxes, depreciation, and amortization) measure of cash flow is extremely liberal. This very generous measure of operating earnings does not consider any of the adjustments noted previously. Specifically, it adds back depreciation and amortization (as in the traditional measure) along with both interest expense and taxes, but does not consider the effect of changes in working capital items (such as additions to receivables and inventory) or the significant impact of capital expenditures. The result is basically operating earnings plus depreciation expense. The following table, which compares this measure to the other three measures of cash flow for Walgreens, demonstrates the large differences among these measures. Notably, because EBITDA does not consider several of these necessary expenditures, it consistently has the highest value among cash flow measures.

Some analysts have used EBITDA as a proxy for cash flow and a metric for valuation similar to earnings—that is, they refer to EBITDA multiples as other analysts would refer to price-earnings (P/E) multiples. Yet given what this measure does not consider, this is a very questionable practice, and the authors do not recommend using EBITDA.

cash flows rather than the typical outflows for a growing firm—that is, Walgreens tightened asset control except for inventory levels.

**Free Cash Flow** Free cash flow modifies cash flow from operations to recognize that some investing and financing activities are critical to the firm. It is assumed that these expenditures must be made before a firm can use its cash flow for other purposes such as reducing debt outstanding or repurchasing common stock. Two additional items are considered: (1) capital expenditures (an investing expenditure), and (2) the disposition of property and equipment (a divestment source of cash). These two items are used to modify Walgreen Co.’s cash flows from operations as follows (most analysts only subtract net capital expenditures, but conservative analysts also subtract dividends).
Thus, ratios are intended to provide meaningful relationships between individual values in the financial statements. Because the major financial statements report numerous individual items, it is possible to produce a vast number of potential ratios, many of which will have little value. Therefore, we limit our examination to the most relevant ratios and group them into categories that will provide information on important economic characteristics of the firm.

### 10.2.1 Importance of Relative Financial Ratios

Just as a single number from a financial statement is of little use, an individual financial ratio has little value except in relation to comparable ratios for other entities. That is, only relative financial ratios are relevant. Therefore, it is important to compare a firm’s performance relative to:

- The aggregate economy
- Its industry or industries
- Its major competitors within the industry
- Its past performance (time-series analysis)

The comparison to the aggregate economy is important because almost all firms are influenced by economic fluctuations. For example, it is unreasonable to expect an increase in the profit margin for a firm during a recession; a stable margin might be encouraging under such conditions. In contrast, a small increase in a firm’s profit margin during a major business expansion may be a sign of weakness. Thus, this analysis that considers the economic environment helps investors understand how a firm reacts to the business cycle and should improve an estimate of the future performance of the firm during subsequent business cycles.

Probably the most significant comparison relates a firm’s performance to that of its industry. Different industries affect the firms within them differently, but this relationship is always significant. The industry effect is strongest for industries with homogeneous products such as steel, rubber, glass, and wood products, because all firms within these industries experience coincidental shifts in demand. In addition, these firms employ fairly similar technology and production processes. As a result, even the best-managed steel firm experiences a decline in sales and profit margins during a recession. In such a case, the relevant question is not whether sales and margins declined, but how bad was the decline relative to other steel firms? In addition, investors should examine an industry’s performance relative to the economy to understand how the industry responds to the business cycle, as discussed in Chapter 13.

When comparing a firm’s financial ratios to industry ratios, investors may not want to use the average (mean) industry value when there is wide variation among firms in the industry. Alternatively, if we believe that a firm has a unique component, a cross-sectional analysis, in which we compare the firm to a subset of industry firms comparable in size or characteristics, may be appropriate. As an example, we would compare the performance of Kroger to that of other national food chains rather than regional food chains or specialty food chains.

Another practical problem with comparing a firm to its industry is that many large firms are multi-industry. Inappropriate comparisons can arise when a multi-industry firm is evaluated against the ratios from a single industry. To mitigate this problem, an alternative is to use a cross-sectional analysis that compares the firm with a rival that operates in many of the same industries. Alternatively, we can construct composite industry average ratios for the firm. To do this, we use the firm’s annual report or 10-K filing to identify each industry in which the firm operates and the proportion of total firm sales and operating earnings derived from each industry. The composite industry ratios would be the weighted-average ratios based on the proportion of firm sales and operating earnings derived from each industry.

For firms involved in leveraged buyouts, this free cash flow number is critical because the new owners typically want to use the firm’s free cash flow as funds available for retiring outstanding debt. It is not unusual for a firm’s free cash flow to be a negative value. For Walgreens, the free cash flow value has been positive but not large because of significant capital expenditures related to store growth. Notably, this free cash flow value or a variation of it will be used in the subsequent cash flow valuation models.2

**EBITDA** The widely-used EBITDA (earnings before interest, taxes, depreciation, and amortization) measure of cash flow is extremely liberal. This very generous measure of operating earnings does not consider any of the adjustments noted previously. Specifically, it adds back depreciation and amortization (as in the traditional measure) along with both interest expense and taxes, but does not consider the effect of changes in working capital items (such as additions to receivables and inventory) or the significant impact of capital expenditures. The result is basically operating earnings plus depreciation expense. The following table, which compares this measure to the other three measures of cash flow for Walgreens, demonstrates the large differences among these measures. Notably, because EBITDA does not consider several of these necessary expenditures, it consistently has the highest value among cash flow measures.

Yet given what this measure does not consider, this is a very questionable practice, and the authors do not recommend using EBITDA.3

### 10.1.6 Purpose of Financial Statement Analysis

Financial statement analysis seeks to evaluate management performance in several important areas, including profitability, efficiency, and risk. Although we will necessarily analyze historical data, the ultimate goal of this analysis is to provide insights that will help us to project future management performance, including pro forma balance sheets, income statements, cash flows, and alternative risk measures. It is the firm’s expected future performance that determines whether we should lend money to a firm or invest in it.

### 10.2 Analysis of Financial Ratios

Analysts use financial ratios because numbers in isolation typically convey little meaning. For example, knowing that a firm earned a net income of $100,000 is not very informative unless we also know the sales figure that generated this income ($1 million or $10 million) and the

---

2As we will show in the next chapter, small modifications of this free cash flow—called free cash flow to equity (FCFE), free cash flow to the firm (FCFF), and net operating profits less applicable taxes (NOPLAT)—are used in valuation models and also the economic value added (EVA) model.

3For a detailed discussion of the problems with using EBITDA, see Greenberg (2000).
assets or capital committed to the enterprise. Thus, ratios are intended to provide meaningful relationships between individual values in the financial statements.

Because the major financial statements report numerous individual items, it is possible to produce a vast number of potential ratios, many of which will have little value. Therefore, we limit our examination to the most relevant ratios and group them into categories that will provide information on important economic characteristics of the firm.

10.2.1 Importance of Relative Financial Ratios

Just as a single number from a financial statement is of little use, an individual financial ratio has little value except in relation to comparable ratios for other entities. That is, only relative financial ratios are relevant. Therefore, it is important to compare a firm’s performance relative to:

- The aggregate economy
- Its industry or industries
- Its major competitors within the industry
- Its past performance (time-series analysis)

The comparison to the aggregate economy is important because almost all firms are influenced by economic fluctuations. For example, it is unreasonable to expect an increase in the profit margin for a firm during a recession; a stable margin might be encouraging under such conditions. In contrast, a small increase in a firm’s profit margin during a major business expansion may be a sign of weakness. Thus, this analysis that considers the economic environment helps investors understand how a firm reacts to the business cycle and should improve an estimate of the future performance of the firm during subsequent business cycles.

Probably the most significant comparison relates a firm’s performance to that of its industry. Different industries affect the firms within them differently, but this relationship is always significant. The industry effect is strongest for industries with homogeneous products such as steel, rubber, glass, and wood products, because all firms within these industries experience coincidental shifts in demand. In addition, these firms employ fairly similar technology and production processes. As a result, even the best-managed steel firm experiences a decline in sales and profit margins during a recession. In such a case, the relevant question is not whether sales and margins declined, but how bad was the decline relative to other steel firms? In addition, investors should examine an industry’s performance relative to the economy to understand how the industry responds to the business cycle, as discussed in Chapter 13.

When comparing a firm’s financial ratios to industry ratios, investors may not want to use the average (mean) industry value when there is wide variation among firms in the industry. Alternatively, if we believe that a firm has a unique component, a cross-sectional analysis, in which we compare the firm to a subset of industry firms comparable in size or characteristics, may be appropriate. As an example, we would compare the performance of Kroger to that of other national food chains rather than regional food chains or specialty food chains.

Another practical problem with comparing a firm to its industry is that many large firms are multi-industry. Inappropriate comparisons can arise when a multi-industry firm is evaluated against the ratios from a single industry. To mitigate this problem, an alternative is to use a cross-sectional analysis that compares the firm with a rival that operates in many of the same industries. Alternatively, we can construct composite industry average ratios for the firm. To do this, we use the firm’s annual report or 10-K filing to identify each industry in which the firm operates and the proportion of total firm sales and operating earnings derived from each industry. The composite industry ratios would be the weighted-average ratios based on the proportion of firm sales and operating earnings derived from each industry.
Finally, time-series analysis, in which we examine a firm’s relative performance over time to determine whether it is progressing or declining, is helpful when estimating future performance. Calculating the 5- or 10-year average of a ratio without considering the time-series trend can result in misleading conclusions. For example, an average rate of return of 10 percent can be the result of rates of return that have increased from 5 percent to 15 percent over time, or the result of a series that declined from 15 percent to 5 percent. Obviously, the difference in the trend for these series would have a major impact on our estimate for the future. Ideally, an analyst should examine a firm’s time series of relative financial ratios compared to its industry and the economy.

10.3 Computation of Financial Ratios
In the following discussion, we divide the financial ratios into five major categories that underscore some important economic characteristics of a firm. The five categories are:

1. Common size statements
2. Internal liquidity (solvency)
3. Operating performance
   a. Operating efficiency
   b. Operating profitability
4. Risk analysis
   a. Business risk
   b. Financial risk
   c. External liquidity risk
5. Growth analysis

10.3.1 Common Size Statements
Common size statements normalize balance sheet and income statement items to allow easier comparison of different sized firms. A common size balance sheet expresses all balance sheet accounts as a percentage of total assets. A common size income statement expresses all income statement items as a percentage of sales. Exhibit 10.4 is the common size balance sheet for Walgreens, and Exhibit 10.5 contains the common size income statement. Common size ratios are useful to quickly compare two different sized firms and to examine trends over time within a single firm. Common size statements also give insight into a firm’s financial condition, for example, the proportion of liquid assets or the proportion of short-term liabilities, and the percentage of sales consumed by production costs or interest expense. In the case of Walgreens, the common size balance sheet shows a significant decline in the percent of current assets from over 56 percent to 45 percent (due to a strong decline in accounts receivable and inventory, partially offset by a small increase in cash). Alternatively, the common size income statement shows that Walgreen Co.’s cost of goods sold was quite stable from 2006 to 2010 as a proportion of sales. In contrast, the firm’s selling and administrative expense as a percent of sales increased by about 1 percent from 2006 to 2010, and this reduction in operating earnings as a percent of sales carried down to a reduction in the net profit margin.

10.4 Evaluating Internal Liquidity
Internal liquidity (solvency) ratios are intended to indicate the ability of the firm to meet future short-term financial obligations. They compare near-term financial obligations, such as accounts payable or notes payable, to current assets or cash flows that will be available to meet these obligations.
These current ratios were relatively constant during the three years and are consistent with the typical current ratio. As always, it is important to compare these values with similar figures for the firm’s industry and the aggregate market. If the ratios differ from the industry results, we need to determine what might explain the difference in terms of specific current assets and liabilities. (We will discuss comparative analysis in a later section.)

Quick Ratio

Some observers question using total current assets to gauge the ability of a firm to meet its current obligations because inventories and some other current assets might not be very liquid. They prefer the quick ratio, which relates current liabilities to only relatively liquid current assets (cash items and accounts receivable) as follows:

$$\text{Quick Ratio} = \frac{\text{Cash} + \text{Short-term Investments} + \text{Receivables}}{\text{Current Liabilities}}$$

Walgreens quick ratios were:

- **2010**: $4,330,743, $0.58
- **2009**: $5,083,676, $0.75
- **2008**: $2,970,664, $0.45

These quick ratios were respectable and relatively stable over the three years. As before, we should compare these values to other firms in the industry and to the aggregate economy.

Cash Ratio

The most conservative liquidity ratio is the cash ratio, which relates the firm’s cash and short-term marketable securities to its current liabilities as follows:

$$\text{Cash Ratio} = \frac{\text{Cash and Marketable Securities}}{\text{Current Liabilities}}$$

Walgreens cash ratios were:

- **2010**: $1,880,743, $0.25
- **2009**: $2,587,676, $0.38
- **2008**: $443,664, $0.07

10.4.1 Internal Liquidity Ratios

**Current Ratio** Clearly, the best-known liquidity measure is the current ratio, which examines the relationship between current assets and current liabilities as follows:

$$\text{Current Ratio} = \frac{\text{Current Assets}}{\text{Current Liabilities}}$$

Walgreens current ratios (in thousands of dollars) were:

- **2010**: \(\frac{11,922}{7,433} = 1.60\)
- **2009**: \(\frac{12,049}{6,769} = 1.78\)
- **2008**: \(\frac{10,433}{6,644} = 1.57\)
The cash ratio was clearly unacceptable in 2008 but increased to reasonable values in 2009 and 2010, given the firm’s very stable growth of sales and earnings along with significant operating cash flows. In addition, the firm has strong bank lines of credit.

Receivables Turnover

In addition to examining total liquid assets, it is useful to analyze the quality (liquidity) of the accounts receivable by calculating how often the firm’s receivables turn over, which implies an average collection period. The faster these accounts are paid, the sooner the firm gets the funds to pay off its own current liabilities. Receivables turnover is computed as:

\[
\text{Receivables Turnover} = \frac{\text{Net Annual Sales}}{\text{Average Receivables}}
\]

The average receivables figure is typically equal to the beginning receivables figure plus the ending value divided by two. Receivables turnover ratios for Walgreens were:

- **2010:** \(\frac{67,420 - 2,450 + 2,496}{2} = 27,250\) times
- **2009:** \(\frac{63,335 - 2,496 + 2,527}{2} = 25,200\) times
- **2008:** \(\frac{59,034 - 2,527 + 2,236}{2} = 24,780\) times

Given these annual receivables turnover figures, the average collection period is:

\[
\text{Average Receivables Collection Period} = \frac{365}{\text{Annual Receivables Turnover}}
\]

For Walgreens,

- **2010:** \(\frac{365}{27,250} = 13.39\) days
- **2009:** \(\frac{365}{25,200} = 14.48\) days
- **2008:** \(\frac{365}{24,780} = 14.73\) days

These results indicate that Walgreens currently collects its accounts receivable in about 14 days, on average. To determine whether these account collection numbers are good or bad, it is essential that they be related to the firm’s credit policy and to comparable numbers for other firms in the industry. The point is, the receivables collection period value varies dramatically for different firms (e.g., from 10 to over 60), and it is mainly due to the firm’s product and its industry. An industry comparison would indicate similar rapid collection periods for other drugstore chains, since most sales are for cash. While these collection periods appear relatively short, they actually have increased since 2000 because a significant change has occurred in pharmacy sales. Specifically, a growing proportion of pharmacy sales (currently about 92 percent) are now to a third party, so they are reimbursed with a lag by a managed-care or insurance company, which has caused the increase in receivables and the collection period.

The receivables turnover is one of the ratios in which a firm does not want to deviate too much from the industry norm. In an industry where the norm is 40 days, a collection period of 80 days would indicate slow-paying customers, which increases the capital tied up in receivables and the possibility of bad debts. Therefore, the firm wants to be somewhat below the norm (e.g., 35 days vs. 40 days). At the same time, a figure substantially below the norm is a red flag for potential problems, so the firm needs to be aware of any changes in its receivables turnover ratio.

- **2009:** \( \frac{63,335}{(2,496 + 2,527)/2} = 25.20 \) times
- **2008:** \( \frac{59,034}{(2,527 + 2,236)/2} = 24.78 \) times

Given these annual receivables turnover figures, the average collection period is:

\[ \text{Average Receivables Collection Period} = \frac{365 \text{ Days}}{\text{Annual Receivables Turnover}} \]

For Walgreens,

- **2010:** \( \frac{365}{27.25} = 13.39 \) days
- **2009:** \( \frac{365}{25.20} = 14.48 \) days
- **2008:** \( \frac{365}{24.78} = 14.73 \) days

These results indicate that Walgreens currently collects its accounts receivable in about 14 days, on average. To determine whether these account collection numbers are good or bad, it is essential that they be related to the firm’s credit policy and to comparable numbers for other firms in the industry. The point is, the receivables collection period value varies dramatically for different firms (e.g., from 10 to over 60), and it is mainly due to the firm’s product and its industry. An industry comparison would indicate similar rapid collection periods for other drugstore chains, since most sales are for cash. Therefore, the firm wants to be somewhat below the norm (e.g., 35 days vs. 40 days). At the same time, a figure substantially below the norm...
of days. Specifically, cash is committed to receivables for the collection period and in inventory for the inventory processing period. At the same time, the firm receives an offset to this capital commitment from its own suppliers who provide interest-free loans to the firm by carrying the firm’s payables. Specifically, the payables payment period is equal to 365 divided by the payables’ turnover ratio. In turn, the payables turnover ratio is:

\[
\text{Payables Turnover Ratio} = \frac{\text{Cost of Goods Sold}}{\text{Average Trade Payables}}
\]

For Walgreens, the payables turnover ratios were:

- **2010:** \(\frac{48,444}{(4,585 + 4,308)/2} = 6.84\) times
- **2009:** \(\frac{45,722}{(6,789 + 7,249)/2} = 6.51\) times
- **2008:** \(\frac{42,391}{(7,249 + 6,790)/2} = 6.04\) times

Given these turnover values, we can compute the average inventory processing time as follows:

\[
\text{Average Inventory Processing Period} = \frac{365}{\text{Annual Inventory Turnover}}
\]

For Walgreens,

- **2010:** \(\frac{365}{6.84} = 53.4\) days
- **2009:** \(\frac{365}{6.51} = 56.1\) days
- **2008:** \(\frac{365}{6.04} = 60.4\) days

Although this seems like a low turnover figure, it is encouraging that the inventory processing period has been gradually declining. Still, it is essential to examine this turnover ratio relative to an industry norm and/or the firm’s prime competition. Notably, this ratio will also be affected by the products carried by the chain—for instance, if a drugstore chain adds high-profit margin items, such as cosmetics and liquor, these products may have a lower turnover.

As with receivables, a firm does not want an extremely low inventory turnover value and long processing time because this implies that capital is being tied up in inventory and could signal obsolete inventory (especially for firms in the technology sector). Alternatively, an abnormally high inventory turnover and a short processing time could mean inadequate inventory that could lead to outages, backorders, and slow delivery to customers, which would eventually have an adverse effect on sales.

**Cash Conversion Cycle** A very useful measure of overall internal liquidity is the cash conversion cycle, which combines information from the receivables turnover, the inventory turnover, and the accounts payable turnover. Cash is tied up in assets for a certain number
of days. Specifically, cash is committed to receivables for the collection period and in inventory for the inventory processing period. At the same time, the firm receives an offset to this capital commitment from its own suppliers who provide interest-free loans to the firm by carrying the firm’s payables. Specifically, the payables’ payment period is equal to 365 divided by the payables’ turnover ratio. In turn, the payables turnover ratio is:

\[
\text{Payables Turnover Ratio} = \frac{\text{Cost of Goods Sold}}{\text{Average Trade Payables}}
\]

For Walgreens, the payables turnover ratios were:

\[
\begin{align*}
2010: & \quad \frac{48,444}{(4,585 + 4,308)/2} = 10.9 \text{ times} \\
2009: & \quad \frac{45,722}{(4,308 + 4,289)/2} = 10.6 \text{ times} \\
2008: & \quad \frac{42,391}{(4,289 + 3,733)/2} = 10.6 \text{ times}
\end{align*}
\]

The payables payment period is:

\[
\text{Payables Payment Period} = \frac{365 \text{ days}}{\text{Payable Turnover}}
\]

For Walgreens, the payables payment periods were:

\[
\begin{align*}
2010: & \quad \frac{365}{10.9} = 33.5 \text{ days} \\
2009: & \quad \frac{365}{10.6} = 34.4 \text{ days} \\
2008: & \quad \frac{365}{10.6} = 34.4 \text{ days}
\end{align*}
\]

Therefore, the cash conversion cycle for Walgreens (with components rounded) equals:

<table>
<thead>
<tr>
<th>Year</th>
<th>Receivables Collection Days</th>
<th>Inventory Processing Days</th>
<th>Payables Payment Period</th>
<th>Cash Conversion Cycle</th>
</tr>
</thead>
<tbody>
<tr>
<td>2010</td>

</tr>
<tr>

</tr>
</tbody>
</table>

Walgreens has experienced small declines in its receivables days and in its inventory processing days and is constant in paying its bills. The overall result is a consistent decline in its cash conversion cycle. Although the overall cash conversion cycle appears to be quite good (currently about 32 days), as always we should examine the firm’s long-term trend and compare it to other drugstore chains.

### 10.5 Evaluating Operating Performance

The operating performance ratios can be divided into two subcategories: (1) operating efficiency ratios and (2) operating profitability ratios. Efficiency ratios examine how the management uses its assets and capital, measured by dollars of sales generated by various asset or capital categories. Profitability ratios analyze the profits as a percentage of sales and as a percentage of the assets and capital employed.
10.5.1 Operating Efficiency Ratios

**Total Asset Turnover** The total asset turnover ratio indicates the effectiveness of the firm’s use of its total asset base (net assets equals gross assets minus depreciation on fixed assets). It is computed as:

\[
\text{Total Asset Turnover} = \frac{\text{Net Sales}}{\text{Average Total Net Assets}}
\]

Walgreens total asset turnover values were:

\[
\begin{align*}
2010: & \quad \frac{67,420}{(26,275 + 25,142)/2} = 2.62 \text{ times} \\
2009: & \quad \frac{63,335}{(25,142 + 22,410)/2} = 2.66 \text{ times} \\
2008: & \quad \frac{59,034}{(22,410 + 19,314)/2} = 2.83 \text{ times}
\end{align*}
\]

This ratio, which has experienced a small steady decline for Walgreens, must be compared to that of other firms within an industry because it varies substantially between industries. For example, total asset turnover ratios range from less than 1 for large, capital-intensive industries (steel, autos, and heavy manufacturing companies) to over 10 for some retailing or service operations. It also can be affected by the use of leased facilities, which could impact the ratios for Walgreens. Specifically, as shown in the appendix to this chapter, the capitalized leases of stores for Walgreen Co. are about $20 billion, and adding this to the total assets on the books would have almost doubled assets and reduced the turnover by almost half. The fact is, most drugstore chains (including CVS) likewise lease their stores, so these ratios are comparable for industry comparisons.

Again, we must consider a range of turnover values consistent with the industry. It is poor management to have an exceedingly high asset turnover relative to the industry because this might imply too few assets for the potential business (sales), or it could be due to the use of outdated, fully depreciated assets. It is equally poor management to have an extremely low asset turnover because this implies that the firm is tying up capital in excess assets relative to the needs of the firm and compared with its competitors.

Beyond the analysis of the firm’s total asset base, it is insightful to examine the utilization of some specific assets, such as receivables, inventories, and fixed assets. This detailed analysis is especially important if the firm has experienced a major decline in its total asset turnover because we want to know the cause of the decline, that is, which of the component turnovers (receivables, inventories, fixed assets) contributed to the decline. We have already examined the very stable receivables and inventory turnover as part of our liquidity analysis; we now examine the fixed asset turnover ratio.

**Net Fixed Asset Turnover** The net fixed asset turnover ratio reflects the firm’s utilization of fixed assets.\(^4\) Because of its growing importance to Walgreens, the following computations for the recent three years will be calculated with total fixed assets, but also with only total tangible assets.

---

\(^4\)When analyzing asset turnover it is important to be aware of intangible assets such as goodwill or patents that can be substantial items. In such cases, analysts will often consider only “tangible” assets or “operating” assets. In the case of Walgreens, this was not a problem until 2006 when it began acquiring firms. As of 2010, it was still not a major factor, but should be considered in the future.
Following an analysis of the firm’s operating efficiency, the next step is to examine its profitability in relation to its sales and capital.

### 10.5.2 Operating Profitability Ratios

There are two facets of profitability: (1) the rate of profit on sales (profit margin) and (2) the percentage return on capital employed. The analysis of profitability of sales actually entails several component profit margins that consider various expense categories. These component margins provide important information relative to the final net profit margin. Thus, if we determine that a firm has experienced a significant increase or decrease in its net profit margin, the analysis of the component profit margins will help us to determine the specific causes of the change. Therefore, we will briefly discuss each of the margins but will defer calculations and comments on the trends until we discuss the common size income statement.

#### Gross Profit Margin

\[
\text{Gross Profit Margin} = \frac{\text{Gross Profit}}{\text{Net Sales}}
\]

This ratio indicates the basic cost structure of the firm. An analysis of this ratio over time shows the firm’s relative cost-price position. As always, we must compare these margins to comparable industry results and to major competitors. Notably, this margin can also be impacted by a change in the firm’s product mix toward higher or lower profit margin items, which is why an analyst would ideally want to know the breakdown of sales by divisions and also the relative profitability of each division.

#### Operating Profit Margin

Operating profit is gross profit minus sales, general, and administrative (SG&A) expenses. It is also referred to as EBIT— earnings before interest and taxes.

\[
\text{Operating Profit Margin} = \frac{\text{Operating Profit}}{\text{Net Sales}}
\]

The variability of the operating profit margin over time is a prime indicator of the business risk for a firm. Again, this volatility should be compared to similar volatility measures for competitors and the industry. A model that measures the volatility of sales and operating income is discussed and presented in Appendix 10C1.

There are two additional deductions from operating profit—interest expense and net foreign exchange loss. After these deductions, we have income before income taxes.

As discussed earlier, some investors add back to the operating income value (EBIT) the firm’s depreciation expense and compute a profit margin that consists of earnings before interest, taxes, depreciation, and amortization (EBITDA). This alternative operating profit margin has been used by some analysts as a proxy for pretax cash flow. As noted earlier, we do not recommend the use of this series because it is a biased cash flow estimate.

#### Net Profit Margin

This margin relates after-tax net income to sales. In the case of Walgreens, this is the same as operating income after taxes, because the firm does not have any significant nonoperating adjustments. This margin is equal to:

\[
\text{Net Profit Margin} = \frac{\text{Net Income}}{\text{Net Sales}}
\]

This ratio should be computed using sales and earnings from continuing operations, because our analysis seeks to derive insights about future expectations. Therefore, we do not want to consider earnings from discontinued operations, or the gain or loss from the sale of these operations. Likewise, you do not want to include any nonrecurring income or expenses.

---

**Equity Turnover** In addition to specific asset turnover ratios, it is useful to examine the turnover for capital components. An important one, equity turnover, is computed as:

\[
\text{Equity Turnover} = \frac{\text{Net Sales}}{\text{Average Equity}}
\]

Equity includes preferred and common stock, paid-in capital, and total retained earnings. This ratio differs from total asset turnover in that it excludes current liabilities and long-term debt. Therefore, when examining this series, it is very important to consider the firm’s capital structure ratios, because the firm can increase (or decrease) its equity turnover ratio by increasing (or decreasing) its proportion of debt capital.

Walgreens equity turnover ratios were:

\[
\begin{align*}
\text{2010:} & \quad \frac{67,420}{(14,400 + 14,376)/2} = 4.69 \text{ times} \\
\text{2009:} & \quad \frac{63,335}{(14,376 + 12,869)/2} = 4.65 \text{ times} \\
\text{2008:} & \quad \frac{59,034}{(12,869 + 11,104)/2} = 4.93 \text{ times}
\end{align*}
\]

This ratio has declined slightly during the past several years. In our subsequent analysis of sustainable growth, we examine the variables that affect the equity turnover ratio to understand what variables might cause changes.

---

5The “DuPont System” section of this chapter contains an analysis of this total asset turnover ratio over a longer term.

6Some investors prefer to consider only owner’s equity, which would not include preferred stock.
Following an analysis of the firm’s operating efficiency, the next step is to examine its profitability in relation to its sales and capital.

10.5.2 Operating Profitability Ratios

There are two facets of profitability: (1) the rate of profit on sales (profit margin) and (2) the percentage return on capital employed. The analysis of profitability of sales actually entails several component profit margins that consider various expense categories. These component margins provide important information relative to the final net profit margin. Thus, if we determine that a firm has experienced a significant increase or decrease in its net profit margin, the analysis of the component profit margins will help us to determine the specific causes of the change. Therefore, we will briefly discuss each of the margins but will defer calculations and comments on the trends until we discuss the common size income statement.

**Gross Profit Margin** Gross profit equals net sales minus the cost of goods sold. The gross profit margin is computed as:

\[
\text{Gross Profit Margin} = \frac{\text{Gross Profit}}{\text{Net Sales}}
\]

This ratio indicates the basic cost structure of the firm. An analysis of this ratio over time shows the firm’s relative cost-price position. As always, we must compare these margins to comparable industry results and to major competitors. Notably, this margin can also be impacted by a change in the firm’s product mix toward higher or lower profit margin items, which is why an analyst would ideally want to know the breakdown of sales by divisions and also the relative profitability of each division.

**Operating Profit Margin** Operating profit is gross profit minus sales, general, and administrative (SG&A) expenses. It is also referred to as EBIT—earnings before interest and taxes.

\[
\text{Operating Profit Margin} = \frac{\text{Operating Profit}}{\text{Net Sales}}
\]

The variability of the operating profit margin over time is a prime indicator of the business risk for a firm. Again, this volatility should be compared to similar volatility measures for competitors and the industry. A model that measures the volatility of sales and operating income is discussed and presented in Appendix 10C1.

There are two additional deductions from operating profit—interest expense and net foreign exchange loss. After these deductions, we have income before income taxes.

As discussed earlier, some investors add back to the operating income value (EBIT) the firm’s depreciation expense and compute a profit margin that consists of earnings before interest, taxes, depreciation, and amortization (EBITDA). This alternative operating profit margin has been used by some analysts as a proxy for pretax cash flow. As noted earlier, we do not recommend the use of this series because it is a biased cash flow estimate.

**Net Profit Margin** This margin relates after-tax net income to sales. In the case of Walgreens, this is the same as operating income after taxes, because the firm does not have any significant nonoperating adjustments. This margin is equal to:

\[
\text{Net Profit Margin} = \frac{\text{Net Income}}{\text{Net Sales}}
\]

This ratio should be computed using sales and earnings from continuing operations, because our analysis seeks to derive insights about future expectations. Therefore, we do not want to consider earnings from discontinued operations, or the gain or loss from the sale of these operations. Likewise, you do not want to include any nonrecurring income or expenses.
**Common Size Income Statement** As noted earlier, these profit margin ratios are basically included in a common size income statement, which lists all expense and income items as a percentage of sales. This statement provides useful insights regarding the trends in cost figures and profit margins.

Exhibit 10.5, presented earlier, contains a common size statement for Walgreens for 2006–2010. As noted when Exhibit 10.5 was presented, the most striking characteristic of the various profit margins for Walgreens (gross, operating, and net) is the significant stability in the gross profit over time, but the small increase in the firm’s SG&A expense caused a small decline in the operating profit margin for the firm and this decline carried down to the net profit margin.

Beyond the analysis of earnings on sales, the ultimate measure of management performance is the profits earned on the assets or the capital committed to the enterprise. Several ratios help us evaluate this important relationship.

**Return on Total Invested Capital** The return on total invested capital ratio (referred to as ROIC) relates the firm’s earnings to all the invested capital involved in the enterprise (debt, preferred stock, and common stock). Therefore, the earnings figure used is the net income from continuing operations (before any dividends) plus the interest paid on debt. While there might be a tendency to equate total capital with total assets, most analysts differentiate due to the term invested capital, which does not include non-interest-bearing liabilities such as trade accounts payable, accrued expenses, income taxes payable, and deferred income taxes. In contrast, short-term debt such as bank borrowings and principal payments due on long-term debt are interest bearing and would be included as invested capital. Therefore, the ratio would be:

\[
\text{Return on Total Invested Capital} = \frac{\text{Net Income} + \text{Interest Expense}}{\text{Average Total Invested Capital}}
\]

*Interest-bearing debt plus shareholders’ equity

Walgreens incurred interest expense for long- and short-term debt. The gross interest expense value used in this ratio differs from the net interest expense item in the income statement, which is measured as gross interest expense minus interest income.\(^7\)

Walgreen Co.’s rates of return on total invested capital (ROIC) were:

- 2010: \(\frac{2,091 + 89}{(18,536 + 18,123)/2} = \frac{2,180}{18,330} = 11.9\%\)
- 2009: \(\frac{2,006 + 89}{(18,123 + 15,699)/2} = \frac{2,095}{16,911} = 12.4\%\)
- 2008: \(\frac{2,157 + 11}{(15,699 + 13,288)/2} = \frac{2,168}{14,494} = 15.0\%\)

This ratio indicates the firm’s return on all its invested capital. It should be compared with the ratio for other firms in the industry and the economy. For Walgreens, the results indicate a steady decline during the last several years following the recession.

**Return on Owner’s Equity** The return on owner’s equity (ROE) ratio is extremely important to the owner of the enterprise (the common stockholder) because it indicates the rate of return that management has earned on the capital provided by stockholders after accounting for payments to all other capital suppliers. If we consider all equity (including preferred stock), this return would equal:

\[\text{\text{Return on Owner’s Equity}} = \frac{\text{Net Income} - \text{Preferred Dividend}}{\text{Average Common Equity}}\]

\(^7\)Subsequently, in connection with the analysis of financial risk, we discuss why and how to capitalize the operating lease payments that are reported in footnotes. When we do this, we will add this capitalized value to the balance sheet in terms of additional leased assets and also lease obligations along with the implied interest on the leases. At that point, we demonstrate the effect of this on the firm’s ROIC and several other financial ratios—mainly financial risk ratios.
Similar to the prior breakdown, this is an identity because we have both multiplied and divided the equity turnover ratio by total assets. This equation indicates that the equity turnover ratio equals the firm’s total asset turnover (a measure of efficiency) times the ratio of total assets to equity (a measure of financial leverage). Specifically, this financial leverage ratio indicates the proportion of total assets financed with debt. All assets have to be financed by either equity or some form of debt (either current liabilities or long-term debt). Therefore, the higher the ratio of assets to equity, the higher the proportion of debt to equity. A total asset-equity ratio of 2, for example, indicates that for every two dollars of assets there is a dollar of equity, which means the firm financed one-half of its assets with equity and the other half with debt. Likewise, a total asset-equity ratio of 3 indicates that only one-third of total assets was financed with equity and two-thirds must have been financed with debt. Thus a firm can increase its equity turnover either by increasing its total asset turnover (becoming more efficient) or by increasing its financial leverage ratio (financing assets with a higher proportion of debt capital). This financial leverage ratio is also referred to as the financial leverage multiplier because the first two ratios (profit margin times total asset turnover) equal return on total assets (ROTA), and ROTA times the financial leverage multiplier equals ROE.

Combining these two breakdowns, we see that a firm’s ROE is composed of three ratios, as follows:

$$\text{Return on Total Equity} = \frac{\text{Net Income}}{\text{Average Total Equity}}$$

If we are concerned only with owner’s equity (the common stockholder’s equity), the ratio would be:

$$\text{Return on Owner’s Equity} = \frac{\text{Net Income} - \text{Preferred Dividend}}{\text{Average Common Equity}}$$

Walgreens’ generated return on owner’s equity of:

2010: \[ \frac{2,091 - 0}{(14,400 + 14,376)/2} = 14.53\% \]

2009: \[ \frac{2,006 - 0}{(14,376 + 12,869)/2} = 14.73\% \]

2008: \[ \frac{2,157 - 0}{(12,869 + 11,104)/2} = 18.00\% \]

This ratio reflects the rate of return on the stockholder’s capital. It should be consistent with the firm’s overall business risk, but it also should reflect the stockholder’s financial risk because of the prior claims of the firm’s bondholders. Unfortunately, these returns declined during the recent three years, but were also lower than in prior years, as shown in Exhibit 10.6 that includes results beginning in 1982.

The DuPont System: The importance of ROE as an indicator of performance makes it desirable to divide the ratio into several component ratios that provide insights into the causes of a firm’s ROE or any changes in it. This breakdown is generally referred to as the DuPont System. First, the return on equity (ROE) ratio can be broken down into two ratios that we have discussed—net profit margin and equity turnover.

$$\text{ROE} = \frac{\text{Net Income}}{\text{Common Equity}} = \frac{\text{Net Income}}{\text{Net Sales}} \times \frac{\text{Net Sales}}{\text{Common Equity}}$$

This breakdown is an identity because we have both multiplied and divided by net sales. To maintain the identity, the common equity value used is the year-end figure rather than the average of the beginning and ending value. This identity reveals that ROE equals the net profit margin times the equity turnover, which implies that a firm can improve its return on equity by either using its equity more efficiently (increasing its equity turnover) or becoming more profitable (increasing its net profit margin).

As noted previously, a firm’s equity turnover is affected by its capital structure. Specifically, a firm can increase its equity turnover by employing a higher proportion of debt capital. We can see this effect by considering the following relationship:

$$\frac{\text{Net Sales}}{\text{Common Equity}} = \frac{\text{Net Sales}}{\text{Total Assets}} \times \frac{\text{Total Assets}}{\text{Common Equity}}$$

---

8In the case of Walgreens, return on total equity and return on owner’s equity is the same, since there is no preferred stock outstanding (it is authorized but not issued).

9The effect of using the year-end equity rather than the average for the year will cause a lower ROE since the equity is generally increasing over time. Two points regarding this difference: First, the conservative bias is generally small—for Walgreens, the average equity result above for 2010 was 14.53% versus 14.52% using the year-end equity. Second, the important trend results will be evident, along with the component trends that are very important.
An Extended DuPont System

Beyond the original DuPont System, some analysts have suggested using an extended DuPont System, which provides additional insights into the effect of financial leverage on the firm and also pinpoints the effect of income taxes on the firm’s ROE. Because both financial leverage and tax rates have changed dramatically over the past decade, these additional insights are important. The concept and use of the model is the same as the basic DuPont System except for a further breakdown of components.

In the prior presentation, we started with the ROE and divided it into components. In contrast, we now begin with the operating profit margin (EBIT divided by sales) and introduce Exhibit 10.6 Components of Return on Total Equity for Walgreen Co.

Ratios use ending balances rather than averages.

Column (3) is equal to column (1) times column (2).

Column (5) is equal to column (3) times column (4).

Note: When you multiply the three component ratios, this product may not be equal to the ROE based on year-end financial statements due to the rounding of the three ratios.

10.22 \[
\frac{\text{Net Income}}{\text{Common Equity}} = \frac{\text{Net Income}}{\text{Net Sales}} \times \frac{\text{Net Sales}}{\text{Total Assets}} \times \frac{\text{Total Assets}}{\text{Common Equity}}
\]

\[
= \frac{\text{Profit Margin}}{\text{Total Asset Turnover}} \times \frac{\text{Financial Leverage}}{\text{Leverage}}
\]

As an example of this important set of relationships, the data in Exhibit 10.6 indicate what has happened to the ROE for Walgreens and the components of its ROE during the 29-year period from 1982 to 2010. As noted, these ratio values employ year-end balance sheet figures (assets and equity) rather than the average of beginning and ending data, so they will differ from our individual ratio computations.

The DuPont results reported in Exhibit 10.6 indicate several significant trends:

1. The total asset turnover ratio was relatively stable through the 1990s with a total range of 3.02 to 3.31, followed by a strong decline in the ratio to a value of 2.57 in 2010.
2. The profit margin series experienced a consistent increase from 2.75 in 1982 to its peak value of 3.80 in 2007, followed by a decline to 3.10 in 2010 reflecting the significant recession in 2008–2009.
3. The product of the total asset turnover and the net profit margin is equal to return on total assets (ROTA), which experienced an overall increase from 9.10 percent in 1982 to a peak of 10.94 percent in 2000, followed by a decline to only 7.96 percent in 2010. The major cause of the long-term decline was the decline in total asset turnover, while the recent decline from 2000 was caused by declines in both the asset turnover and the profit margin.
4. The financial leverage multiplier (total assets/equity) experienced an overall decline from 2.06 in 1982 to 1.82 in 2010. Notably, most of this debt was previously trade credit, which is non-interest-bearing. Prior to 2008, the firm had almost no interest-bearing debt, except for the long-term leases on drugstores that are not on the formal balance sheet but are discussed and analyzed in the subsequent financial risk section. The firm sold long-term debt of $1.3 billion in 2008 and added further debt for a total of $2.4 billion in 2010.
5. Finally, as a result of the decline in ROTA and along with a decline in financial leverage, the firm’s ROE has experienced an overall decline from 18.75 percent in 1982 to 14.52 percent in 2010.
additional ratios to derive an ROE value. Combining the operating profit margin and the total asset turnover ratio yields the following:

\[
\frac{\text{EBIT}}{\text{Total Assets}} \times \frac{\text{Net Sales}}{\text{Net Sales}} = \frac{\text{EBIT}}{\text{Total Assets}}
\]

This ratio is the operating profit return on total assets. To consider the negative effects of financial leverage, we examine the effect of interest expense as a percentage of total assets:

\[
\frac{\text{EBIT}}{\text{Total Assets}} - \frac{\text{Interest Expense}}{\text{Total Assets}} = \frac{\text{Net Before Tax}}{\text{Total Assets}}
\]

To consider the positive effect of financial leverage we include the financial leverage multiplier as follows:

\[
\frac{\text{Net Before Tax}}{\text{Total Assets}} \times \frac{\text{Total Assets}}{\text{Common Equity}} = \frac{\text{Net Before Tax}}{\text{Common Equity}}
\]

This indicates the pretax return on equity. Finally, to arrive at ROE, we must consider the tax-rate effect. We do this by multiplying the pre-tax ROE by a tax-retention rate as follows:

\[
\frac{\text{Net Before Tax}}{\text{Common Equity}} \times \frac{100% - \text{Income Taxes}}{\text{Net Before Tax}} = \frac{\text{Net Income}}{\text{Common Equity}}
\]

In summary, we have the following five components:

1. \(\frac{\text{EBIT}}{\text{Sales}} = \text{Operating Profit Margin}\)
2. \(\frac{\text{Sales}}{\text{Total Assets}} = \text{Total Asset Turnover}\)
3. \(\frac{\text{Interest Expense}}{\text{Total Assets}} = \text{Interest Expense Rate}\)
4. \(\frac{\text{Total Assets}}{\text{Common Equity}} = \text{Financial Leverage Multiplier}\)
5. \(100% - \frac{\text{Income Taxes}}{\text{Net Before Tax}} = \text{Tax Retention Rate}\)

To demonstrate the use of this extended DuPont system, Exhibit 10.7 contains the calculations, using the five components for the years 1982 through 2010. The first column indicates that the firm’s operating profit margin peaked in 1985, declined to a low point in 1990, increased to a new peak of 5.86 percent in 2007, but ended in 2010 at 5.13. We know from the prior discussion that the firm’s total asset turnover (Column 2) experienced an overall decline to 2.57 in 2010. These two ratios combined for an operating profit return on assets that declined to its low point in 2009, followed by a small recovery in 2010. As discussed, because of relatively little interest-bearing debt (except off-balance-sheet-leases), Column 4 shows a small negative impact on leverage. Column 5 reflects the firm’s operating performance before the positive impact of financing (the leverage multiplier) and the impact of taxes. These results for Walgreens have historically been very similar to Column 3 (which experienced a decline) due to low debt. Column 6 reflects the overall decline in non-lease financial leverage. As a result of the lower pre-tax ROA and the reduced leverage multiplier, the before-tax ROE in Column 7 declined since 1984 to its lowest value in 2009. Column 8 shows the positive effect of lower tax rates, which caused a higher tax-retention rate that increased from the mid-50 percent range to the recent 62–63 percent rate.

Note: When you multiply the three component ratios, this product may not be equal to the ROE based on year-end statements due to the rounding of the three ratios.

An Extended DuPont System. Beyond the original DuPont System, some analysts have suggested using an extended DuPont System,¹¹ which provides additional insights into the effect of financial leverage on the firm and also pinpoints the effect of income taxes on the firm’s ROE. Because both financial leverage and tax rates have changed dramatically over the past decade, these additional insights are important. The concept and use of the model is the same as the basic DuPont System except for a further breakdown of components.

In the prior presentation, we started with the ROE and divided it into components. In contrast, we now begin with the operating profit margin (EBIT divided by sales) and introduce

¹¹The original DuPont System was the three-component breakdown discussed in the prior section. Because this extended analysis also involves the components of ROE, some still refer to it as the DuPont System. In our presentation, we refer to it as the extended DuPont System to differentiate it from the original three-component analysis.
additional ratios to derive an ROE value. Combining the operating profit margin and the total asset turnover ratio yields the following:

\[
\frac{EBIT}{Net Sales} \times \frac{Net Sales}{Total Assets} = \frac{EBIT}{Total Assets}
\]

This ratio is the operating profit return on total assets. To consider the negative effects of financial leverage, we examine the effect of interest expense as a percentage of total assets:

\[
\frac{EBIT}{Total Assets} - \frac{Interest Expense}{Total Assets} = \frac{Net Before Tax (NBT)}{Total Assets}
\]

To consider the positive effect of financial leverage we include the financial leverage multiplier as follows:

\[
\frac{Net Before Tax (NBT)}{Total Assets} \times \frac{Total Assets}{Common Equity} = \frac{Net Before Tax (NBT)}{Common Equity}
\]

This indicates the pretax return on equity. Finally, to arrive at ROE, we must consider the tax-rate effect. We do this by multiplying the pre-tax ROE by a tax-retention rate as follows:

\[
\frac{Net Before Tax}{Common Equity} \times \left(100\% - \frac{Income Taxes}{Net Before Tax}\right) = \frac{Net Income}{Common Equity}
\]

In summary, we have the following five components:

1. \(\frac{EBIT}{Sales}\) = Operating Profit Margin
2. \(\frac{Sales}{Total Assets}\) = Total Asset Turnover
3. \(\frac{Interest Expense}{Total Assets}\) = Interest Expense Rate
4. \(\frac{Total Assets}{Common Equity}\) = Financial Leverage Multiplier
5. \(\left(100\% - \frac{Income Taxes}{Net Before Tax}\right)\) = Tax Retention Rate

To demonstrate the use of this extended DuPont system, Exhibit 10.7 contains the calculations, using the five components for the years 1982 through 2010. The first column indicates that the firm’s operating profit margin peaked in 1985, declined to a low point in 1990, increased to a new peak of 5.86 percent in 2007, but ended in 2010 at 5.13. We know from the prior discussion that the firm’s total asset turnover (Column 2) experienced an overall decline to 2.57 in 2010. These two ratios combined for an operating profit return on assets that declined to its low point in 2009, followed by a small recovery in 2010. As discussed, because of relatively little interest-bearing debt (except off-balance-sheet leases), Column 4 shows a small negative impact on leverage.

Column 5 reflects the firm’s operating performance before the positive impact of financing (the leverage multiplier) and the impact of taxes. These results for Walgreens have historically been very similar to Column 3 (which experienced a decline) due to low debt. Column 6 reflects the overall decline in non-lease financial leverage. As a result of the lower pre-tax ROA and the reduced leverage multiplier, the before-tax ROE in Column 7 declined since 1984 to its lowest value in 2009. Column 8 shows the positive effect of lower tax rates, which caused a higher tax-retention rate that increased from the mid-50 percent range to the recent 62–63 percent rate.
The total risk of the firm has two internal components: business risk and financial risk. We first discuss the concept of business risk: how to measure it, what causes it, and how to measure its individual causes. Then we consider financial risk and the several ratios by which we measure it. Following this analysis of a firm’s internal risk factors, we discuss an important external risk factor, external liquidity risk — that is, the ability to buy or sell the firm’s stock in the secondary equity market.

10.6.1 Business Risk

Recall that business risk is the uncertainty of operating income caused by the firm’s industry. In turn, this uncertainty is due to the firm’s variability of operating earnings caused by its products, customers, and the way it produces its products. Specifically, a firm’s business risk is measured by the volatility of the firm’s operating income over time. In turn, this volatility of operating earnings is due to two factors: (1) the volatility of the firm’s sales over time, and (2) how the firm produces its products in terms of its mix of fixed and variable costs — that is, its operating leverage. Specifically, a firm’s operating earnings vary over time because its sales and production costs vary. As an example, the earnings for a steel firm will probably vary more than those of a grocery chain because (1) over the business cycle, steel sales are more volatile than grocery sales; and (2) the steel firm’s large fixed production costs (high operating leverage) make its operating earnings vary more than its sales.

Business risk is generally measured by the variability of the firm’s operating income over time, which is measured by the standard deviation of the historical operating earnings series. You will recall from Chapter 1 that the standard deviation is influenced by the size of the numbers, so investors standardize this measure of volatility by dividing it by the mean value for the series (i.e., the average operating earnings). The resulting ratio of the standard deviation of operating earnings divided by the average operating earnings is the coefficient of variation (CV) of operating earnings:

\[
\text{Business Risk} = \frac{\text{Coefficient of Variation of Operating Earnings}}{\text{Standard Deviation of Operating Earnings}} = \frac{\text{Standard Deviation of Operating Earnings}}{\text{Mean Operating Earnings}}
\]

The CV of operating earnings allows comparisons between standardized measures of business risk for firms of different sizes. To compute the CV of operating earnings, you need a minimum of 5 years up to about 10 years. Less than 5 years is not very meaningful, and data more than 10 years old are typically out of date. Besides measuring overall business risk, it is very insightful to examine the two factors that contribute to the variability of operating earnings: sales variability and operating leverage.

Sales Variability
Sales variability is the prime determinant of operating earnings variability. In turn, the variability of sales is mainly caused by a firm’s industry and is largely outside the control of management. For example, sales for a firm in a cyclical industry, such as automobiles or steel, will be quite volatile over the business cycle compared to sales of a firm in a noncyclical industry, such as retail food or hospital supplies. Like operating earnings, the

1. Column (3) is equal to column (1) times column (2).
2. Column (5) is equal to column (3) minus column (4).
3. Column (7) is equal to column (5) times column (6).
4. Column (9) is equal to column (7) times column (8).

In summary, this breakdown helps you to understand what happened to a firm’s ROE and why it happened. The intent is to determine what happened to the firm’s internal operating results, what has been the negative and positive effect of its financial leverage policy, and what was the effect of external government tax policy. Although the two breakdowns should provide the same ending value, they typically differ by small amounts because of the rounding of components.

10.6 Risk Analysis

Risk analysis examines the uncertainty of income flows for the total firm and for the individual sources of capital (that is, debt, preferred stock, and common stock). The typical approach examines the major factors that cause a firm’s income flows to vary. More volatile income flows mean greater risk (uncertainty) facing the investor.
The total risk of the firm has two internal components: business risk and financial risk. We first discuss the concept of business risk: how to measure it, what causes it, and how to measure its individual causes. Then we consider financial risk and the several ratios by which we measure it. Following this analysis of a firm’s internal risk factors, we discuss an important external risk factor, external liquidity risk—that is, the ability to buy or sell the firm’s stock in the secondary equity market.

### 10.6.1 Business Risk
Recall that business risk\(^{11}\) is the uncertainty of operating income caused by the firm’s industry. In turn, this uncertainty is due to the firm’s variability of operating earnings caused by its products, customers, and the way it produces its products. Specifically, a firm’s business risk is measured by the volatility of the firm’s operating income over time. In turn, this volatility of operating earnings is due to two factors: (1) the volatility of the firm’s sales over time, and (2) how the firm produces its products in terms of its mix of fixed and variable costs—that is, its operating leverage. Business risk is generally measured by the variability of the firm’s operating income over time, which is measured by the standard deviation of the historical operating earnings series. You will recall from Chapter 1 that the standard deviation is influenced by the size of the numbers, so investors standardize this measure of volatility by dividing it by the mean value for the series (i.e., the average operating earnings). The resulting ratio of the standard deviation of operating earnings divided by the average operating earnings is the coefficient of variation (CV) of operating earnings:

\[
\text{Business Risk} = f \left( \text{Coefficient of Variation of Operating Earnings} \right) = \frac{\text{Standard Deviation of Operating Earnings (OE)}}{\text{Mean Operating Earnings}} = \frac{\sqrt{\sum_{i=1}^{n} (OE_i - \bar{OE})^2 / n}}{\sum_{i=1}^{n} OE_i / n}
\]

The CV of operating earnings allows comparisons between standardized measures of business risk for firms of different sizes. To compute the CV of operating earnings, you need a minimum of 5 years up to about 10 years. Less than 5 years is not very meaningful, and data more than 10 years old are typically out of date. Besides measuring overall business risk, it is very insightful to examine the two factors that contribute to the variability of operating earnings: sales variability and operating leverage.

**Sales Variability** Sales variability is the prime determinant of operating earnings variability. In turn, the variability of sales is mainly caused by a firm’s industry and is largely outside the control of management. For example, sales for a firm in a cyclical industry, such as automobiles or steel, will be quite volatile over the business cycle compared to sales of a firm in a noncyclical industry, such as retail food or hospital supplies. Like operating earnings, the

---

\(^{11}\)For further discussion of this topic, see Brigham andGapenski (2006), Chapters 6 and 10.
variability of a firm’s sales is typically measured by the CV of sales during the most recent 5 to 10 years. The CV of sales equals the standard deviation of sales divided by the mean sales for the period.

\[
\text{Sales Volatility} = f(\text{Coefficient of Variation of Sales}) = \sqrt{\frac{\sum_{i=1}^{n} (S_i - \bar{S})^2}{n}}
\]

*Adjusting Volatility Measures for Growth* Besides normalizing the standard deviation of EBIT and sales for size by computing the CV, it is also important to recognize that the standard deviation is measured relative to the mean value for the series—that is, it computes deviations from “expected value.” The problem arises for firms that experience significant growth that will create very large deviations from the mean for the series even if it is constant growth. The way to avoid this bias due to growth is to measure deviations from the growth path of the series. For details, see Section C of this chapter’s appendix, which demonstrates this adjustment using 10 years of sales and operating earnings for Walgreens.

*Operating Leverage* The variability of a firm’s operating earnings also depends on its mixture of production costs. Total production costs of a firm with no fixed production costs would vary directly with sales, and operating profits would be a constant proportion of sales. In such an example, the firm’s operating profit margin would be constant and its operating profits would have the same relative volatility as its sales. Realistically, firms always have some fixed production costs such as buildings, machinery, or relatively permanent personnel. Fixed production costs cause operating profits to vary more than sales over the business cycle. Specifically, during recessions, operating profits will decline by a larger percentage than sales, while during an economic expansion, operating profits will increase by a larger percentage than sales.

The employment of fixed production costs is referred to as operating leverage. Clearly, greater operating leverage (caused by a higher proportion of fixed production costs) makes the operating earnings series more volatile relative to the sales series (see Lee, Finnerty, and Norton, 2006). This basic relationship between operating profit and sales leads us to measure operating leverage as the average of the annual percentage change in operating earnings relative to the percentage change in sales during a specified period as follows:

\[
\text{Operating Leverage} = \frac{\sum_{i=1}^{n} \left| \frac{\%\Delta OE}{\%\Delta S} \right|}{n}
\]

We compute the absolute value of the percentage changes because the two series can move in opposite directions. The direction of the change is not important, but the relative size of the change is relevant. By implication, the more volatile the operating earnings as compared to the volatility of sales, the greater the firm’s operating leverage. Again, Section C of this chapter’s appendix contains an example of this computation for Walgreens.

**10.6.2 Financial Risk**

Financial risk, you will recall, is the additional uncertainty of returns to equity holders due to a firm’s use of fixed financial obligation securities. This financial uncertainty is in addition to the firm’s business risk. When a firm sells bonds to raise capital, the interest payments on this capital precede the computation of common stock earnings, and these interest payments are fixed contractual obligations. As with operating leverage, during an economic expansion, the
net earnings available for common stock after the fixed interest payments will experience a larger percentage increase than operating earnings. In contrast, during a business decline, the earnings available to stockholders will decline by a larger percentage than operating earnings because of these fixed financial costs (i.e., interest payments). Notably, as a firm increases its relative debt financing with fixed contractual obligations, it increases its financial risk and the possibility of default and bankruptcy.

**Relationship between Business Risk and Financial Risk** A very important point to remember is that the acceptable level of financial risk for a firm depends on its business risk. If the firm has low business risk (i.e., stable operating earnings), investors are willing to accept higher financial risk. For example, retail food companies typically have stable operating earnings over time, which implies low business risk, and means that investors and bond-rating firms will allow the firms to have higher financial risk. In contrast, if a firm is in an industry that is subject to high business risk (i.e., it experiences high sales volatility and it has high operating leverage), such as steel, auto, and airline companies, an investor would not want these firms to also have high financial risk. The two risks would compound, and the probability of bankruptcy could be substantial.\(^{12}\)

In our analysis, we employ three sets of financial ratios to measure financial risk, and *all three* sets should be considered. First, balance sheet ratios indicate the proportion of capital derived from debt securities to equity capital. Second, there are ratios that compare the earnings or cash flows available relative to the required fixed financial charges. The third set of ratios considers the cash flows available and relate these cash flows to the book value of the outstanding debt. Before we discuss and demonstrate these financial risk ratios, it is necessary to consider the topic of operating lease obligations.

**Consideration of Lease Obligations** Many firms lease facilities (buildings) and equipment rather than borrow the funds and purchase the assets. For these firms, it is basically a lease or a borrow decision since the lease contract is like a bond obligation. The accounting for the lease obligation depends on the type of lease. If it is a capital lease, the value of the asset and the lease obligation is included on the balance sheet as an asset and liability. If it is an operating lease, it is included in the footnotes but is not specifically included on the balance sheet.\(^{13}\)

Because operating leases are a form of financing used extensively by retailers (such as Walgreens, Sears, and McDonald’s) and airlines that tend to lease their aircraft, it is necessary to recognize this obligation. The appropriate treatment is to capitalize estimated future lease payments and include this capitalized lease value on the balance sheet as both an asset and a long-term liability. In the following subsection, we discuss how to do this, and demonstrate the significant impact this adjustment can have on several important financial risk ratios.

**Capitalizing Operating Leases** Capitalizing leases basically involves an estimate of the present value of a firm’s future required lease payments. Therefore, an analyst must estimate: (1) an appropriate discount rate (typically the firm’s long-term debt rate), and (2) the firm’s future lease payment obligations as specified in a footnote.

An estimate of the discounted value of the future lease payments can be either (1) a multiple of the forthcoming minimum lease payments, or (2) a detailed computation of the discounted value of the future lease payments provided in the annual report as the firm’s cost of long-term debt. The traditional multiple technique multiplies the minimum lease payment in

---

\(^{12}\)Support for this specific relationship is found in a set of tables (see Standard & Poor’s, 2002, p. 57) that suggest specific required financial risk ratios necessary for a firm to be considered for a specific bond rating. The required ratios differ on the basis of the perceived business risk of the firm.

\(^{13}\)A discussion of the technical factors that will cause a lease to be capital versus operating is beyond the scope of this book, but it is covered in most intermediate accounting texts.
year $t + 1$ by 8. In the case of Walgreens, the future minimum lease payments in the annual report for the year 2010 are as follows:

<table>
<thead>
<tr>
<th>Years Relating to Year-End</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
<th>5</th>
<th>Later</th>
</tr>
</thead>
<tbody>
<tr>
<td>Minimum Payments ($ millions)</td>
<td>2,301</td>
<td>2,329</td>
<td>2,296</td>
<td>2,248</td>
<td>2,188</td>
<td>25,428</td>
</tr>
</tbody>
</table>

Given these data, the estimate using the multiple technique would produce an estimate of $8 \times 2,301$ million = $18.41$ billion. To derive an estimate using the discounted value technique, we need to estimate the firm’s cost of long-term debt and consider how to handle the lump-sum later payments. Our debt rate estimate is 7.00 percent, which is consistent with the prevailing interest rate on 20-year, A-rated corporate bonds, which is consistent with Walgreens bond rating (as of August 31, 2010, the long-term debt rating was A2 by Moody’s and A by Standard & Poor’s). For the later lump-sum payment, we need to derive a reasonable estimate regarding how many years to assume for this payout. A liberal assumption is that the lump-sum payment is spread evenly over 15 years, based on the standard building lease for Walgreens of 20 years ($25,428/15 = $1,695 million per year). An alternative estimate of the spread period is derived by dividing the lump-sum payment in the later period by the $t + 5$ payment, which implies a time estimate ($25,428/2,188 = 11.62$). If we round this up to 12 years, we have an annual payment of $25,428/12 = $2,119 million per year for 12 years.

If we discount at 7.00 percent all the annual flows and the later flows over 15 years, we derive an estimate of the lease debt of $20.34 billion. A similar computation using the 12-year spread indicates an estimate of lease debt of $21.33 billion. Therefore, we have the following three estimates:\(^1\)

- 8 times the $t + 1$ lease payment: $18.41$ billion
- Discounting the lease payments assuming a 15-year spread: $20.34$ billion
- Discounting the lease payments assuming a 12-year spread: $21.33$ billion

We will use the $20.34$ billion discounted lease payment estimate since this estimate is midway between the liberal multiple method and the conservative discounting method that assumes a 12-year spread. If we add this amount (or that estimated by the other methods) to both fixed assets and long-term debt, we will have a better measure of the assets utilized by the firm and the complete funding of the assets (recognition of substantially more debt).

**Implied Interest for Leased Assets** When computing the return on total capital (ROTC) that considers these leased assets, we must also add the implied interest expense for the leases. The interest expense component of a lease is typically estimated by bond-rating agencies and many other analysts as equal to one-third of the lease payment in year $t + 1$ (in our example, $2,308 \text{ million}/3 = 769$ million).

An alternative to this rule of thumb would be to derive a specific estimate based on an estimate of the firm’s cost of debt capital (7.00 percent) and the estimate of the present value (PV) of the lease obligation, as follows:

<table>
<thead>
<tr>
<th>Estimating Technique</th>
<th>PV of Lease Obligation ($ Billion)</th>
<th>Interest Expense at 7.00 Percent ($ Million)</th>
</tr>
</thead>
<tbody>
<tr>
<td>8 times estimate of $t + 1$ payment</td>
<td>18.41</td>
<td>1,289</td>
</tr>
<tr>
<td>PV with 15-year spread</td>
<td>20.34</td>
<td>1,424</td>
</tr>
<tr>
<td>PV with 12-year spread</td>
<td>21.33</td>
<td>1,493</td>
</tr>
</tbody>
</table>

\(^1\)Notably, the “8 times” estimate almost always provides the lowest estimate of debt value, which means that this rule of thumb will tend to underestimate the financial leverage for these firms and the resulting implied interest expense. As noted, we have opted to use the discounted value of future lease payments, assuming a 15-year spread of the later payments because the standard lease contract for Walgreens is for 20 years. The computations are demonstrated in Section A of this chapter’s appendix.
Notably, all of these estimates of the implied interest expense are substantially higher than the one-third rule-of-thumb estimate of $769 million. Again, the rule of thumb underestimates the financial leverage related to these lease obligations.

To calculate the ROTC for 2009 and 2010, we need to compute the value of the lease obligations and the implied interest expense for the three years (2008, 2009, and 2010) as follows:

<table>
<thead>
<tr>
<th>Year</th>
<th>Estimate of PV of Lease Obligation^a ($ Billion)</th>
<th>Estimate of Interest Component of Lease^b ($ Million)</th>
</tr>
</thead>
<tbody>
<tr>
<td>2010</td>

<td>19.11</td>
<td>1,338</td>
</tr>
<tr>
<td>2008</td>
<td>19.19</td>
<td>1,273</td>
</tr>
</tbody>
</table>

^aSee calculations in Section B of this chapter’s appendix.
^bEqual to 0.07 of the PV of lease obligation.

Adding these values to the prior ratios results in the following lease-adjusted return on total invested capital (ROIC) values:

\[
2010: \frac{2,091 + 85 + 1,424}{(42,786 + 37,483)/2} = 8.97\% \\
2009: \frac{2,006 + 83 + 1,338}{(37,483 + 33,956)/2} = 9.59\% \\
2008: \frac{2,157 + 11 + 1,273}{(33,956 + 28,449)/2} = 11.03\%
\]

As shown, the ROICs that include the lease assets and lease debt are lower (about 10 percent versus about 13 percent), but they are still quite reasonable.

**Implied Depreciation of Leased Assets** Another factor is the implied depreciation expense that would be taken if these were not leased assets. One way to calculate this value is to simply use the typical term of the lease or weighted-average term. In the case of Walgreens, this is reasonably clear since almost all leases are 20-year leases on buildings. A second alternative is to recognize that the lease payment is a combination of the financing cost and the depreciation of the fixed asset. Given this assumption implies that the depreciation would be the total lease payment minus the estimated interest component estimated earlier. The estimate for 2010 would equal the lease payment ($2,301) minus the interest estimate of $1,424 equals a depreciation estimate of $877.

^*Assumes straight-line depreciation of a 20-year life.
**Estimated Depreciation = Total Lease Payment – Estimated Interest.

These implied depreciation charges should be included in ratios that include depreciation expenses.

**Proportion of Debt (Balance Sheet) Ratios** The proportion of debt ratios indicate what proportion of the firm’s capital is derived from debt compared to other sources of capital, such as preferred stock, common stock, and retained earnings. A higher proportion of debt
capital compared to equity capital makes earnings more volatile (i.e., more financial leverage) and increases the probability that a firm could default on the debt. Therefore, higher proportion of debt ratios indicates greater financial risk. The following are the major proportion of debt ratios used to measure financial risk.

**Debt-Equity Ratio** The debt-equity ratio is:

10.23  \[
\text{Debt-Equity Ratio} = \frac{\text{Total Long-Term Debt}}{\text{Total Equity}}
\]

The debt figure includes all long-term fixed obligations, including subordinated convertible bonds. The equity typically is the book value of equity and includes preferred stock, common stock, and retained earnings. Some analysts prefer to exclude preferred stock and consider only common equity. Total equity is preferable if some of the firms being analyzed have preferred stock.

Notably, debt ratios can be computed *with and without deferred taxes*. Most balance sheets include an accumulated deferred tax figure. There is some controversy regarding whether these deferred taxes should be treated as a liability or as part of permanent capital. Some argue that if the deferred tax has accumulated because of the difference in accelerated and straight-line depreciation, this liability may never be paid. That is, as long as the firm continues to grow and add new assets, this total deferred tax account continues to grow. Alternatively, if the deferred tax account is caused by differences in the recognition of income on long-term contracts, there will be a reversal, and this liability must eventually be paid. As suggested by White, Sondhi, and Fried (2003), to resolve this question the analyst must determine the reason for the deferred tax account and examine its long-term trend. Walgreen Co.’s deferred tax account is because of a depreciation difference, and it has typically grown over time.

A second consideration when computing debt ratios is the existence of operating leases. As noted, given a firm like Walgreens with extensive leased facilities, it is necessary to include an estimate of the present value of the lease payments as long-term debt.

To show the effect of these two significant items on the financial risk of Walgreens, we define the ratios to include both of these factors, but they will be broken out to identify the effect of each of the components of total debt. Thus, the debt-equity ratio is:

10.24  \[
\text{Debt-Equity Ratio} = \frac{\text{Total Long-Term Debt}}{\text{Total Equity}} = \frac{\text{Noncurrent Liabilities} + \text{Deferred Taxes} + \text{PV of Lease Obligations}}{\text{Total Equity}}
\]

For Walgreens, the debt-equity ratios were:

- 2010:  \[
\frac{4,124 + 318 + 20,340}{14,400} = \frac{24,782}{14,400} = 172.1\%
\]
- 2009:  \[
\frac{3,732 + 265 + 19,110}{14,376} = \frac{23,108}{14,376} = 160.7\%
\]
- 2008:  \[
\frac{2,747 + 150 + 18,190}{12,869} = \frac{21,087}{12,869} = 164.0\%
\]

These ratios demonstrate the significant impact of including the present value of the lease payments as part of long-term debt—for example, the debt-equity percent for 2010 went from about 31 percent without lease obligations to over 172 percent when capitalized leases were included.
The long-term debt-total capital ratio indicates the proportion of long-term capital derived from long-term debt capital. It is computed as:

\[
\text{Long-Term Debt - Total Capital Ratio} = \frac{\text{Long-Term Debt}}{\text{Total Capital Ratio}} = \frac{\text{Total Long-Term Debt}}{\text{Total Long-Term Capital}}
\]

The total long-term debt values are the same as above. The total long-term capital would include all long-term debt, any preferred stock, and total equity. The long-term debt-total capital ratios for Walgreens were:

A. Include deferred taxes and lease obligations as long-term debt.
B. Do not include deferred taxes but do include leased obligations.

\[
\begin{array}{c|c|c}
\text{Year} & \text{A} & \text{B} \\
2010: & \frac{24,782}{24,782 + 14,400} = 62.5\% & 62.4\% \\
2009: & \frac{23,108}{23,108 + 14,376} = 61.6\% & 60.9\% \\
2008: & \frac{21,087}{21,087 + 12,869} = 62.1\% & 61.2\%
\end{array}
\]

Again, the A ratios, which include both deferred taxes and the present value of lease obligations, show that a significant percent of long-term capital involves debt obligations (about 62 percent). This result differs substantially from a ratio without deferred taxes and the lease obligations. The B ratios that do not include deferred taxes are virtually identical to the A ratios, which implies it is the inclusion of lease obligations that is important. But the deletion or inclusion of deferred taxes is not important—at least, not for Walgreens.

**Earnings and Cash Flow Coverage Ratios** In addition to ratios that indicate the proportion of debt on the balance sheet, investors are very conscious of ratios that relate the flow of earnings or cash flows available to meet the required interest and lease payments. A higher ratio of available earnings or cash flow relative to fixed financial charges indicates lower financial risk.

**Interest Coverage Ratio** The standard interest coverage ratio is computed as:

\[
\text{Interest Coverage} = \frac{\text{Income before Interest and Taxes (EBIT)}}{\text{Debt Interest Charges}} = \frac{\text{Net Income + Income Taxes + Gross Interest Expense}}{\text{Gross Interest Expense}}
\]

This ratio indicates how many times the fixed interest charges are earned, based on the earnings available to pay these expenses.\(^{15}\) Alternatively, 1 minus the reciprocal of the interest coverage ratio indicates how far earnings could decline before it would be impossible to pay the interest charges from current earnings. For example, a coverage ratio of 5 means that earnings could decline by 80 percent (1 minus \(\frac{1}{5}\)), and the firm could still pay its fixed financial...

\(^{15}\)The interest expense for Walgreens other than for leased assets is clearly insignificant (about $200,000), so it is not included in the computations although it is in the formulas to be considered for other firms. It is important to use “gross” interest expense rather than “net” interest expense that equals gross interest expense minus interest income, which is often reported in income statements. The interest income is a component of other income and is included in the net income value.
charges. Again, for firms like Walgreens that have heavy lease obligations, it is necessary to consider the impact of the lease obligations on this ratio because if we only consider Walgreen Co.’s public interest-bearing debt, the interest cost is very small on a relative basis and the coverage ratio exceeds 2,000 times. In contrast, if we recognize the lease obligations as debt and include the implied interest on the capitalized leases as computed earlier, the coverage ratio would be restated as follows:

10.27

Fixed Financial Cost Coverage = \frac{\text{Net Income + Income Taxes + Interest Expense + Implied Lease Interest}}{\text{Gross Interest Expense + Implied Lease Interest}}

Hence, the fixed financial cost coverage ratios for Walgreens were:

2010: \frac{2,091 + 1,282 + 85 + 1,424}{85 + 1,424} = 3.24 times

2009: \frac{2,006 + 1,158 + 83 + 1,338}{83 + 1,338} = 3.23 times

2008: \frac{2,157 + 1,273 + 11 + 1,273}{11 + 1,273} = 3.67 times

These fixed financial cost coverage ratios show a substantially different picture than the coverage ratios that do not consider the impact of the lease obligations. These coverage ratios are clearly not large, but they are not unreasonable for a firm with very low business risk.

The trend of Walgreen Co.’s coverage ratios has been consistent with the overall trend in the proportion of debt ratios. The point is, the proportion of debt ratios and the earnings flow ratios are not always consistent because the proportion of debt ratios are not sensitive to changes in the interest rates on the debt or to changes in earnings. For example, if interest rates increase or if the firm replaces old debt with new debt that has a higher interest rate, no change would occur in the proportion of debt ratios, but the interest coverage ratio would decline. Also, the interest coverage ratio is sensitive to an increase or decrease in earnings, which is not true for proportion of debt ratios. Therefore, as noted, the results using balance sheet ratios and coverage ratios can differ. If there is a difference between the two sets of ratios, we have a strong preference for the earnings or cash flow coverage ratios that reflect the ability of the firm to meet its financial obligations.

Alternatives to these earnings coverage ratios are several ratios that relate the cash flow available from operations to either interest expense or total fixed charges.

**Cash Flow Coverage Ratio** The motivation for this ratio is that a firm’s earnings and cash flow typically will differ substantially (these differences have been noted and will be considered in a subsequent section). The cash flow value used is the cash flow from operating activities contained in the cash flow statement. As such, it includes depreciation expense, deferred taxes, and the impact of all working capital changes. Again, it is appropriate to specify the ratio in terms of total fixed financial costs including leases, as follows:

10.28

\text{Cash Flow Coverage of Fixed Financial Cost} = \frac{\text{Net Cash Flow from Operating Activities + Interest Expense + Implied Lease Interest}}{\text{Interest Expense + Implied Lease Interest}}

We use the values given in the cash flow statement, since we are specifically interested in the cash flow effect.
Alternative Measures of Cash Flow

As noted, many past studies that included a cash flow variable used the traditional measure of cash flow. The requirement that companies must prepare and report the statement of cash flows to stockholders has raised interest in other exact measures of cash flow. The first alternative measure is the cash flows from operations, which is taken directly from the statement of cash flows and is the one we have used. A second alternative measure is free cash flow, which is a modification of the cash flows from operations—that is, capital expenditures (minus the cash flow from the sale of assets) are also deducted. Finally, some analysts also subtract dividends. The following table summarizes the values for Walgreens derived earlier in the section entitled “Measures of Cash Flow.”

Given these alternative cash flow specifications, some analysts will use the free cash flow variable in this cash flow–long-term debt ratio because, as noted previously, one can think of the free cash flow as funds after all operating requirements. Therefore, these funds are available for retiring debt or paying higher dividends. This is very important to investors involved in leveraged buyouts because they can use this ratio to determine how fast they can retire the debt issued in the acquisition. For example, if the free cash flow to long-term debt ratio is 25 percent or above, it implies that it might be possible to use the firm’s earnings to pay off the debt issued in about four years.

Cash Flow-Outstanding Debt Ratios

Cash Flow-Long-Term Debt Ratio Several studies have used a ratio that relates cash flow to a firm’s outstanding debt. The cash flow-outstanding debt ratios are unique because they relate the flow of earnings plus noncash expenses to the stock of outstanding debt. These ratios have been significant variables in numerous studies concerned with predicting bankruptcies and bond ratings. (These studies are listed in the reference section.) Again, the cash flow figure we use is the cash flow from operating activities. Obviously, the higher the percent of cash flow to long-term debt, the stronger the company—that is, the lower its financial risk. This ratio would be computed as:

\[
\text{Cash Flow-Outstanding Debt Ratio} = \frac{\text{Cash Flow from Operating Activities}}{\text{Book Value of Long-Term Debt} + \text{Present Value of Lease Obligations}}
\]

For Walgreens, the ratios were as follows, assuming that deferred taxes are not included, since they are not interest-bearing. Thus, the long-term debt is noncurrent liabilities and the lease obligations:

<table>
<thead>
<tr>

<tr>
<td>2008</td>

<td>2,747 + 18,190</td>
<td>(\frac{3,039}{2,747 + 18,190})</td>
<td>(14.5)%</td>
</tr>
</tbody>
</table>

Given that an acceptable ratio is in the 15–20 percent range, the Walgreen results are reasonable because of the firm’s low business risk. Strong results would be above 30 or 40 percent and outstanding firms would be above 60 percent.

Cash Flow-Total Debt Ratio Investors also should consider the relationship of cash flow to total debt to check that a firm has not had a significant increase in its short-term borrowing.

\[
\text{Cash Flow-Total Debt Ratio} = \frac{\text{Cash Flow from Operating Activities}}{\text{Total Long-Term Debt} + \text{Interest-Bearing Current Liabilities}}
\]

For Walgreens, these ratios are the same as with long-term debt because the firm does not have any interest-bearing short-term debt. When firms do have short-term debt, the percents for this ratio will be lower; how much lower will indicate the amount of short-term borrowing by the firm. As before, it is important to compare these flow ratios with similar ratios for other companies in the industry and with the overall economy to gauge the firm’s relative performance over a period of 5 to 10 years.
Alternative Measures of Cash Flow\textsuperscript{16} As noted, many past studies that included a cash flow variable used the traditional measure of cash flow. The requirement that companies must prepare and report the statement of cash flows to stockholders has raised interest in other exact measures of cash flow. The first alternative measure is the cash flows from operations, which is taken directly from the statement of cash flows and is the one we have used. Finally, some analysts also subtract dividends. The following table summarizes the values for Walgreens derived earlier in the section entitled “Measures of Cash Flow.”

Given these alternative cash flow specifications, some analysts will use the free cash flow variable in this cash flow–long-term debt ratio because, as noted previously, one can think of the free cash flow as funds after all operating requirements. Therefore, these funds are available for retiring debt or paying higher dividends. This is very important to investors involved in leveraged buyouts because they can use this ratio to determine how fast they can retire the debt issued in the acquisition. For example, if the free cash flow to long-term debt ratio is 25 percent or above, it implies that it might be possible to use the firm’s earnings to pay off the debt issued in about four years.

As shown, Walgreens has strong cash flow from operations even after considering significant working capital requirements. In addition, the firm experiences positive free cash flow before dividends after substantial net capital expenditures necessitated by the firm’s growth. Finally, except for 2008, the firm has positive free cash flows even after considering a growing dividend payout.

10.6.3 External Market Liquidity Risk

External Market Liquidity Defined In Chapter 1, we discussed external market liquidity as the ability to buy or sell an asset quickly with little price change from a prior transaction assuming no new information. GE and Pfizer are examples of liquid common stocks because investors can sell them quickly with little price change from the prior trade. Investors might be able to sell an illiquid stock quickly, but the price would be significantly different from the prior price. Alternatively, the broker might be able to get a specified price, but it could take several days to do it.

Determinants of External Market Liquidity Investors should know the liquidity characteristics of the securities they currently own or may buy because liquidity can be important if they want to change the composition of their portfolios. Although the major determinants of market liquidity are reflected in market trading data, several internal corporate variables are good proxies for these market variables. The most important determinant of external market liquidity is the number of shares or the dollar value of shares traded (the dollar value adjusts for different price levels). More trading activity indicates a greater probability that one can find someone to take the other side of a desired transaction. A very good measure that is usually

\textsuperscript{16}A list of studies in which financial ratios or cash flow variables are used to predict bankruptcies or bond ratings is included in the reference section.
available is trading turnover (the percentage of outstanding shares traded during a period of time), which indicates relative trading activity. The specific measure of trading turnover is:

\[
\text{Trading Turnover} = \frac{\text{Number of Shares Traded during the Year}}{\text{Average Number of Shares Outstanding during the Year}}
\]

The average shares outstanding is typically estimated as the mean of the shares outstanding (in thousands) at the beginning and end of the fiscal year. For Walgreens, the trading turnover values were:

- 2010: \( \frac{1,027,156}{(938.605 + 988.561)/2} = 107\% \)
- 2009: \( \frac{978,244}{(988.561 + 989.176)/2} = 99\% \)
- 2008: \( \frac{931,661}{(989.176 + 991.141)/2} = 94\% \)

This compares with the average turnover for the NYSE of about 110 percent. Another measure of market liquidity is the bid-ask spread, where a smaller spread indicates greater liquidity. In addition, certain corporate variables are correlated with these trading variables:

1. Total market value of common shares outstanding.
2. Number of security owners.

Numerous studies have shown that the main determinant of the bid-ask spread (besides price) is the dollar value of trading, which is highly correlated with the market value of the outstanding securities.\(^\text{17}\)

We can estimate the market value of Walgreen Co.’s outstanding stock as the average number of shares outstanding during the year (as computed above) times the average market price for the year (equal to the high price plus the low price divided by 2), as follows:\(^\text{18}\)

- 2010: \( 963,583 \times \frac{40 + 26}{2} = $31.80 \text{ billion} \)
- 2009: \( 988,868 \times \frac{36 + 21}{2} = $28.18 \text{ billion} \)
- 2008: \( 990,158 \times \frac{38 + 26}{2} = $31.69 \text{ billion} \)

These market values clearly would place Walgreens in the large-cap category, which usually begins at about $5 billion. Walgreens stockholders number 102,000, including more than 650 institutions that own approximately 56 percent of the outstanding stock. These large values for total market value, the number of stockholders, institutional holders, and strong trading turnover indicate a highly liquid market in Walgreens stock, which implies low external liquidity risk.

## 10.7 Analysis of Growth Potential

### 10.7.1 Importance of Growth Analysis

The analysis of sustainable growth potential examines ratios that indicate how fast a firm should grow. Analysis of a firm’s growth potential is important for both lenders and owners.

\(^\text{17}\) Studies on this topic were discussed in Chapter 4.

\(^\text{18}\) These stock prices (which are for the calendar year) are rounded to the nearest whole dollar.
Owners know that the value of the firm depends on its future growth in earnings, cash flows, and dividends. In the following chapter, we discuss various valuation models that are based on alternative cash flows, the investor’s required rate of return for the stock, and the firm’s expected growth rate of earnings and cash flows.

Creditors also are interested in a firm’s growth potential because the firm’s future success is the major determinant of its ability to pay obligations, and the firm’s future success is influenced by its growth. Some credit analysis ratios measure the book value of a firm’s assets relative to its financial obligations, assuming that the firm can sell these assets to pay off the loan in case of default. Selling assets in a forced liquidation will typically yield only about 10 to 15 cents on the dollar. Currently, it is widely recognized that the more relevant analysis is the ability of the firm to pay off its obligations as an ongoing enterprise, which is impacted by its growth potential. This analysis of growth is also relevant to changes of bond ratings.

### 10.7.2 Determinants of Growth

The growth of business, like the growth on any economic entity, including the aggregate economy, depends on:

1. The amount of resources retained and reinvested in the entity.
2. The rate of return earned on the reinvested funds.

The more a firm reinvests, the greater its potential for growth. Alternatively, for a given level of reinvestment, a firm will grow faster if it earns a higher rate of return on the funds reinvested. Therefore, the growth rate of equity earnings and cash flows is a function of two variables: (1) the percentage of net earnings retained (the firm’s retention rate), and (2) the rate of return earned on the firm’s equity capital (the firm’s ROE), because when earnings are retained they become part of the firm’s equity.

\[
g = \text{Percentage of Earnings Retained} \times \text{Return on Equity} = RR \times \text{ROE}
\]

where:
- \( g \) = potential (i.e., sustainable) growth rate
- \( RR \) = the retention rate of earnings
- \( \text{ROE} \) = the firm’s return on equity

The retention rate is a decision by the board of directors based on the investment opportunities available to the firm. Theory suggests that the firm should retain earnings and reinvest them as long as the expected rate of return on the investment exceeds the firm’s cost of capital.

As discussed earlier regarding the DuPont System, a firm’s ROE is a function of three components:

- Net profit margin
- Total asset turnover
- Financial leverage (total assets/equity)

Therefore, a firm can increase its ROE by increasing its profit margin, by becoming more efficient (increasing its total asset turnover), or by increasing its financial leverage (and its financial risk). As discussed, investors should examine and estimate each of the components when estimating the ROE for a firm.

The sustainable growth potential analysis for Walgreens begins with the retention rate (RR):

\[
\text{Retention Rate} = 1 - \frac{\text{Dividends Declared}}{\text{Net Earnings}}
\]
Walgreens, RR figures were:

\[
\begin{align*}
2010: & \quad 1 - \frac{541}{2,091} = 0.74 \\
2009: & \quad 1 - \frac{446}{2,006} = 0.78 \\
2008: & \quad 1 - \frac{376}{1,157} = 0.83
\end{align*}
\]

The historical results in Exhibit 10.8 indicate that the retention rate for Walgreens was relatively stable during the 29-year period. Specifically, it has almost always been in excess of 70 percent, prior to increasing to a peak of 86 percent in 2003–2004 and then declining in 2009–2010 to the mid-70 percent level.

Exhibit 10.6 contains the three components of ROE for the period 1982–2010. Exhibit 10.8 contains the two factors that determine a firm’s growth potential and the implied growth rate during the past 29 years. Overall, Walgreens experienced a slight decline in its growth

potential during the early 1990s, but during the period 1999–2008 the firm has experienced a potential growth rate of about 14 percent. Unfortunately, sustainable growth declined to less than 11 percent in 2009–2010 due to a small decline in the retention rate and a clear decline in ROE, as discussed earlier.

Exhibit 10.8 reinforces our understanding of the importance of the firm’s ROE. Walgreen Co.’s retention rate was fairly stable throughout the period with small decreases during the last two years. Even with this, it has been the firm’s ROE that has mainly determined its sustainable growth rate. This analysis indicates that the important consideration is the long-run outlook for the components of return on equity. Investors need to project changes in each of the components of ROE and employ these projections to estimate a ROE to use in the growth model along with an estimate of the firm’s long-run retention rate. We will return to these concepts on numerous occasions when discussing stock valuation. A detailed analysis of ROE is extremely important for growth companies where the ROEs are necessarily above average for the economy and, therefore, vulnerable to competition.

### 10.8 Comparative Analysis of Ratios

We have discussed the importance of comparative analysis, but so far we have concentrated on the selection and computation of specific ratios. Exhibit 10.9 contains most of the ratios discussed for Walgreens, the retail drugstore industry (as derived from the S&P Analysts Handbook), and the S&P Industrials Index. The three-year comparison should provide some insights, although we typically would want to examine data for a 5- to 10-year period. It was necessary to do the comparison for the period 2007–2009 because industry and market data from Standard and Poor’s were not available for 2010 at the time of this writing.

#### 10.8.1 Internal Liquidity

The three basic ratios (current ratio, quick ratio, and cash ratio) provided mixed results regarding liquidity for Walgreens relative to the industry and market. The current ratio is generally above both the industry and the market. The firm’s receivables collection period is substantially faster than the S&P Industrials and below the retail drugstore industry. Because the collection period has been fairly steady, the difference is due to the firm’s basic credit policy related to third-party payers of prescriptions, as noted previously.

Overall, the comparisons indicate reasonably strong internal liquidity. An additional positive liquidity factor is the firm’s external sources of funding—that is, its ability to sell high-grade commercial paper and the availability of several major bank credit lines.

#### 10.8.2 Operating Performance

This segment of the analysis considers efficiency ratios (turnovers) and profitability ratios. The major comparison is relative to the industry. Walgreen Co.’s turnover ratios were mixed relative to those of the retail drugstore industry. Total asset and receivables turnover were better than the industry, but inventory and fixed asset turnover were below the industry.

The comparison of profitability from sales was mixed over time. Operating profit margins were consistently lower than the industry, but net margins were similar to the industry performance in 2007 and 2008 but clearly lower in 2009.

The profit to invested capital was historically strong. The return on total capital (including capitalized leases) for Walgreens was above both the S&P Industrials and the retail drugstore industry during 2008 and 2009. Walgreens likewise always attained higher ROEs than the market and its industry.
10.8.3 Risk Analysis

Walgreen Co.'s financial risk ratios, measured in terms of proportion of debt, were consistently inferior to those of the industry and the market when both deferred taxes and capitalized leases were included as long-term debt for Walgreens, but it was not possible to do a comparable adjustment of lease obligations for the S&P Industrials or the industry. Such an adjustment would have a significant impact on the industry results. Similarly, the financial risk ratios that use cash flow for Walgreens were below the market and its industry. These comparisons indicate that Walgreens has a fair amount of financial risk, but this is potentially offset because the firm has very low business risk. Notably, there are no specific comparative ratios available for both business and external liquidity risk. (Specifically, the analysis of relative sales and EBIT volatility adjusted for growth as demonstrated in the appendix indicated that the adjusted volatility for Walgreens was fairly low, indicating relatively low business risk.) Also, the earlier analysis of Walgreen stock trading turnover and market value data indicated low external liquidity risk.

10.8.4 Growth Analysis

Walgreens recently experienced a sustainable growth rate below its longer-term performance but above its industry, because of a higher ROE, and above the aggregate market, based on both a higher ROE and a consistently higher retention rate.

In sum, Walgreens has adequate liquidity; a good operating record, including a relatively consistent growth record that implies low business risk; above-average financial risk when we consider the leases on stores; and above-average growth performance relative to the aggregate market. Your success as an investor depends on how well you use these historical numbers to derive meaningful estimates of future performance for use in a valuation model. As noted previously, everybody is generally aware of the valuation models, so it is the individual who can provide the best estimates of relevant valuation variables (including the rate of growth and the duration of growth) who will experience superior risk-adjusted performance.

10.9 A Analysis of Non-U.S. Financial Statements

As we have stressed several times, your portfolio should encompass other economies and markets, numerous global industries, and many foreign firms in these global industries. However, because accounting conventions differ among countries, non-U.S. financial statements will differ from those in this chapter and from what you will see in a typical accounting course. While it is beyond the scope of this text to discuss these alternative accounting conventions in detail, we encourage you to examine the sources in the "Suggested Readings" section entitled Analysis of International Financial Statements.

10.10 The Quality of Financial Statements

Analysts sometimes speak of the quality of a firm's earnings or the quality of a firm's balance sheet. In general, quality financial statements are a good reflection of reality; accounting tricks and one-time changes are not used to make the firm appear stronger than it really is. Some factors that lead to lower-quality financial statements were mentioned previously when we discussed ratio analysis. Other quality influences are discussed here and in Palepu, Healy, and Bernard (2007, Chapter 3).

10.10 The Quality of Financial Statements
Analysts sometimes speak of the quality of a firm’s earnings or the quality of a firm’s balance sheet. In general, quality financial statements are a good reflection of reality; accounting tricks and one-time changes are not used to make the firm appear stronger than it really is. Some factors that lead to lower-quality financial statements were mentioned previously when we discussed ratio analysis. Other quality influences are discussed here and in Palepu, Healy, and Bernard (2007, Chapter 3).

10.10.1 Balance Sheet
A high-quality balance sheet typically has limited use of debt or leverage. Therefore, the potential of financial distress resulting from excessive debt is quite low. Little use of debt also
The fact is, the opposite is true. Analysis of financial statements allows the analyst to gain knowledge of a firm’s operating and financial strategy and structure. This, in turn, assists the analyst in determining the effects of future events on the firm’s cash flows. Combining knowledge of the firm’s operating and financial leverage, its strategy, and possible macro- and microeconomic scenarios is necessary to determine an appropriate market value for the firm’s stock. Combining the analysis of historical data with potential future scenarios allows analysts to evaluate the risks facing the firm and then to develop an expected return and cash flow forecast based on these risks. The final outcome of the process, as future chapters will detail, is the determination of the firm’s current intrinsic value based on expected cash flows, which is compared to the stock’s current market price to determine your investment decision. The point is, the detailed analysis of the historical results ensures a better estimation of the expected cash flows and an appropriate discount rate, which in turn leads to a superior estimate of the intrinsic value of the firm.

10.12 SPECIFIC USES OF FINANCIAL RATIOS

In addition to measuring firm performance and risk, financial ratios have been used in three major areas in investments: (1) stock valuation, (2) assigning credit quality ratings on bonds, and (3) predicting insolvency (bankruptcy) of firms.

10.12.1 Stock Valuation Models

As we will discuss in the following chapter, most valuation models attempt to derive a value based on one of several present value of cash flow models or appropriate relative valuation ratios for a stock. As will be noted, all the valuation models require an estimate of the expected growth rate of earnings, cash flows, or dividends and the required rate of return on the stock. Clearly, financial ratios can help in estimating these critical inputs. The growth rate estimate for earnings, cash flows, or dividends employs the ratios discussed in the potential growth rate section.

When estimating the required rate of return on an investment (i.e., either the cost of equity, \( k \); or the weighted average cost of capital, WACC), recall that these estimates depend on the risk premium for the security, which is a function of its business risk, financial risk, and liquidity risk. Business risk typically is measured in terms of earnings variability; financial risk is identified by either the debt proportion ratios or the earnings or cash flow ratios. Insights regarding a stock’s liquidity risk can be obtained from the external liquidity measures we discussed.

The typical empirical valuation model has examined a cross section of companies and used a multiple regression model that relates one of the relative valuations ratios for the sample firms to some of the following corporate variables (the averages generally consider the past 5 or 10 years).

- Average debt-equity
- Average interest coverage
- Average dividend payout
- Average return on equity
- Average retention rate
- Average market price to book value
- Average market price to cash flow
- Average market price to sales

A list of studies in this area appears in the “Suggested Readings” section at the end of the chapter.

10.10.2 Income Statement

High-quality earnings are repeatable earnings. For example, they arise from sales to customers who are expected to do repeat business with the firm and reflected in costs that are not artificially low as a result of unusual and short-lived input price reductions. One-time and nonrecurring items—such as accounting changes, mergers, and asset sales—should be ignored when examining earnings. Unexpected exchange rate fluctuations that work in the firm’s favor to raise revenues or reduce costs should also be viewed as nonrecurring.

High-quality earnings result from the use of conservative accounting principles that do not result in overstated revenues and understated costs. The closer the earnings are to cash, the higher the quality of the income statement. An example would be a firm that sells furniture on credit by allowing customers to make monthly payments. A higher-quality income statement will recognize revenue using the “installment” principle; that is, as the cash is collected each month, in turn, annual sales will reflect only the cash collected from sales during the year. A lower-quality income statement will recognize 100 percent of the revenue at the time of sale, even though payments may stretch well into next year. There is a detailed discussion of income items in Stickney, Brown, and Wahlen (2007, Chapter 5).

10.10.3 Footnotes

A word to the wise: read the footnotes! They have come to include at least three or more pages in most annual reports—the 2010 Walgreen Co. report had 11 pages of footnotes. The purpose of the footnotes is to provide information on how the firm handles balance sheet and income items. While the footnotes may not reveal everything you should know (e.g., Enron), if you do not read them you cannot hope to be informed. The fact is, many analysts recommend that you should read an annual report backward, that is, you would read the footnotes first!

10.11 THE VALUE OF FINANCIAL STATEMENT ANALYSIS

Financial statements, by their nature, are backward-looking. They report the firm’s assets, liabilities, and equity as of a certain (past) date; they report a firm’s revenues, expenses, or cash flows over some (past) time period. An efficient capital market will have already incorporated this past information into security prices, so it may seem, at first glance, that analysis of a firm’s financial statements and ratios is a waste of the analyst’s time.
The fact is, the opposite is true. Analysis of financial statements allows the analyst to gain knowledge of a firm’s operating and financial strategy and structure. This, in turn, assists the analyst in determining the effects of future events on the firm’s cash flows. Combining knowledge of the firm’s operating and financial leverage, its strategy, and possible macro- and microeconomic scenarios is necessary to determine an appropriate market value for the firm’s stock. Combining the analysis of historical data with potential future scenarios allows analysts to evaluate the risks facing the firm and then to develop an expected return and cash flow forecast based on these risks. The final outcome of the process, as future chapters will detail, is the determination of the firm’s current intrinsic value based on expected cash flows, which is compared to the stock’s current market price to determine your investment decision. The point is, the detailed analysis of the historical results ensures a better estimation of the expected cash flows and an appropriate discount rate, which in turn leads to a superior estimate of the intrinsic value of the firm.

10.12 Specific Uses of Financial Ratios

In addition to measuring firm performance and risk, financial ratios have been used in three major areas in investments: (1) stock valuation, (2) assigning credit quality ratings on bonds, and (3) predicting insolvency (bankruptcy) of firms.

10.12.1 Stock Valuation Models

As we will discuss in the following chapter, most valuation models attempt to derive a value based on one of several present value of cash flow models or appropriate relative valuation ratios for a stock. As will be noted, all the valuation models require an estimate of the expected growth rate of earnings, cash flows, or dividends and the required rate of return on the stock. 10.12.3 Predicting Insolvency (Bankruptcy)

Analysts have always been interested in using financial ratios to identify firms that might default on a loan or declare bankruptcy.

The typical study examines a sample of firms that have declared bankruptcy against a matched sample of firms in the same industry and of comparable size that have not failed. The analysis involves examining a number of financial ratios expected to reflect declining liquidity for several years prior to the declaration of bankruptcy. The goal is to determine which set of ratios correctly predicts that a firm will be in the bankrupt or nonbankrupt group. The better models have typically correctly classified more than 80 percent of the firms one year prior to failure. Some of the financial ratios included in successful models were as follows:

In addition to the several studies that have used financial ratios to predict bond ratings and failures, other studies have also used cash flow variables or a combination of financial ratios and cash flow variables for these predictions, and the results have been quite successful. These studies are listed in the "Suggested Readings" section at the end of the chapter. The five ratios designated by an asterisk (*) are the ratios used in the well-known Altman Z-score model (Altman, 1968).

10.12.4 Limitations of Financial Ratios

We must reinforce an earlier point: you should always consider relative financial ratios. In addition, you should be aware of other questions and limitations of financial ratios:

1. Are alternative firms' accounting treatments comparable? As you know from prior accounting courses, there are several generally accepted methods for treating various accounting items, and the alternatives can cause a difference in results for the same event. Therefore, you should check on the accounting treatment of significant items and adjust the values for major differences. Comparability becomes a critical consideration when dealing with non-U.S. firms.

2. How homogeneous is the firm? Many companies have divisions that operate in different industries, which can make it difficult to derive comparable industry ratios.

3. Are the implied results consistent? It is important to develop a total profile of the firm and not depend on only one set of ratios (e.g., internal liquidity ratios). As an example, a firm may be having short-term liquidity problems but be very profitable — the profitability will eventually alleviate the short-run liquidity problems.

4. Is the ratio being analyzed within a reasonable range for the industry? As noted previously, you typically want to consider a range of appropriate values for the ratio because a value that is either too high or too low for the industry can be a problem.

A list of studies in this area appears in the "Suggested Readings" section at the end of the chapter.

Variability Measures

1. Coefficient of variation of operating earnings (adjusted for growth)
2. Coefficient of variation of sales (adjusted for growth)
3. Coefficient of variation of net income (adjusted for growth)
4. Systematic risk (beta)

Nonratio Variable

1. Average growth rate of earnings and cash flows

These ratios can also be used as a filter to derive a subset of stocks to analyze from some total universe of stocks. For example, starting with a universe of 5,000 stocks, you would screen on the basis of consistent growth rates, profitability, and stability of sales and earnings to generate a subset of 250 stocks that you would analyze in depth.

10.12.2 Estimating the Ratings on Bonds

As discussed in Chapter 3, three financial services assign credit ratings to bonds on the basis of the issuing company’s ability to meet all its obligations related to the bond. An AAA or Aaa rating indicates very high quality and almost no chance of default, whereas a C rating indicates the bond is already in default. Numerous studies have used financial ratios to predict the rating to be assigned to a bond. The major financial variables considered in these studies were as follows:

Financial Ratios

1. Long-term debt–total assets
2. Total debt–total capital
3. Net income plus depreciation (cash flow)–long-term senior debt
4. Cash flow–total debt
5. Earnings before interest and taxes (EBIT)–interest expense (fixed charge coverage)
6. Cash flow from operations plus interest–interest expense (cash flow coverage)
7. Market value of stock–par value of bonds
8. Net operating profit–sales
9. Net income–owners’ equity (ROE)
10. Net income plus interest expense–total assets (ROA)
11. Working capital–sales
12. Sales–net worth (equity turnover)

Variability Measures

1. Coefficient of variation of sales (adjusted for growth)
2. Coefficient of variation of operating earnings (adjusted for growth)
3. Coefficient of variation of net earnings (adjusted for growth)
4. Coefficient of variation of return on assets

Nonratio Variables

1. Subordination of the issue
2. Size of the firm (total assets)
3. Size of the firm (market value of stock)
4. Issue size for alternative bond issues
5. Par value of all publicly traded bonds of the firm

21 The major variables considered in these studies were as follows:

A list of studies in this area appears in the “Suggested Readings” section at the end of the chapter.

In addition to the several studies that have used financial ratios to predict bond ratings and failures, other studies have also used cash flow variables or a combination of financial ratios and cash flow variables for these predictions, and the results have been quite successful. These studies are listed in the “Suggested Readings” section at the end of the chapter. The five ratios designated by an asterisk (*) are the ratios used in the well-known Altman Z-score model (Altman, 1968).

10.12.4 Limitations of Financial Ratios

We must reinforce an earlier point: you should always consider relative financial ratios. In addition, you should be aware of other questions and limitations of financial ratios:

1. Are alternative firms’ accounting treatments comparable? As you know from prior accounting courses, there are several generally accepted methods for treating various accounting items, and the alternatives can cause a difference in results for the same event. Therefore, you should check on the accounting treatment of significant items and adjust the values for major differences. Comparability becomes a critical consideration when dealing with non-U.S. firms.
2. How homogeneous is the firm? Many companies have divisions that operate in different industries, which can make it difficult to derive comparable industry ratios.
3. Are the implied results consistent? It is important to develop a total profile of the firm and not depend on only one set of ratios (e.g., internal liquidity ratios). As an example, a firm may be having short-term liquidity problems but be very profitable—the profitability will eventually alleviate the short-run liquidity problems.
4. Is the ratio being analyzed within a reasonable range for the industry? As noted previously, you typically want to consider a range of appropriate values for the ratio because a value that is either too high or too low for the industry can be a problem.

*A list of studies on this topic appears in the “Suggested Readings” section at the end of the chapter.
SUMMARY

- The overall purpose of financial statement analysis is to help investors make decisions on investing in a firm’s bonds or stock. Financial ratios should be examined relative to the economy, the firm’s industry, the firm’s main competitors, and the firm’s past relative ratios.
- The specific ratios can be divided into four categories, depending on the purpose of the analysis: internal liquidity, operating performance, risk analysis, and growth analysis.
- When analyzing the financial statements for non-U.S. firms, analysts must consider differences in format and in accounting principles that cause different values for specific ratios.
- Three major uses of financial ratios are (1) stock valuation, (2) assigning credit ratings on bonds, and (3) predicting insolvency (bankruptcy).
- A final caveat: you can envision numerous financial ratios to examine almost every possible relationship. The goal is not more ratios, but to limit and group the ratios so you can examine them in a meaningful way. This entails analyzing the ratios over time relative to the economy, the industry, or the past. You should concentrate on deriving better comparisons for a limited number of ratios that provide insights into the questions of interest to you.

Financial Ratios and Stock Valuation Models

Financial Ratios and Bond Ratings
When examining a firm’s financial structure, would you be concerned with the firm’s business risk? Why or why not?

Give an example of how a cash flow ratio might differ from a proportion of debt ratio. Assuming these ratios differ for a firm (e.g., the cash flow ratios indicate high financial risk, while the proportion of debt ratio indicates low risk), which ratios would you follow? Justify your choice.

Why is the analysis of growth potential important to the common stockholder? Why is it important to the debt investor?

Discuss the general factors that determine the rate of growth of any economic unit.

A firm is earning 24 percent on equity and has low business and financial risk. Discuss why you would expect it to have a high or low retention rate.

The Gold Company earned 18 percent on equity, whereas the Blue Company earned only 14 percent on equity. Does this mean that Gold will grow faster than Blue? Explain.

In terms of the factors that determine market liquidity, why do investors consider real estate to be a relatively illiquid asset?

Discuss some internal company factors that would indicate a firm’s market liquidity.

Select one of the limitations of ratio analysis and indicate why you believe it is a major concern.

**PROBLEMS**

1. The Shamrock Vegetable Company has the following results.

   a. Compute Shamrock’s ROE directly. Confirm this using the three components.
   b. Using the ROE computed in Part a, what is the expected sustainable growth rate for Shamrock?
   c. Assuming the firm’s net profit margin went to 0.04, what would happen to Shamrock’s ROE?
   d. Using the ROE in Part c, what is the expected sustainable growth rate? What if dividends were only $40,000?

2. Three companies have the following results during the recent period.

**QUESTIONS**

1. Discuss briefly two decisions that require the analysis of financial statements.
2. Why do analysts use financial ratios rather than the absolute numbers? Give an example.
3. Besides comparing a company’s performance to its total industry, discuss what other comparisons should be considered within the industry.
4. How might a jewelry store and a grocery store differ in terms of asset turnover and profit margin? Would you expect their return on total assets to differ assuming equal business risk? Discuss.
5. Describe the components of business risk, and discuss how the components affect the variability of operating earnings (EBIT).
6. Would you expect a steel company or a retail food chain to have greater business risk? Discuss this expectation in terms of the components of business risk.

5. David Wright, CFA, an analyst with Blue River Investments, is considering buying a Montrose Cable Company corporate bond. He has collected the following balance sheet and income statement information for Montrose as shown in Exhibit 10.10. He has also calculated the three ratios shown in Exhibit 10.11, which indicate that the bond is currently rated “A” according to the firm’s internal bond-rating criteria shown in Exhibit 10.13. Wright has decided to consider some off-balance-sheet items in his credit analysis, as shown in Exhibit 10.12. Specifically, Wright wishes to evaluate the impact of each of the off-balance-sheet items on each of the ratios found in Exhibit 10.11.

a. Calculate the combined effect of the three off-balance-sheet items in Exhibit 10.12 on each of the following three financial ratios shown in Exhibit 10.11.

i. EBITDA/interest expense
ii. Long-term debt/equity
iii. Current assets/current liabilities

The bond is currently trading at a credit premium of 55 basis points. Using the internal bond-rating criteria in Exhibit 10.13, Wright wants to evaluate whether or not the credit yield premium incorporates the effect of the off-balance-sheet items.

b. State and justify whether or not the current credit yield premium compensates Wright for the credit risk of the bond based on the internal bond-rating criteria found in Exhibit 10.13.

4. (Question 4 is composed of two parts.) The DuPont formula defines the net return on shareholders’ equity as a function of the following components:

- Operating margin
- Asset turnover
- Interest burden
- Financial leverage
- Income tax rate

Using only the data in the table shown below:

a. Calculate each of the five components listed above for 2010 and 2014, and calculate the return on equity (ROE) for 2010 and 2014, using all of the five components. Show calculations.

b. Briefly discuss the impact of the changes in asset turnover and financial leverage on the change in ROE from 2010 to 2014.

Exhibit 10.12 Montrose Off-Balance-Sheet Items

- Montrose has guaranteed the long-term debt (principal only) of an unconsolidated affiliate. This obligation has a present value of $995,000.
- Montrose has sold $500,000 of accounts receivable with recourse at a yield of 8 percent.
- Montrose is a lessee in a new noncancelable operating leasing agreement to finance transmission equipment. The discounted present value of the lease payments is $6,144,000 using an interest rate of 10 percent. The annual payment will be $1,000,000.

Use the Thomson One—Business School Edition Online Database to answer the following questions.

1. Update the ratio analysis for Walgreens presented in this chapter.
2. In Chapter 7 you made a retail sales stock index using price and share data from Amazon (AMZN), Family Dollar (FDO), J.C. Penney (JCP), Target (TGT), and Walmart (WMT). Now download balance sheet and income statement data into a spreadsheet and sum similar accounting categories to create an industry balance sheet and an industry income statement. Compute the following ratios and compare the performance of Walmart’s ratios against the industry ratios:
   a. Current ratio
   b. Inventory turnover
   c. Total asset turnover
   d. Net profit margin
   e. Debt-equity
3. Using common-size financial statements, compare the operating characteristics of a retail firm (Walgreens), a technology firm (Microsoft), and one involved in oil production and distribution (ExxonMobil).
4. Using the firms in Problem 3, compare their returns on equity using a DuPont analysis.
5. Find Walgreen Co.’s peers using Thomson One: Business School Edition. Click on “financials” and review the financial ratios of Walgreens and its peers. Comment on the strengths and weaknesses of Walgreens compared to these firms.
Appendix 10C.1 Adjusting Volatility Measure for Growth

As shown with the Walgreen example for sales in Exhibit 10C.1, the coefficient of variation based on the standard deviation from the mean with no adjustment for growth indicates a significant level of sales volatility (41 percent), in contrast to the volatility assuming linear growth, where the relative measure of volatility declines to 5 percent. Finally, when you compute the firm’s sales deviation from a compound growth curve of 13 percent, the relative volatility is 11 percent. These results indicate fairly low sales volatility when the measurement considers constant linear growth.

The results when we measure the volatility of operating earnings (EBIT) are similar. Specifically, the relative volatility is 38 percent when compared to the overall mean, 9 percent when examined relative to the linear growth curve, and 20 percent when computed relative to the compound growth curve of 10 percent a year. This implies what can be seen in the graphs—the growth rates for sales and operating earnings are fairly high, but the growth is quite stable when measured against a constant linear growth line—this means that there is not the uncertainty (risk) implied if the volatility is measured relative to the overall mean.

Appendix 10C.2 Measuring Operating Leverage

In addition to examining sales and operating income (EBIT) relative to its growth curve, we also discussed a specific measure of operating leverage that computes the average of the annual ratios of percent change in EBIT relative to the percent change in sales. The understanding is that the higher this average ratio (i.e., the more volatile EBIT is relative to the volatility of sales), the greater the operating leverage for the firm that is caused by fixed operating expenses. Assuming that a firm has only variable operating expense, this ratio should be theoretically equal to unity (1.00). In the case of Walgreens, it is shown in Exhibit 10C.2 that the annual ratio varied from 0.77 to 1.24, and during 5 of 10 years the ratio exceeded 1.00. The overall mean of the annual ratios was 0.99, which implies a low operating leverage value, which is consistent with Walgreen’s overall low business risk as indicated by the low relative volatility of sales and operating earnings measured above.

CHAPTER 11
An Introduction to Security Valuation

After you read this chapter, you should be able to answer the following questions:

1. What are the two major approaches to the investment process?
2. What are the specifics and logic of the top-down (three-step) approach?
3. What empirical evidence supports the usefulness of the top-down approach?
4. When valuing an asset, what are the required inputs?
5. After you have valued an asset, what is the investment decision process?
6. How do you determine the value of bonds?
7. How do you determine the value of preferred stock?
8. What are the two primary approaches to the valuation of common stock?
9. Under what conditions is it best to use the present value of cash flow approach for valuing a company's equity?
10. Under what conditions is it best to use the relative valuation techniques for valuing a company's equity?
11. How do you apply the discounted cash flow valuation approach, and what are the major discounted cash flow valuation techniques?
12. What is the dividend discount model (DDM), and what is its logic?
13. What is the effect of the assumptions of the DDM when valuing a growth company?
14. How do you apply the DDM to the valuation of a firm that is expected to experience temporary supernormal growth?
15. How do you apply the present value of operating cash flow technique?
16. How do you apply the present value of free cash flow to equity technique?
17. How do you apply the relative valuation approach?
18. What are the major relative valuation ratios?
19. How can you use the DDM to develop an earnings multiplier model?
20. What does the DDM model imply are the factors that determine a stock's P/E ratio?
21. What two general variables need to be estimated in any valuation approach?
22. How do you estimate the major inputs to the stock valuation models: (1) the required rate of return, and (2) the expected growth rate of earnings, cash flows, or dividends?
23. What additional factors must be considered when estimating the required rate of return and growth rate for a foreign security?

At the start of this book, we defined an investment as a commitment of funds for a period of time to derive a rate of return that would compensate the investor for the time during which the funds are invested, for the expected rate of inflation during the investment horizon, and for the uncertainty involved. From this definition, we know that the first step in making an investment is determining your required rate of return.

Once you have determined this rate, some investment alternatives, such as savings accounts and T-bills, are fairly easy to evaluate because they provide stated cash flows. Most investments have expected cash flows and a stated market price (e.g., common stock).

NOVERVIEW OF THE
ALUATION
PROCESS
Psychologists suggest that the success or failure of an individual can be caused as much by his or her social, economic, and family environment as by genetic gifts. Extending this idea to the valuation of securities means we should consider a firm’s economic and industry environment during the valuation process. Regardless of the qualities or capabilities of a firm and its management, the economic and industry environment will have a major influence on the success of a firm and the realized rate of return on its stock.

As an example, assume you own shares of the strongest and most successful firm producing home furnishings. If you own the shares during a strong economic expansion, the sales and earnings of the firm will increase and your rate of return on the stock should be quite high. In contrast, if you own the same stock during a major economic recession, the sales, earnings, and cash flows of this firm (and probably most or all of the firms in the industry) would likely experience a decline, and the price of its stock would be stable or decline. Therefore, when assessing the future value of a security, it is necessary to analyze the outlook for the aggregate economy and the firm’s specific industry.

The valuation process is like the chicken-and-egg dilemma. Do you start by analyzing the macroeconomy and various industries before individual stocks, or do you begin with individual securities and gradually combine these firms into industries and the industries into the entire economy? For reasons discussed in the next section, we contend that the discussion should begin with an analysis of aggregate economies and overall securities markets and progress to different industries with a global perspective. Only after a thorough analysis of a global industry are you in a position to properly evaluate the securities issued by individual firms within the better industries. Thus, we recommend a three-step, top-down valuation process in which you first examine the influence of the general economy on all firms and the security markets, then analyze the prospects for alternative global industries in this economic environment, and finally turn to the analysis of individual firms in the alternative industries and to the common stock of these firms. Exhibit 11.1 indicates the procedure recommended.

11.2 W
THREE
ALUATION
PROCESS

11.2.1 General Economic Influences
Monetary and fiscal policy measures enacted by various agencies of national governments influence the aggregate economies of those countries. The resulting economic conditions influence all industries and companies within the economies.

Fiscal policy initiatives, such as tax credits or tax cuts, can encourage spending, whereas additional taxes on income, gasoline, cigarettes, and liquor can discourage spending. Increases or decreases in government spending on defense, on unemployment insurance, retraining programs, or on highways also influence the general economy. These fiscal policies influence the business environment for firms that rely directly on such government expenditures. In addition, we know that government spending has a strong multiplier effect. For example, increases in road building increase the demand for earth-moving equipment and concrete materials. As a result, in addition to construction workers, the employees of industries that supply the equipment and materials have more to spend on consumer goods, which raises the demand for consumer goods, which, in turn, affects another set of suppliers.

Monetary policy produces similar economic changes. A restrictive monetary policy that reduces the growth rate of the money supply reduces the supply of funds for working capital and expansion for all businesses. Alternatively, a restrictive monetary policy that targets interest rates would raise market interest rates and therefore firms’ costs and make it more expensive for individuals to finance home mortgages and to purchase other durable goods, such as autos.

This investment decision process is similar to the process you follow when deciding on a corporate investment or when shopping for clothes, a stereo, or a car. In each case, you examine the item and decide how much it is worth to you (its value). If the price equals its estimated value or is less, you would buy it. The same technique applies to securities, except that the determination of a security’s value is more formal.

We start our investigation of security valuation by discussing the valuation process. There are two general approaches to the valuation process: (1) the top-down, three-step approach, or (2) the bottom-up, stock valuation, stockpicking approach. Both of these approaches can be implemented by either fundamentalists or technicians. The difference between the two approaches is the perceived importance of the economy and a firm’s industry on the valuation of a firm and its stock.

Advocates of the top-down, three-step approach believe that both the economy/market and the industry effect have a significant impact on the total returns for individual stocks. In contrast, those who employ the bottom-up, stockpicking approach contend that it is possible to find stocks that are undervalued relative to their market price, and these stocks will provide superior returns regardless of the market and industry outlook.

Both of these approaches have numerous supporters, and advocates of both approaches have been quite successful. In this book, we advocate and present the top-down, three-step approach because of its logic and empirical support. Although we believe that a portfolio manager or an investor can be successful using the bottom-up approach, we believe that it is more difficult to be successful because these stock-pickers are ignoring substantial information from an analysis of the outlook for the market and the firm’s industry.

Although we know that the value of a security is determined by its quality and profit potential, we also believe that the economic environment and the performance of a firm’s industry influence the value of a security and its rate of return. Therefore, we describe these influences and explain how they can be incorporated into the analysis of a security’s value. Subsequently, we describe the theory of value and emphasize the factors that affect the value of individual securities.

Next, we apply these valuation concepts to the valuation of different assets—bonds, preferred stock, and common stock. In this section, we show how the valuation models help investors calculate how much they should pay for these assets. In the final section, we emphasize the estimation of the variables that affect value (the required rate of return and the expected growth rate of cash flows). We conclude with a discussion of additional factors that must be considered when evaluating international securities.

1For the history and selection process of Warren Buffett, a legendary stockpicker, see Hagstrom (2001) or Lowenstein (1995).
11.1 An Overview of the Valuation Process

Psychologists suggest that the success or failure of an individual can be caused as much by his or her social, economic, and family environment as by genetic gifts. Extending this idea to the valuation of securities means we should consider a firm’s economic and industry environment during the valuation process. Regardless of the qualities or capabilities of a firm and its management, the economic and industry environment will have a major influence on the success of a firm and the realized rate of return on its stock.

If you own the shares during a strong economic expansion, the sales and earnings of the firm will increase and your rate of return on the stock should be quite high. In contrast, if you own the same stock during a major economic recession, the sales, earnings, and cash flows of this firm (and probably most or all of the firms in the industry) would likely experience a decline, and the price of its stock would be stable or decline. Therefore, when assessing the future value of a security, it is necessary to analyze the outlook for the aggregate economy and the firm’s specific industry.

The valuation process is like the chicken-and-egg dilemma. Do you start by analyzing the macroeconomy and various industries before individual stocks, or do you begin with individual securities and gradually combine these firms into industries and the industries into the entire economy? Exhibit 11.1 indicates the procedure recommended.

11.2 Why a Three-Step Valuation Process?

11.2.1 General Economic Influences

Monetary and fiscal policy measures enacted by various agencies of national governments influence the aggregate economies of those countries. The resulting economic conditions influence all industries and companies within the economies.

Fiscal policy initiatives, such as tax credits or tax cuts, can encourage spending, whereas additional taxes on income, gasoline, cigarettes, and liquor can discourage spending. Increases or decreases in government spending on defense, on unemployment insurance, retraining programs, or on highways also influence the general economy. These fiscal policies influence the business environment for firms that rely directly on such government expenditures. In addition, we know that government spending has a strong multiplier effect. For example, increases in road building increase the demand for earth-moving equipment and concrete materials. As a result, in addition to construction workers, the employees of industries that supply the equipment and materials have more to spend on consumer goods, which raises the demand for consumer goods, which, in turn, affects another set of suppliers.

Monetary policy produces similar economic changes. A restrictive monetary policy that reduces the growth rate of the money supply reduces the supply of funds for working capital and expansion for all businesses. Alternatively, a restrictive monetary policy that targets interest rates would raise market interest rates and therefore firms’ costs and make it more expensive for individuals to finance home mortgages and to purchase other durable goods, such as autos
and appliances. Monetary policy therefore affects all segments of an economy and that economy's relationship with other economies.

Any economic analysis requires the consideration of inflation. As discussed, inflation causes differences between real and nominal interest rates and changes the spending, saving, and investment behaviors of consumers and corporations. In addition, unexpected changes in the rate of inflation make it difficult for firms to plan, which inhibits growth and innovation. Beyond the impact on the domestic economy, differential inflation and interest rates also influence the trade balance between countries and the exchange rate for currencies.

In addition to monetary and fiscal policy actions, such events as war, political upheavals in foreign countries, or international monetary devaluations produce changes in the business environment that add to the uncertainty of sales and earnings expectations and therefore the risk premium required by investors. For example, the political uncertainty in Russia during the late 1990s caused a significant increase in the risk premium for investors in Russia and a reduction in investment and spending in Russia. In contrast, the end of apartheid in South Africa and the country’s open election in the mid-1990s were viewed as positive events and have led to a significant increase in economic activity in the country. Similarly, the peace accord in Northern Ireland in the late 1990s caused a major influx of investment and tourist dollars. Finally, the debt problems in Greece and several other European countries in 2010 and 2011 have threatened the European Union and the value of the euro currency.

In short, it is difficult to conceive of any industry or company that can avoid the impact of macroeconomic developments that affect the total economy. Because aggregate economic

Chapter 11: An Introduction to Security Valuation
events have a profound effect on all industries and companies within these industries, these macroeconomic factors should be considered before industries are analyzed.

Taking a global portfolio perspective, the asset allocation for a country within a global portfolio will be affected by its economic outlook. If a recession is imminent in a country, you would expect a negative impact on its security prices. Because of these economic expectations, investors would be apprehensive about investing in most industries in the country. Given these expectations, the country will be underweighted in portfolios relative to its weight based on its market value. Further, given these pessimistic expectations, any funds that are invested in the country would be directed to low-risk sectors (industries) of the economy.

In contrast, optimistic economic and stock market outlooks for a given country should lead an investor to increase the overall allocation to this country (overweight the country compared to its weights determined by its relative market value). After allocating funds among countries, the investor looks for outstanding industries in each country. This search for the best industries is enhanced by the economic analysis because the future performance of most industries depends on the country’s economic outlook and the industry’s expected relationship to the economy during the particular phase of the business cycle.

### 11.2.2 Industry Influences

The second step in the valuation process is to identify global industries that will prosper or suffer in the long run or during the expected near-term economic environment. Examples of conditions that affect specific industries are strikes within a major producing country, import or export quotas or taxes, a worldwide shortage or an excess supply of a resource or product, or government-imposed regulations on an industry.

You should remember that alternative industries react to economic changes at different points in the business cycle. For example, firms typically increase capital expenditures when they are operating at full capacity at the peak of the economic cycle. Therefore, industries that provide plant and equipment will typically be affected toward the end of a cycle. In addition, alternative industries have different responses to the business cycle. As an example, cyclical industries, such as steel, autos, and airlines, typically do much better than the aggregate economy during expansions, but they suffer more during contractions. In contrast, noncyclical industries, such as retail food and household products, would not experience a significant decline during a recession but also would not experience a strong increase during an economic expansion.

Another factor that will have a differential effect on industries is demographics. For example, it is widely recognized that the U.S. population is weighted toward baby boomers in their late 50s and that there has been a large surge in the number of citizens over age 65. These two groups have heavy demand for second homes and medical care and the industries related to these segments (e.g., home furnishings and pharmaceuticals).

Firms that sell in international markets can benefit or suffer as foreign economies shift. An industry with a substantial worldwide market might experience low demand in its domestic market but benefit from growing demand in its international market. As an example, much of the growth for Coca-Cola and Pepsi and the fast-food chains, such as McDonald’s and Burger King, has come from international expansion in Europe and the Far East.

In general, an industry’s prospects within the global business environment will determine how well or poorly an individual firm will fare, so industry analysis should precede company analysis. Few companies perform well in a poor industry, so even the best company in an industry with a negative outlook is a bad prospect for investment. For example, a poor sales and earnings outlook in the farm equipment industry would have a negative impact on Deere and

---

2We will show an example of a global asset allocation in Chapter 12.
These results from academic studies support the use of the three-step investment process. This investment decision approach is consistent with the discussion in Chapter 2, which contended that the most important decision is the asset allocation decision. The asset allocation specifies: (1) what proportion of your portfolio will be invested in various nations' economies, (2) within each country, how you will divide your assets among stocks, bonds, or other assets, and (3) your industry selections, based on which industries are expected to prosper in the projected economic environment. We provide an example of global asset allocation in Chapter 12.

Now that we have described and justified the three-step process, we need to consider the theory of valuation. The application of this theory allows us to compute estimated intrinsic values for the market, for alternative industries, and for the stocks of individual firms. Finally, we compare these estimated intrinsic values to current market prices and determine appropriate investment decisions.

11.2.3 Company Analysis
After determining an industry's outlook, an investor can analyze and compare an individual firm's performance relative to the entire industry using financial ratios and cash flow values. As we discussed in Chapter 10, many financial ratios for firms are valid only when they are compared to the performance of their industries.

You undertake company analysis to identify the best company in a promising industry. This involves examining a firm's past performance and, more important, its future prospects. After you understand the firm and its outlook, you can estimate its value using one of several valuation models. An important point that will be emphasized is that it is your estimated inputs to the valuation models that are critical, and the quality of these inputs depends on your prior market-industry-company analysis. In the final step, you compare your estimated intrinsic value to the prevailing market price of the firm's stock and decide whether its stock is a good investment.

Your final goal is to select the best stock within a desirable industry and include it in your portfolio based on its relationship (correlation) with all other assets in your portfolio. As we discuss in more detail in Chapter 14, the best stock for investment purposes may not necessarily be issued by the best company because the stock of the finest company in an industry may be overpriced, which would cause it to be a poor investment. You cannot know whether a security is undervalued or overvalued until you have thoroughly analyzed the company, estimated its intrinsic value, and compared your estimated intrinsic value to the market price of the firm's stock.

11.2.4 Does the Three-Step Process Work?
Although you might agree with the logic of the three-step investment process, you might wonder how well this process works in selecting investments. The results of several academic studies have supported this technique. First, studies indicated that most changes in an individual firm's earnings could be attributed to changes in aggregate corporate earnings and changes in earnings for the firm's industry, with the aggregate earnings changes being more important. Although the relative influence of the general economy and the industry on a firm's earnings varied among individual firms, the results consistently demonstrated that the economic environment had a significant effect on firm earnings.

Second, studies by Moore and Cullity (1988) and Siegel (1991) found a relationship between aggregate stock prices and various economic series, such as employment, income, and production. These results supported the view that a relationship exists between stock prices and economic expansions and contractions.

Third, an analysis of the relationship between rates of return for the aggregate stock market, alternative industries, and individual stocks showed that most of the changes in rates of return for individual stocks could be explained by changes in the rates of return for the aggregate stock market and the stock's industry. As shown by Meyers (1973), although the importance of the market effect tended to decline over time and the significance of the industry effect varied among industries, the combined market-industry effect on an individual stock's rate of return was still important.
These results from academic studies support the use of the three-step investment process. This investment decision approach is consistent with the discussion in Chapter 2, which contended that the most important decision is the asset allocation decision. The asset allocation specifies: (1) what proportion of your portfolio will be invested in various nations’ economies, (2) within each country, how you will divide your assets among stocks, bonds, or other assets, and (3) your industry selections, based on which industries are expected to prosper in the projected economic environment. We provide an example of global asset allocation in Chapter 12.

Now that we have described and justified the three-step process, we need to consider the theory of valuation. The application of this theory allows us to compute estimated intrinsic values for the market, for alternative industries, and for the stocks of individual firms. Finally, we compare these estimated intrinsic values to current market prices and determine appropriate investment decisions.

### 11.3 THEORY OF VALUATION

You may recall from your studies in accounting, economics, or corporate finance that the value of an asset is the present value of its expected returns. Specifically, you expect an asset to provide a stream of returns during the period of time you own it. To convert this estimated stream of returns to a value for the security, you must discount this stream at your required rate of return. This process of valuation requires estimates of: (1) the stream of expected returns and (2) the required rate of return on the investment (its discount rate).

#### 11.3.1 Stream of Expected Returns (Cash Flows)

An estimate of the expected returns from an investment encompasses not only the size but also the form, time pattern, and uncertainty of returns, which affect the required rate of return.

**Form of Returns** The returns from an investment can take many forms, including earnings, cash flows, dividends, interest payments, or capital gains (increases in value) during a period. We will consider several alternative valuation techniques that use different forms of returns. As an example, one common stock valuation model applies a multiplier to a firm’s future earnings, whereas another valuation model computes the present value of a firm’s alternative cash flows, and a third model estimates the present value of dividend payments. Returns or cash flows can come in many forms, and you must consider all of them to evaluate an investment accurately.

**Time Pattern and Growth Rate of Returns** You cannot calculate an accurate value for a security unless you can estimate when you will receive the returns or cash flows. Because money has a time value, you must estimate the time pattern and growth rate of returns (cash flows) from an investment. This knowledge will make it possible to properly value the stream of returns relative to alternative investments that have a different time pattern and growth rate of returns or cash flows.

#### 11.3.2 Required Rate of Return

**Uncertainty of Returns (Cash Flows)** You will recall from Chapter 1 that the required rate of return on an investment is determined by: (1) the economy’s real risk-free rate of return, plus (2) the expected rate of inflation during the holding period, plus (3) a risk premium that is determined by the uncertainty of returns. All investments are affected by the risk-free rate

---

3The classic studies that established the importance of asset allocation are Brinson, Hood, and Beebower (1986), followed by Brinson, Singer, and Beebower (1991). A subsequent well-regarded application of these concepts is contained in Cohen (1996).
and the expected rate of inflation because these two variables determine the nominal risk-free rate. Therefore, the factor that causes a difference in required rates of return is the risk premium for alternative investments. In turn, this risk premium depends on the uncertainty of returns or cash flows from an investment.

We can identify the sources of the uncertainty of returns by the internal characteristics of assets or by market-determined factors. Earlier, we subdivided the internal characteristics for a firm into business risk (BR), financial risk (FR), liquidity risk (LR), exchange rate risk (ERR), and country risk (CR). The market-determined risk measures are the systematic risk of the asset (its beta) or a set of multiple risk factors that were discussed in Chapter 9.

### 11.3.3 Investment Decision Process: A Comparison of Estimated Values and Market Prices

To ensure that you receive your required return on an investment, you must estimate the intrinsic value of the investment at your required rate of return and then compare this estimated intrinsic value to the prevailing market price. You should not buy an investment if its market price exceeds your estimated value because the difference will prevent you from receiving your required rate of return on the investment. In contrast, if the estimated intrinsic value of the investment exceeds the market price, you should buy the investment. In summary:

- If Estimated Intrinsic Value > Market Price, Buy or Hold it if You Own It.
- If Estimated Intrinsic Value < Market Price, Don’t Buy or Sell it if You Own It.

For example, assume you read about a firm that produces athletic shoes, and its stock is listed on the NYSE. Using one of the valuation models we will discuss and making estimates of the earnings, or cash flows, and the growth of these variables based on the company’s annual report and other information, you estimate the company’s intrinsic stock value using your required rate of return as $20 a share. After estimating this value, you look in the paper and see that the stock is currently being traded at $15 a share. You would want to buy this stock because you think it is worth $20 a share and you can buy it for $15 a share. In contrast, if the current market price were $25 a share, you would not want to buy the stock because, based upon your valuation, it will cost more than you estimate it is worth—it is overvalued.

The theory of value provides a common framework for the valuation of all investments. Different applications of this theory generate different estimated values for alternative investments because of the different payment streams and characteristics of the securities. The interest and principal payments on a bond differ substantially from the expected dividends and future selling price for a common stock. The initial discussion that follows applies the discounted cash flow method to bonds, preferred stock, and common stock. This presentation demonstrates that the same basic model is useful across a range of investments. Subsequently, because of the difficulty in estimating the value of common stock, we consider two general approaches and numerous techniques for the valuation of stock.

### 11.4 Valuation of Alternative Investments

#### 11.4.1 Valuation of Bonds

Calculating the value of bonds is relatively easy because the size and time pattern of cash flows from the bond over its life are known. A bond typically promises the following:

1. Interest payments every six months equal to one-half the coupon rate times the face value of the bond
2. The payment of the principal on the bond’s maturity date
As was true with a bond, stated payments are made on specified dates although the issuer of this stock does not have the same legal obligation to pay investors as do issuers of bonds. Payments are made only after the firm meets its bond interest payments. Because this reduced legal obligation increases the uncertainty of returns, investors should require a higher rate of return on a firm’s preferred stock than on its bonds. Although this differential in required return should exist in theory, it generally does not exist in practice because of the tax treatment accorded dividends paid to corporations. As described in Chapter 3, 80 percent of intercompany preferred dividends are tax exempt, making the effective tax rate on preferred dividends about 6.8 percent, assuming a corporate tax rate of 34 percent. This tax advantage stimulates the demand for preferred stocks by corporations, and because of this demand, the yield on preferred stocks has generally been below that on the highest-grade corporate bonds.

Because preferred stock is a perpetuity, its value is simply the stated annual dividend divided by the required rate of return on preferred stock ($k_p$) as follows:

$$V = \frac{\text{Dividend}}{k_p}$$

Consider a preferred stock has a $100 par value and a dividend of $8 a year. Because of the expected rate of inflation, the uncertainty of the dividend payment, and the tax advantage to you as a corporate investor, assume that your required rate of return on this stock is 9 percent. Therefore, the value of this preferred stock to you is:

$$V = \frac{\$8}{0.09} = \$88.89$$

Given this estimated value, you would inquire about the current market price to decide whether you would want to buy this preferred stock. If the current market price is $95, you would decide against a purchase, whereas if it is $80, you would buy the stock. Also, given the market price of preferred stock, you can derive its promised yield. Assuming a current market price of $85, the promised yield would be:

$$k_p = \frac{\text{Dividend}}{\text{Price}} = \frac{\$8}{\$85} = 0.0941$$

11.4.3 Approaches to the Valuation of Common Stock

Because of the complexity and importance of valuing common stock, various valuation techniques have been devised over time. These techniques fall into one of two general approaches: (1) the discounted cash flow valuation techniques, where the value of the stock is estimated based upon the present value of some measure of cash flow, including dividends, operating cash flow, and free cash flow; and (2) the relative valuation techniques, where the value of a stock is estimated based upon its current price relative to variables considered to be significant to valuation, such as earnings, cash flow, book value, or sales. Exhibit 11.2 provides a visual presentation of the alternative approaches and specific techniques.

An important point is that both of these approaches and all of these valuation techniques have several common factors. First, all of them are significantly affected by the investor’s required rate of return on the stock because this rate becomes the discount rate or is a major component of the discount rate. Second, all valuation approaches are affected by the estimated growth rate of the variable used in the valuation technique—for example, dividends, earnings, cash flow, or sales. As noted in the efficient market discussion, both of these critical variables must be estimated. As a result, different analysts using the same valuation techniques will produce different values.

The present value of the semiannual interest payments is an annuity for 30 periods (15 years every six months) at one-half the required return (5 percent):$^4$

$$500 \times 15.3725 = 7,686$$

(Present Value of Interest Payments at 10 Percent)

The present value of the principal is likewise discounted at 5 percent for 30 periods:$^5$

$$10,000 \times 0.2314 = 2,314$$

(Present Value of the Principal Payment at 10 Percent)

This can be summarized as follows:

<table>
<thead>
<tr>
<th>Present Value of Interest Payments</th>
<th>$500 \times 15.3725 = 7,686</th>
</tr>
</thead>
<tbody>
<tr>
<td>Present Value of Principal Payment</td>
<td>$10,000 \times 0.2314 = 2,314</td>
</tr>
<tr>
<td>Total Present Value of Bond at 10 Percent</td>
<td>$10,000</td>
</tr>
</tbody>
</table>

This is the amount that an investor should be willing to pay for this bond, assuming that the required rate of return on a bond of this risk class is 10 percent. If the market price of the bond is above this value, the investor should not buy it because the promised yield to maturity at this higher price will be less than the investor’s required rate of return.

Alternatively, assuming an investor requires a 12 percent return on this bond, its value would be:

$$500 \times 13.7648 = 6,882$$

$$10,000 \times 0.1741 = 1,741$$

Total Present Value of Bond at 12 Percent = $8,623

This example shows that if you want a higher rate of return, you will not pay as much for an asset; that is, a given stream of cash flows has a lower value to you. It is this characteristic that leads to the often-used phrase that the prices of bonds move in an opposite direction of yields. As before, you would compare this computed present value to the market price of the bond to determine whether you should invest in it.$^6$

11.4.2 Valuation of Preferred Stock

The owner of a preferred stock receives a promise that it will pay a stated dividend, usually each quarter, for an infinite period. Preferred stock is a perpetuity because it has no maturity.

---

$^4$The annuity factors and present value factors are contained in Appendix C at the end of the book.

$^5$If we used annual compounding, this would be 0.239 rather than 0.2314. We use semiannual compounding because it is consistent with the interest payments and is used in practice.

$^6$To test your mastery of bond valuation, check that if the required rate of return were 8 percent, the value of this bond would be $11,729.
As was true with a bond, stated payments are made on specified dates although the issuer of this stock does not have the same legal obligation to pay investors as do issuers of bonds. Payments are made only after the firm meets its bond interest payments. Because this reduced legal obligation increases the uncertainty of returns, investors should require a higher rate of return on a firm’s preferred stock than on its bonds. Although this differential in required return should exist in theory, it generally does not exist in practice because of the tax treatment accorded dividends paid to corporations. As described in Chapter 3, 80 percent of intercompany preferred dividends are tax exempt, making the effective tax rate on preferred dividends about 6.8 percent, assuming a corporate tax rate of 34 percent. This tax advantage stimulates the demand for preferred stocks by corporations, and because of this demand, the yield on preferred stocks has generally been below that on the highest-grade corporate bonds.

Because preferred stock is a perpetuity, its value is simply the stated annual dividend divided by the required rate of return on preferred stock \( k_p \) as follows:

\[
V = \frac{\text{Dividend}}{k_p}
\]

Consider a preferred stock has a $100 par value and a dividend of $8 a year. Because of the expected rate of inflation, the uncertainty of the dividend payment, and the tax advantage to you as a corporate investor, assume that your required rate of return on this stock is 9 percent. Therefore, the value of this preferred stock to you is:

\[
V = \frac{8}{0.09} = \$88.89
\]

Given this estimated value, you would inquire about the current market price to decide whether you would want to buy this preferred stock. If the current market price is $95, you would decide against a purchase, whereas if it is $80, you would buy the stock. Also, given the market price of preferred stock, you can derive its promised yield. Assuming a current market price of $85, the promised yield would be:

\[
k_p = \frac{\text{Dividend}}{\text{Price}} = \frac{8}{85.00} = 0.0941
\]

### 11.4.3 Approaches to the Valuation of Common Stock

Because of the complexity and importance of valuing common stock, various valuation techniques have been devised over time. These techniques fall into one of two general approaches: (1) the discounted cash flow valuation techniques, where the value of the stock is estimated based upon the present value of some measure of cash flow, including dividends, operating cash flow, and free cash flow; and (2) the relative valuation techniques, where the value of a stock is estimated based upon its current price relative to variables considered to be significant to valuation, such as earnings, cash flow, book value, or sales. Exhibit 11.2 provides a visual presentation of the alternative approaches and specific techniques.

An important point is that both of these approaches and all of these valuation techniques have several common factors. First, all of them are significantly affected by the investor’s required rate of return on the stock because this rate becomes the discount rate or is a major component of the discount rate. Second, all valuation approaches are affected by the estimated growth rate of the variable used in the valuation technique—for example, dividends, earnings, cash flow, or sales. As noted in the efficient market discussion, both of these critical variables must be estimated. As a result, different analysts using the same valuation techniques will
derive different estimates of value for a stock because they have different estimates for these critical variable inputs. Put another way, you should assume that most investors are aware of the valuation models and it is the inputs to the models that make a difference—that is, your estimates of the discount rate and the growth rate of earnings and cash flows. If you are better at estimating these inputs, you will be a superior analyst.

The following discussion of equity valuation techniques considers the specific models and the theoretical and practical strengths and weaknesses of each of them. Notably, the authors’ intent is to present these two approaches as complementary, not competitive, approaches—that is, you should learn and use both of them.

### 11.4.4 Why and When to Use the Discounted Cash Flow Valuation Approach

These discounted cash flow valuation techniques are obvious choices for valuation because they are the epitome of how we describe value—that is, the present value of expected cash flows. The major difference between the alternative techniques is how one specifies cash flow—that is, the measure of cash flow used.

The cleanest and most straightforward measure of cash flow is dividends because these are clearly cash flows that go directly to the equity investor, which implies that you should use the cost of equity as the discount rate. However, this dividend technique is difficult to apply to firms that do not pay dividends during periods of high growth, or that currently pay very limited dividends because they have high rate of return investment alternatives available. On the other hand, an advantage is that the reduced form of the dividend discount model (DDM) is very useful when discussing valuation for a stable, mature entity where the assumption of relatively constant growth of dividends for the long term is appropriate (a good example is the aggregate stock market).

The second specification of cash flow is the operating free cash flow, which is generally described as cash flows after direct costs (cost of goods and selling, general and administrative expenses) and after allowing for cash flows to support working capital outlays and capital expenditures required for future growth, but before any payments to capital suppliers. Because we are dealing with the cash flows available for all capital suppliers, the discount rate employed is the firm’s weighted average cost of capital (WACC). This is a very useful model when comparing firms with diverse capital structures because you determine the value of the total firm (the entity
value) and then subtract the value of the firm’s debt obligations to arrive at a value for the firm’s equity.

The third cash flow measure is free cash flow to equity, which is a measure of cash flows similar to the operating free cash flow described above, but after payments to debt holders, which means that these are cash flows available to equity owners. Therefore, the appropriate discount rate is the firm’s cost of equity.

Beyond being theoretically correct, these models allow a substantial amount of flexibility in terms of changes in sales and expenses that implies changing growth rates over time. Once you understand how to compute each measure of cash flow, you can estimate cash flow for each year by constructing a pro forma statement for each year or you can estimate overall growth rates for the alternative cash flow values as we will demonstrate with the DDM.

A potential difficulty with these cash flow techniques is that they are very dependent on the two significant inputs—(1) the growth rates of cash flows (both the rate of growth and the duration of growth), and (2) the estimate of the discount rate. As we will show in several instances, a small change in either of these values can have a significant impact on the estimated value. As noted earlier, everyone knows and uses similar valuation models, but it is the inputs that are critical—remember the saying, “GIGO: garbage in, garbage out!” This is similar to the discussion in Chapter 6 regarding being a superior analyst in a world with an efficient market.

11.4.5 Why and When to Use the Relative Valuation Techniques

As noted, a benefit but also a potential problem with the discounted cash flow valuation models is that it is possible to derive intrinsic values that are substantially above or below prevailing prices depending on how you adjust your estimated inputs to the prevailing environment.

An advantage of the relative valuation techniques is that they provide information about how the market is currently valuing stock at several levels—that is, the aggregate market, alternative industries, and individual stocks within industries. Following this chapter, which provides the background for these two approaches, in subsequent chapters we demonstrate the alternative relative valuation ratios for the aggregate market, for an industry relative to the market, and for an individual company relative to the aggregate market, to its industry, and to other stocks in its industry.

The good news is that this relative valuation approach provides information on how the market is currently valuing securities. The bad news is that it is providing information on current valuation. The point is, the relative valuation approach provides this information on current valuation, but it does not provide guidance on whether these current valuations are appropriate—that is, all valuations at a point in time could be too high or too low. For example, assume that the market becomes significantly overvalued. If you were to compare the value for an industry to the very overvalued market, you might contend based on such a comparison that an industry is undervalued relative to the market. Unfortunately, your judgment may be wrong because of the benchmark you are using—that is, you might be comparing a fully valued industry to a very overvalued market. Alternatively, if you compare an undervalued industry to an aggregate market that is grossly undervalued, the industry will appear overvalued by comparison.

Put another way, the relative valuation techniques are appropriate to consider under two conditions:

1. You have a good set of comparable entities—that is, comparable companies that are similar in terms of industry, size, and, it is hoped, risk.
2. The aggregate market and the company’s industry are not at a valuation extreme—that is, they are not either seriously undervalued or seriously overvalued.
11.4.6 Discounted Cash Flow Valuation Techniques

All of these valuation techniques are based on the basic valuation model, which asserts that the value of an asset is the present value of its expected future cash flows, as follows:

\[ V_j = \sum_{t=1}^{\infty} \frac{CF_t}{(1 + k)^t} \]

where:
- \( V_j \) = value of Stock \( j \)
- \( n \) = life of the asset
- \( CF_t \) = cash flow in Period \( t \)
- \( k \) = the discount rate that is equal to the investors’ required rate of return for Asset \( j \), which is determined by the uncertainty (risk) of the asset’s cash flows

As noted, the specific cash flows used will differ between techniques. They range from dividends (the best-known model) to operating free cash flow and free cash flow to equity. We begin with a fairly detailed presentation of the present-value-of-dividend model, referred to as the dividend discount model (DDM), because it is intuitively appealing and a very well-known model. Also, its general approach is similar to the other discounted cash flow models.

**The Dividend Discount Model (DDM)**

This model assumes that the value of a share of common stock is the present value of all future dividends as follows:

\[ V_j = \frac{D_1}{(1 + k)} + \frac{D_2}{(1 + k)^2} + \frac{D_3}{(1 + k)^3} + \cdots + \frac{D_\infty}{(1 + k)^\infty} \]

\[ = \sum_{t=1}^{\infty} \frac{D_t}{(1 + k)^t} \]

where:
- \( V_j \) = value of common Stock \( j \)
- \( D_t \) = dividend during Period \( t \)
- \( k \) = required rate of return on Stock \( j \)

An obvious question is: What happens when the stock is not held for an infinite period? A sale of the stock at the end of Year 2 would imply the following formula:

\[ V_j = \frac{D_1}{(1 + k)} + \frac{D_2}{(1 + k)^2} + \frac{SP_{j2}}{(1 + k)^2} \]

The value is equal to the two dividend payments during Years 1 and 2 plus the sale price (\( SP_j \)) for stock \( j \) at the end of Year 2. The expected selling price of stock \( j \) at the end of Year 2 (\( SP_{j2} \)) is simply the value of all remaining dividend payments.

\[ SP_{j2} = \frac{D_3}{(1 + k)} + \frac{D_4}{(1 + k)^2} + \cdots + \frac{D_\infty}{(1 + k)^\infty} \]

If \( SP_{j2} \) is discounted back to the present by \( 1/(1 + k)^2 \), this equation becomes:

\[ PV(SP_{j2}) = \frac{D_3}{(1 + k)^3} + \frac{D_4}{(1 + k)^4} + \cdots + \frac{D_\infty}{(1 + k)^\infty} \]

\[ = \frac{D_3}{(1 + k)^3} + \frac{D_4}{(1 + k)^4} + \cdots + \frac{D_\infty}{(1 + k)^\infty} \]

\[ = \frac{D_1}{(1 + k)} + \frac{D_2}{(1 + k)^2} + \frac{SP_{j2}}{(1 + k)^2} \]

This model was initially set forth in Williams (1938) and subsequently reintroduced and expanded by Gordon (1962).
The long-run dividend yield on stocks has been between 1.50 percent and 5.00 percent, but in recent years (since 1980) it has been 1.50 to 4.00 percent, which implies a midpoint of 2.75 percent. Using this estimate with the $1.10 dividend gives an estimated price of

$$V = \frac{D_1}{(1 + k)} + \frac{D_2}{(1 + k)^2} + \frac{D_3}{(1 + k)^3} + \cdots + \frac{D_m}{(1 + k)^m}$$

where:

$$D_1 = 0; D_2 = 0$$

The investor expects that when the firm starts paying dividends in Period 3, it will be a large initial amount and dividends will grow faster than those of a comparable stock that had paid out dividends. The stock has value because of these future dividends. We will apply this model to several cases having different holding periods that will show how it works.

**One-Year Holding Period** Assume an investor wants to buy the stock, hold it for one year, and then sell it. To determine the value of the stock—that is, how much the investor should be willing to pay for it—using the DDM, we must estimate the dividend to be received during the period, the expected sale price at the end of the holding period, and the investor’s required rate of return.

To estimate the dividend for the coming year, adjust the current dividend for expectations regarding the change in the dividend during the year. Assume the company we are analyzing earned $2.50 a share last year and paid a dividend of $1 a share. Assume further that the firm has been fairly consistent in maintaining this 40 percent payout over time. The consensus of financial analysts is that the firm will earn about $2.75 during the coming year and will raise its dividend to $1.10 per share.

A crucial estimate is the expected selling price for the stock a year from now. You can estimate this expected selling price by one or more of three alternative procedures. In the first, you can apply the dividend discount model where you estimate the specific dividend payments for a number of years into the future and calculate the value of the stock from these estimates. In the second procedure, the earnings multiplier model, you multiply the future expected earnings for the stock by an earnings multiple, which you likewise estimate, to find an expected sale price. We will discuss the earnings multiple model in a later section of the chapter.

In the third method, you estimate the firm’s future earnings and its dividend payout ratio to arrive at an estimate of its expected dividend at your sale date. Given this dividend and an estimate of the dividend yield on stocks, you can derive a price estimate.

Given the estimated earnings and dividend above (earnings of $2.75, and dividend of $1.10), we can use the earnings multiplier and the dividend yield procedures as follows:

The long-run forward P/E of stocks is between 12 and 16. Using the midpoint of 14, we get an estimated price of

$$14 \times \$2.75 = \$35.50$$
The long-run dividend yield on stocks has been between 1.50 percent and 5.00 percent, but in recent years (since 1980) it has been 1.50 to 4.00 percent, which implies a midpoint of 2.75 percent. Using this estimate with the $1.10 dividend gives an estimated price of

\[
\frac{1.10}{0.0275} = 40.00
\]

The average of these two estimates is $37.75, which is rounded to $38.

Finally, you must determine the required rate of return. As discussed before, the nominal risk-free rate is determined by the real risk-free rate and the expected rate of inflation. A widely used proxy for this rate is the promised yield on 10-year government bonds because the typical investment horizon (expected holding period) is 5 to 10 years. You estimate the stock’s risk premium by comparing its risk level to the risk of other potential investments. In later chapters, we discuss how you can estimate this risk. For the moment, assume that 10-year government bonds are yielding 6 percent, and you believe that a 4 percent risk premium over the yield of these bonds is appropriate for this stock. Thus, you specify a required rate of return of 10 percent.

In summary, you have estimated the dividend at $1.10 (payable at year’s end), an ending sale price of $38, and a required rate of return of 10 percent. Given these inputs, you would estimate the value of this stock as follows:

\[
V = \frac{D_0}{1 + k} + \frac{D_0}{(1 + k)^2} + \frac{D_1}{(1 + k)^n} + \frac{D_0}{(1 + k)^{n+1}}
\]

\[
= \frac{1.10}{1.10} + \frac{1.10 	imes 1.07}{1.10^2}
\]

\[
= 1.00 + 34.55
\]

\[
= 35.55
\]

Note that we have not mentioned the current market price of the stock. This is because the market price is not relevant to you as an investor except as a comparison to the independently derived intrinsic value based on your estimates of the relevant variables. Once we have calculated the stock’s intrinsic value as $35.55, we can compare it to the market price and apply the investment decision rule: If the stock’s market price is more than $35.55, do not buy; if it is equal to or less than $35.55, buy.

**Multiple-Year Holding Period** If you anticipate holding the stock for several years and then selling it, the valuation estimate is harder. You must forecast several future dividend payments and estimate the sale price of the stock several years in the future.

The difficulty with estimating future dividend payments is that the future stream can have numerous forms. The exact estimate of the future dividends depends on two projections. The first is your outlook for earnings growth because earnings are the source of dividends. The second projection is the firm’s dividend policy, which can take several forms. A firm can have a constant percent payout of earnings each year, which implies a change in dividend each year, or the firm could follow a step pattern in which it increases the dividend rate by a variable dollar amount each year or every two or three years. The easiest dividend policy is to assume that the firm enjoys a constant growth rate in earnings and maintains a constant dividend payout. This set of assumptions implies that the dividend stream will experience a constant growth rate that is equal to the earnings growth rate. Clearly, the important estimate by the analyst is the growth rate of earnings, which will provide the dividend estimates and ending estimates for earnings and the dividends that are used to derive the ending price estimate as
above. As before, the estimated intrinsic value is simply the discounted value of these cash flows at your required cost of equity. Finally, compare this estimated intrinsic value for the stock to its current market price to determine whether you should buy it.

At this point, you should recognize that the valuation procedure discussed here is similar to that used in corporate finance when making investment decisions, except that the cash flows are from dividends instead of returns to an investment project. Also, rather than estimating the scrap value or salvage value of a corporate asset, we are estimating the ending sale price for the stock. Finally, rather than discounting cash flows using the firm’s cost of capital, we use the individual’s required rate of return on the company’s equity. In both cases, we are looking for excess present value, which means that the present value of expected cash inflows—that is, the estimated intrinsic value of the asset—exceeds the present value of cash outflows, which is the market price of the asset.

**Infinite Period Model** We can extend the multiperiod model by extending our estimates of dividends, but the benefits derived from these extensions would be minimal. Instead, we will move to the infinite period dividend discount model, which assumes that investors estimate future dividend payments for an infinite number of periods.

Needless to say, this is a formidable task. We must make some simplifying assumptions about this future stream of dividends to make the task viable. The easiest assumption is that the future dividend stream will grow at a constant rate for an infinite period. This is a rather heroic assumption in many instances, but where it does hold, we can use the model to value individual stocks as well as the aggregate stock market and alternative industries. This model is generalized as follows:

\[ V_j = \frac{D_0(1 + g)}{(1 + k)} + \frac{D_0(1 + g)^2}{(1 + k)^2} + \cdots + \frac{D_0(1 + g)^n}{(1 + k)^n} \]

where:

- \( V_j \) = the value of Stock \( j \)
- \( D_0 \) = the dividend payment in the current period
- \( g \) = the constant growth rate of dividends
- \( k \) = the required rate of return on Stock \( j \)
- \( n \) = the number of periods, which we assume to be infinite

In the appendix to this chapter, we show that with certain assumptions this infinite period constant growth rate model can be simplified to the following expression (referred to as the reduced form DDM):

\[ V_j = \frac{D_1}{k - g} \]

You will probably recognize this formula as one that is widely used in corporate finance to estimate the cost of equity capital for the firm—that is, \( k = D/V + g \).

To use this model for valuation, you must estimate: (1) the required rate of return \( (k) \) and (2) the expected constant growth rate of dividends \( (g) \). After estimating \( g \), it is a simple matter to estimate \( D_1 \) because it is the current dividend \( (D_0) \) times \( (1 + g) \).

Consider the example of a stock with a current dividend of $1 a share. You believe that, over the long run, this company’s earnings and dividends will grow at 7 percent; your estimate of \( g \) is 0.07, which implies that you expect the dividend next year \( (D_1) \) to be $1.07. For the long run, you expect a nominal risk-free rate of about 6 percent and a risk premium for this
that the required rate of return for a corporation is its weighted average cost of capital (WACC). An example might be Intel, which has a WACC of about 12 percent, but is currently earning about 20 percent on its invested capital. Therefore, we would consider Intel a growth company. To exploit these outstanding investment opportunities, these growth firms generally retain a high percentage of earnings for reinvestment, and their earnings will grow faster than those of the typical firm. You will recall from the discussion in Chapter 10 that a firm’s sustainable growth is a function of its retention rate and its return on equity (ROE). Notably, as discussed subsequently, the earnings growth pattern for these growth companies is inconsistent with the assumptions of the infinite period DDM.

First, the infinite period DDM assumes dividends will grow at a constant rate for an infinite period. This assumption seldom holds for companies currently growing at above-average rates. As an example, both Apple and Google have grown at rates in excess of 20 percent a year for several years. It is unlikely that they can maintain such extreme rates of growth because of the inability to continue earning the ROEs implied by this growth for an infinite period in an economy where other firms will compete with them for these high rates of return.

Second, during the periods when these firms experience abnormally high rates of growth, their rates of growth probably exceed their required rates of return. There is no automatic relationship between growth and risk; a high-growth company is not necessarily a high-risk company. In fact, a firm growing at a high constant rate would have lower risk (less uncertainty) than a low-growth firm with an unstable earnings pattern.

In summary, some firms experience periods of abnormally high rates of growth for some finite periods of time. The infinite period DDM cannot be used to value these true growth firms because these high-growth conditions are temporary and, therefore, inconsistent with the assumptions of the DDM. In the following section, we discuss how to adjust the DDM to value a firm with temporary supernormal growth. In Chapter 14, we will discuss additional models used for estimating the stock value of growth companies.

11.4.8 Valuation with Temporary Supernormal Growth
Thus far, we have considered how to value a firm with different growth rates for short periods of time (one to three years) and how to value a stock using a model that assumes a constant growth rate for an infinite period. As noted, the assumptions of the model make it impossible to use the infinite period constant growth model to value true growth companies. The point is, in a competitive free enterprise economy, it is not reasonable to expect a company to permanently maintain a growth rate higher than its required rate of return because competition will eventually enter this apparently lucrative business, which will reduce the firm’s profit margins and therefore its ROE and growth rate. Therefore, after a few years of exceptional growth—that is, a period of temporary supernormal growth—a firm’s growth rate is expected to decline. Eventually, its growth rate is expected to stabilize at a constant level consistent with the assumptions of the infinite period DDM.

To determine the value of a temporary supernormal growth company, you must combine the previous models. In analyzing the initial years of exceptional growth, you examine each year individually. If the company is expected to have two or three stages of supernormal growth, you must examine each year during these stages of growth. When the firm’s growth rate stabilizes at a rate below the required rate of return, you can compute the remaining value of the firm assuming constant growth using the DDM and discount this lump-sum constant growth value back to the present. The technique should become clear as you work through the following example.

The Bourke Company has a current dividend ($D_0$) of $2 a share. The following are the expected annual growth rates for dividends.

\[ g = 0.07 \]
\[ k = 0.11 \]
\[ D_1 = 1.07(1.00 \times 1.07) \]
\[ V = \frac{1.07}{0.11 - 0.07} \]
\[ = \frac{1.07}{0.04} \]
\[ = 26.75 \]

A small change in any of the original estimates will have a large impact on $V$, as shown by the following examples:

1. $g = 0.07; k = 0.12; D_1 = 1.07$. (We assume an increase in $k$.)

\[ V = \frac{1.07}{0.12 - 0.07} \]
\[ = \frac{1.07}{0.05} \]
\[ = 21.40 \]

2. $g = 0.08; k = 0.11; D_1 = 1.08$ (We assume an increase in $g$.)

\[ V = \frac{1.08}{0.11 - 0.08} \]
\[ = \frac{1.08}{0.03} \]
\[ = 36.00 \]

These examples show that as small a change as 1 percent in either $g$ or $k$ produces a large difference in the estimated value of the stock. The crucial relationship that determines the value of the stock is the spread between the required rate of return ($k$) and the expected growth rate of dividends ($g$). Anything that causes a decline in the spread will cause an increase in the computed value, whereas any increase in the spread will decrease the computed value of the stock.

11.4.7 Infinite Period DDM and Growth Companies
As noted in the appendix to this chapter, the infinite period DDM has the following assumptions:

1. Dividends grow at a constant rate.
2. The constant growth rate will continue for an infinite period.
3. The required rate of return ($k$) is greater than the infinite growth rate ($g$). If it is not, the model gives meaningless results because the denominator becomes negative.

What is the effect of these assumptions if you want to use this model to value the stock of growth companies, such as Intel, Pfizer, Microsoft, Apple, and Google? Growth companies are firms that have the opportunities and abilities to earn rates of return on investments that are consistently above their required rates of return. You will recall from corporate finance

---

*Growth companies are discussed in Salomon (1963) and Miller and Modigliani (1961). Models to value growth companies are discussed in Chapter 14.*
that the required rate of return for a corporation is its weighted average cost of capital (WACC). An example might be Intel, which has a WACC of about 12 percent, but is currently earning about 20 percent on its invested capital. Therefore, we would consider Intel a growth company. To exploit these outstanding investment opportunities, these growth firms generally retain a high percentage of earnings for reinvestment, and their earnings will grow faster than those of the typical firm. You will recall from the discussion in Chapter 10 that a firm’s sustainable growth is a function of its retention rate and its return on equity (ROE). Notably, as discussed subsequently, the earnings growth pattern for these growth companies is inconsistent with the assumptions of the infinite period DDM.

First, the infinite period DDM assumes dividends will grow at a constant rate for an infinite period. This assumption seldom holds for companies currently growing at above-average rates. As an example, both Apple and Google have grown at rates in excess of 20 percent a year for several years. It is unlikely that they can maintain such extreme rates of growth because of the inability to continue earning the ROEs implied by this growth for an infinite period in an economy where other firms will compete with them for these high rates of return.

Second, during the periods when these firms experience abnormally high rates of growth, their rates of growth probably exceed their required rates of return. There is no automatic relationship between growth and risk; a high-growth company is not necessarily a high-risk company. In fact, a firm growing at a high constant rate would have lower risk (less uncertainty) than a low-growth firm with an unstable earnings pattern.

In summary, some firms experience periods of abnormally high rates of growth for some finite periods of time. The infinite period DDM cannot be used to value these true growth firms because these high-growth conditions are temporary and, therefore, inconsistent with the assumptions of the DDM. In the following section, we discuss how to adjust the DDM to value a firm with temporary supernormal growth. In Chapter 14, we will discuss additional models used for estimating the stock value of growth companies.

### 11.4.8 Valuation with Temporary Supernormal Growth

Thus far, we have considered how to value a firm with different growth rates for short periods of time (one to three years) and how to value a stock using a model that assumes a constant growth rate for an infinite period. As noted, the assumptions of the model make it impossible to use the infinite period constant growth model to value true growth companies. The point is, in a competitive free enterprise economy, it is not reasonable to expect a company to permanently maintain a growth rate higher than its required rate of return because competition will eventually enter this apparently lucrative business, which will reduce the firm’s profit margins and therefore its ROE and growth rate. Therefore, after a few years of exceptional growth—that is, a period of temporary supernormal growth—a firm’s growth rate is expected to decline. Eventually, its growth rate is expected to stabilize at a constant level consistent with the assumptions of the infinite period DDM.

To determine the value of a temporary supernormal growth company, you must combine the previous models. In analyzing the initial years of exceptional growth, you examine each year individually. If the company is expected to have two or three stages of supernormal growth, you must examine each year during these stages of growth. When the firm’s growth rate stabilizes at a rate below the required rate of return, you can compute the remaining value of the firm assuming constant growth using the DDM and discount this lump-sum constant growth value back to the present. The technique should become clear as you work through the following example.

The Bourke Company has a current dividend ($D_0$) of $2 a share. The following are the expected annual growth rates for dividends.
The derivation of its reduced form, we noted that the infinite period DDM cannot be applied to
the valuation of stock for growth companies because the abnormally high growth rate of earn-
ings for the growth company is inconsistent with the assumptions of the infinite period
constant-growth DDM model. Subsequently, we modified the DDM model to evaluate compa-
nies with temporary supernormal growth. In the following sections, we discuss the other pres-
ent value of cash flow techniques assuming a similar set of scenarios.

11.4.9 Present Value of Operating Free Cash Flows

In this model, you are deriving the value of the total firm because you are discounting the op-
erating free cash flows prior to the payment of interest to the debt holders but after deducting
funds needed to maintain the firm’s asset base (capital expenditures). Also, because you are
discounting the total firm’s operating free cash flow, you would use the firm’s weighted aver-
age cost of capital \( \text{WACC} \) as your discount rate. Therefore, once you estimate the value of
the total firm, you subtract the value of debt, assuming your goal is to estimate the value of
the firm’s equity. The total value of the firm is equal to:

\[
V_j = \frac{X_n}{1 + \text{WACC}_j} = \sum_{t=1}^{n} \frac{OFCF_t}{(1 + \text{WACC}_j)^t} + \frac{OFCF_1(1 + g)}{(0.14 - 0.09)}
\]

where:
- \( V_j \) = value of Firm \( j \)
- \( n \) = number of periods assumed to be infinite
- \( OFCF_t \) = the firm’s operating free cash flow in Period \( t \)
- \( \text{WACC}_j \) = Firm \( j \)’s weighted average cost of capital

Similar to the process with the DDM, it is possible to envision this as a model that requires
estimates for an infinite period. Alternatively, if you are dealing with a mature firm whereby
its operating cash flows have reached a stage of stable growth, you can adapt the infinite
period constant growth DDM model as follows:

\[
V_j = \frac{OFCF_1}{\text{WACC}_j - g} = \sum_{t=1}^{n} \frac{OFCF_t}{(1 + \text{WACC}_j)^{t-1}}
\]

where:
- \( OFCF_1 \) = operating free cash flow in Period 1 equal to \( OFCF_0(1 + g) \)
- \( g \) = long-term constant growth rate of operating free cash flow

Alternatively, assuming that the firm is expected to experience several different rates of growth
for \( OFCF \), these estimates can be divided into three or four stages, as demonstrated with the
temporary supernormal dividend growth model. Similar to the dividend model, the analyst
must estimate the rate of growth and the duration of growth for each of these periods of
super-normal growth as follows:

<table>
<thead>
<tr>
<th>Year</th>
<th>Dividend Growth Rate</th>
</tr>
</thead>
<tbody>
<tr>
<td>1-3</td>
<td>25%</td>
</tr>
<tr>
<td>4-6</td>
<td>20%</td>
</tr>
<tr>
<td>7-9</td>
<td>15%</td>
</tr>
<tr>
<td>10 on</td>
<td>9%</td>
</tr>
</tbody>
</table>

The required rate of return for the stock (the company’s cost of equity) is 14 percent. There-
fore, the value equation becomes (Exhibit 11.3 presents it in a table):

\[
V_j = \frac{2.00(1.25)}{1.14} + \frac{2.00(1.25)^2}{(1.14)^2} + \frac{2.00(1.25)^3}{(1.14)^3} + \frac{2.00(1.25)^4}{(1.14)^4} + \frac{2.00(1.25)^5}{(1.14)^5} + \frac{2.00(1.25)^6}{(1.14)^6} + \frac{2.00(1.25)^7}{(1.14)^7} + \frac{2.00(1.25)^8}{(1.14)^8} + \frac{2.00(1.25)^9}{(1.14)^9} + \frac{2.00(1.25)^10}{(1.14)^10} + \frac{OFCF_{10}}{(1.14)^{10}}
\]

The computations in Exhibit 11.3 indicate that the total value of the stock is $94.36. As before,
you would compare this estimate of intrinsic value to the market price of the stock when de-
ciding whether to purchase the stock. The difficult part of the valuation is both estimating the
supernormal growth rates and determining how long each of the growth rates will last.

To summarize this section, the initial present value of cash flow stock valuation model con-
sidered was the dividend discount model (DDM). After explaining the basic model and the

derivation of its reduced form, we noted that the infinite period DDM cannot be applied to the valuation of stock for growth companies because the abnormally high growth rate of earnings for the growth company is inconsistent with the assumptions of the infinite period constant-growth DDM model. Subsequently, we modified the DDM model to evaluate companies with temporary supernormal growth. In the following sections, we discuss the other present value of cash flow techniques assuming a similar set of scenarios.

### 11.4.9 Present Value of Operating Free Cash Flows

In this model, you are deriving the value of the total firm because you are discounting the operating free cash flows prior to the payment of interest to the debt holders but after deducting funds needed to maintain the firm’s asset base (capital expenditures). Also, because you are discounting the total firm’s operating free cash flow, you would use the firm’s weighted average cost of capital (WACC) as your discount rate. Therefore, once you estimate the value of the total firm, you subtract the value of debt, assuming your goal is to estimate the value of the firm’s equity. The total value of the firm is equal to:

\[ V_j = \sum_{t=1}^{n} \frac{OCF_F_{t}}{(1 + WACC)\cdot t} \]

where:

- \( V_j \) = value of Firm \( j \)
- \( n \) = number of periods assumed to be infinite
- \( OCF_F_{t} \) = the firm’s operating free cash flow in Period \( t \). The detailed specification of operating free cash flow will be discussed in Chapter 14.
- \( WACC_j \) = Firm \( j \)’s weighted average cost of capital. The computation of the firm’s WACC will be discussed in Chapter 14.

Similar to the process with the DDM, it is possible to envision this as a model that requires estimates for an infinite period. Alternatively, if you are dealing with a mature firm whereby its operating cash flows have reached a stage of stable growth, you can adapt the infinite period constant growth DDM model as follows:

\[ V_j = \frac{OCF_F_{1}}{WACC_j - \delta_{OCF}} \]

where:

- \( OCF_F_{1} \) = operating free cash flow in Period 1 equal to \( OCF_F_{0}(1 + \delta_{OCF}) \)
- \( \delta_{OCF} \) = long-term constant growth rate of operating free cash flow

Alternatively, assuming that the firm is expected to experience several different rates of growth for \( OCF_F \), these estimates can be divided into three or four stages, as demonstrated with the temporary supernormal dividend growth model. Similar to the dividend model, the analyst must estimate the rate of growth and the duration of growth for each of these periods of super-normal growth as follows:

<table>
<thead>
<tr>
<th>Year</th>
<th>( OCF F ) Growth Rate</th>
</tr>
</thead>
<tbody>
<tr>
<td>1–4</td>
<td>20%</td>
</tr>
<tr>
<td>5–7</td>
<td>15</td>
</tr>
<tr>
<td>8–10</td>
<td>10</td>
</tr>
<tr>
<td>11 on</td>
<td>6</td>
</tr>
</tbody>
</table>

Therefore, the calculations would estimate the specific \( OCF_F \)'s for each year through Year 10 based on the expected growth rates, but you would use the infinite growth model estimate when the growth rate reached stability after Year 10. As noted, after determining the value of
the total firm \( V_f \), you must subtract the value of all nonequity items, including accounts payable, total interest-bearing debt, deferred taxes, and preferred stock, to arrive at the estimated value of the firm’s equity. This calculation is demonstrated in Chapter 14.

### 11.4.10 Present Value of Free Cash Flows to Equity

The third discounted cash flow technique deals with “free” cash flows to equity, which would be derived after operating free cash flows have been adjusted for debt payments (interest and principal). Also, these cash flows precede dividend payments to the common stockholder. Such cash flows are referred to as free because they are what is left after providing the funds needed to maintain the firm’s asset base (similar to operating free cash flow). They are specified as free cash flows to equity because they also adjust for payments to debt holders and to preferred stockholders.

Notably, because these are cash flows available to equity owners, the discount rate used is the firm’s cost of equity \( (k) \) rather than the firm’s WACC.

\[
V_j = \sum_{t=1}^{n} \frac{FCFE_t}{(1+k)^t}
\]

where:
- \( V_j \) = value of the stock of Firm \( j \)
- \( n \) = number of periods assumed to be infinite
- \( FCFE_t \) = the firm’s free cash flow to equity in Period \( t \). The detailed specification of free cash flow to equity is discussed in Chapter 14.

Again, how an analyst would implement this general model depends upon the firm’s position in its life cycle. That is, if the firm is expected to experience stable growth, analysts can use the infinite growth model. In contrast, if the firm is expected to experience a period of temporary supernormal growth, analysts should use the multistage growth model similar to the process used with dividends and for operating free cash flow.

### 11.5 Relative Valuation Techniques

In contrast to the various discounted cash flow techniques that attempt to estimate a specific value for a stock based on its estimated growth rates and its discount rate, the relative valuation techniques implicitly contend that it is possible to determine the value of an economic entity (i.e., the market, an industry, or a company) by comparing it to similar entities on the basis of several relative ratios that compare its stock price to relevant variables that affect a stock’s value, such as earnings, cash flow, book value, and sales. Therefore, in this section, we discuss the following relative valuation ratios: (1) price/earnings (P/E), (2) price/cash flow (P/CF), (3) price/book value (P/BV), and price/sales (P/S). We begin with the P/E ratio, also referred to as the earnings multiplier model, because it is the most popular relative valuation ratio. In addition, we will show that the P/E ratio can be directly related to the DDM in a manner that indicates the variables that affect the P/E ratio.

#### 11.5.1 Earnings Multiplier Model

As noted, many investors prefer to estimate the value of common stock using an earnings multiplier model. The reasoning for this approach recalls the basic concept that the value of any investment is the present value of future returns. In the case of common stocks, the returns that investors are entitled to receive are the net earnings of the firm. Therefore, one way investors can estimate value is by determining how many dollars they are willing to pay for a dollar of expected earnings (typically represented by the estimated earnings during the
following 12-month period or an estimate of “normalized earnings”). For example, if investors are willing to pay 10 times expected or “normal” earnings, they would value a stock they expect to earn $2 a share during the following year at $20. You can compute the prevailing earnings multiplier, also referred to as the price/earnings (P/E) ratio, as follows:

\[
\text{Earnings Multiplier} = \frac{\text{Price}}{\text{Earnings Ratio}} = \frac{\text{Current Market Price}}{\text{Expected 12-Month Earnings}}
\]

This computation of the current earnings multiplier (P/E ratio) indicates the prevailing attitude of investors toward a stock’s value. Investors must decide if they agree with the prevailing P/E ratio (that is, is the earnings multiplier too high or too low?) based upon how it compares to the P/E ratio for the aggregate market, for the firm’s industry, and for similar firms and stocks.

To answer this question in a defensible manner, we must consider what influences the earnings multiplier (P/E ratio) over time. For example, over time the aggregate stock market P/E ratio, as represented by the S&P Industrials Index, has varied from about six times earnings to about 30 times earnings. The infinite period dividend discount model can be used to indicate the variables that should determine the value of the P/E ratio as follows:

\[
P_t = \frac{D_t}{k - g}
\]

If we divide both sides of the equation by \( E_t \) (expected earnings during the next 12 months), the result is:

\[
\frac{P_t}{E_t} = \frac{D_t/E_t}{k - g}
\]

Thus, this model implies that the P/E ratio is determined by:

1. The expected dividend payout ratio (dividends divided by earnings)
2. The estimated required rate of return on the stock (\( k \))
3. The expected growth rate of dividends for the stock (\( g \))

As an example, if we assume a stock has an expected dividend payout of 50 percent, a required rate of return of 12 percent, and an expected growth rate for dividends of 8 percent, this would imply that the stock’s P/E ratio should be

\[
\frac{D/E}{= \frac{0.50}{0.12 - 0.08}} = \frac{0.50}{0.04} = 12.5
\]

When computing historical P/E ratios, the practice is to use earnings for the past 12 months rather than expected earnings. Although this practice of using historical earnings will influence the level, it demonstrates the changes in the P/E ratio over time. Although it may be appropriate to use historical P/E ratios for past comparison, we strongly believe that investment decisions should emphasize future or forward P/E ratios that use expected earnings.

In this formulation of the model, we use \( P \) rather than \( V \) (that is, the value is stated as the estimated price of the stock). Although the factors that determine the P/E are the same for growth companies, this formula cannot be used to estimate a specific value because: (1) these firms often do not have dividends, (2) the infinite growth rate assumption is not valid, and (3) the \((k - g)\) assumptions don’t apply.
Again, a small difference in either \( k \) or \( g \) or both will have a large impact on the earnings multiplier, as shown in the following three examples.

1. \( D/E = 0.50; k = 0.13; g = 0.08 \). (In this example, we assume a higher \( k \) for the stock.)

\[
P/E = \frac{0.50}{0.13 - 0.08} = \frac{0.50}{0.05} = 10
\]

2. \( D/E = 0.50; k = 0.12; g = 0.09 \). (In this example, we assume a higher \( g \) for the stock and the original \( k \).)

\[
P/E = \frac{0.50}{0.12 - 0.09} = \frac{0.50}{0.03} = 16.7
\]

3. \( D/E = 0.50; k = 0.11; g = 0.09 \). (In this example, we assume a fairly optimistic scenario where the \( k \) for the stock is only 11 percent and there is a higher expected growth rate of dividends of 9 percent.)

\[
P/E = \frac{0.50}{0.11 - 0.09} = \frac{0.50}{0.02} = 25
\]

As before, the spread between \( k \) and \( g \) is the main determinant of the size of the \( P/E \) ratio. Although the dividend payout ratio has an impact, we are generally referring to a firm’s long-run target payout, which is typically rather stable with little effect on year-to-year changes in the \( P/E \) ratio (earnings multiplier).

After estimating the earnings multiple, you would apply it to your estimate of earnings for the next year \( (E_t) \) to arrive at an estimated value. In turn, \( E_t \) is based on the earnings for the current year \( (E_0) \) and your expected growth rate of earnings. Using these two estimates, you would compute an estimated value of the stock and compare this estimated value to its market price.

Consider the following estimates for an example firm:

\[
D/E = 0.50 \\
k = 0.12 \\
g = 0.09 \\
E_0 = $2.00
\]

Using these estimates, you would compute an earnings multiple of

\[
P/E = \frac{0.50}{0.12 - 0.09} = \frac{0.50}{0.03} = 16.7
\]

Given current earnings \( (E_0) \) of $2.00 and a \( g \) of 9 percent, you would expect \( E_t \) to be $2.18. Therefore, you would estimate the value (price) of the stock as:

\[
V = 16.7 \times 2.18 = \$36.41
\]
As before, you would compare this estimated value of the stock to its current market price to decide whether you should invest in it. This estimate of value is referred to as a two-step process because it requires you to estimate future earnings \((E_t)\) and a \(P/E\) ratio based on expectations of \(k\) and \(g\). These two estimates are discussed in Chapter 14.

### 11.5.2 The Price/Cash Flow Ratio

The growth in popularity of the relative price/cash flow valuation ratio can be traced to concern over the propensity of some firms to manipulate earnings per share, whereas cash flow values are generally less prone to manipulation. Also, as noted, cash flow values are important in fundamental valuation (when computing the present value of cash flow), and they are critical when doing credit analysis where “cash is king.” The price to cash flow ratio is computed as follows:

\[
P/CF = \frac{P_t}{CF_{t+1}}
\]

where:
- \(P/CF\) = the price/cash flow ratio for Firm \(j\)
- \(P_t\) = the price of the stock in Period \(t\)
- \(CF_{t+1}\) = the expected cash flow per share for Firm \(j\)

Regarding what variables affect this valuation ratio, the factors are similar to the \(P/E\) ratio. Specifically, the main variables should be (1) the expected growth rate of the cash flow variable used, and (2) the risk of the stock as indicated by the uncertainty or variability of the cash flow series over time. The specific cash flow measure used will vary depending upon the nature of the company and industry and which cash flow specification (for example, operating cash flow or free cash flow) is the best measure of performance for this industry. An appropriate ratio can also be affected by the firm’s capital structure.

### 11.5.3 The Price/Book Value Ratio

The price/book value \((P/BV)\) ratio has been widely used for many years by analysts in the banking industry as a measure of relative value. The book value of a bank is typically considered a good indicator of intrinsic value because most bank assets, such as bonds and commercial loans, have a value equal to book value. This ratio gained in popularity and credibility as a relative valuation technique for all types of firms based upon a study by Fama and French (1992) that indicated a significant inverse relationship between \(P/BV\) ratios and excess rates of return for a cross section of stocks. The \(P/BV\) ratio is specified as follows:

\[
P/BV = \frac{P_t}{BV_{t+1}}
\]

where:
- \(P/BV\) = the price/book value ratio for Firm \(j\)
- \(P_t\) = the price of the stock in Period \(t\)
- \(BV_{t+1}\) = the estimated end-of-year book value per share for Firm \(j\)

As with other relative valuation ratios, it is important to match the current price with the future book value that is expected to prevail at the end of the year. The difficulty is that this future book value is not generally available. One can derive an estimate of the end-of-year

\[\text{While there has been a tendency to employ EBITDA as the proxy for cash flow, we do not recommend or encourage this because of the strong upward bias of this series compared to other cash flow measures, as noted in Chapter 10.}\]
To illustrate this process, consider the following example wherein you want to value the stock of a pharmaceutical company and you decide to employ the P/E relative valuation technique. As part of this analysis, you compare the P/E ratios for this firm over time (e.g., the last 15 years) to similar ratios for the S&P Industrials, the pharmaceutical industry, and specific competitors. This comparison indicates that the company’s P/E ratios are consistently larger than the other sets. Following this initial observation, the second part of the analysis considers whether the fundamental factors that affect the P/E ratio (i.e., the firm’s growth rate and its required rate of return) justify the higher P/E. A positive scenario would be that the firm had a historical and expected growth rate that was substantially above all the comparables and your risk analysis indicates it should have a lower required rate of return. This would indicate that the higher P/E ratio is clearly justified; the subsequent question that needs to be considered is, how much higher should the P/E ratio be? Alternatively, the negative scenario for this stock with a P/E ratio above most comparables would be if the company’s expected growth rate was equal to or lower than the industry’s and competitors while its required k was higher than for the industry and competitors. This set of conditions would signal a stock that is apparently overpriced, based on the fundamental factors that determine a stock’s P/E ratio.

In subsequent sections, we discuss how an analyst arrives at estimates for g and k, and we demonstrate the process in subsequent chapters. At this point, the reader should understand the overall process required by the relative valuation technique.

11.5.4 The Price/Sales Ratio

The price/sales (P/S) ratio has a volatile history. It was a favorite of Phillip Fisher (1984), a well-known money manager in the late 1950s, as well as his son Kenneth Fisher (1984) and Sanchek and Martin (1987). Recently, the P/S ratio has been suggested as useful by Martin Leibowitz (1997), a widely admired stock and bond portfolio manager. These advocates consider this ratio meaningful and useful for two reasons. First, they believe that strong and consistent sales growth is a requirement for a growth company. Although they note the importance of an above-average profit margin, they contend that the growth process must begin with sales. Second, given all the data in the balance sheet and income statement, sales information is subject to less manipulation than any other data item. The specific P/S ratio is

\[ \frac{P_t}{S_{t+1}} \]

where:

- \( P_t \) = the price to sales ratio for Firm j
- \( P_t \) = the price of the stock in Period t
- \( S_{t+1} \) = the expected sales per share for Firm j

Again, it is important to match the current stock price with the firm’s expected sales per share, which may be difficult to estimate for a large cross section of stocks. Two caveats are relevant to the price to sales ratio. First, this particular relative valuation ratio varies dramatically by industry. For example, the sales per share for retail firms, such as Kroger or Walmart, are typically much higher than sales per share for computer or microchip firms. The second consideration is the profit margin on sales. The point is, retail food stores have high sales per share, which will cause a low P/S ratio, which is encouraging until one realizes that these firms have low net profit margins. Therefore, your relative valuation analysis using the P/S ratio should be between firms in the same or similar industries.

11.5.5 Implementing the Relative Valuation Technique

To properly implement the relative valuation technique, it is essential not only to compare the various ratios but also to understand what factors affect each of the valuation ratios and, therefore, know why they should differ. The first step is to compare the valuation ratio over time (e.g., the P/E ratio) for a company to the comparable ratio for the market, for the stock’s industry, and to other stocks in the industry to determine how it compares—that is, is the firm’s P/E ratio similar to these other P/Es, or is it consistently at a premium or discount? Beyond knowing the overall relationship to the market, industry, and competitors, the real analysis is involved in understanding why the ratio has this relationship or why it should not have this relationship and the implications of this mismatch. Specifically, the second step is to explain the relationship. To do this, you need to understand what factors determine the specific valuation ratio and then compare these relevant factors for the stock being valued versus the same factors for the market, industry, and other stocks.
To illustrate this process, consider the following example wherein you want to value the stock of a pharmaceutical company and you decide to employ the P/E relative valuation technique. As part of this analysis, you compare the P/E ratios for this firm over time (e.g., the last 15 years) to similar ratios for the S&P Industrials, the pharmaceutical industry, and specific competitors. This comparison indicates that the company P/E ratios are consistently larger than the other sets. Following this initial observation, the second part of the analysis considers whether the fundamental factors that affect the P/E ratio (i.e., the firm’s growth rate and its required rate of return) justify the higher P/E. A positive scenario would be that the firm had a historical and expected growth rate that was substantially above all the comparables and your risk analysis indicates it should have a lower required rate of return. This would indicate that the higher P/E ratio is clearly justified; the subsequent question that needs to be considered is, how much higher should the P/E ratio be? Alternatively, the negative scenario for this stock with a P/E ratio above most comparables would be if the company’s expected growth rate was equal to or lower than the industry’s and competitors’ while its required k was higher than for the industry and competitors. This set of conditions would signal a stock that is apparently overpriced, based on the fundamental factors that determine a stock’s P/E ratio.

In subsequent sections, we discuss how an analyst arrives at estimates for g and k, and we demonstrate the process in subsequent chapters. At this point, the reader should understand the overall process required by the relative valuation technique.

11.6 Estimating the Inputs: The Required Rate of Return and the Expected Growth Rate of Valuation Variables

This section deals with estimating two inputs that are critical to the valuation process irrespective of which approach or technique is being used: the required rate of return (k) and the expected growth rate of earnings and other valuation variables—that is, book value, cash flow, sales, and dividends.

We will review these factors and discuss how the estimation of these variables differs for domestic versus foreign securities. Although the valuation procedure is the same for securities around the world, k and g differ among countries. Therefore, we will review the components of the required rate of return for U.S. securities and then consider the components for foreign securities. Subsequently, we consider the estimation of the growth rate of earnings, cash flow, and dividends for domestic stocks and then for foreign stocks.

11.6.1 Required Rate of Return (k)

This discussion reviews the determinants of the nominal required rate of return on an investment, including a consideration of factors for non-U.S. markets. This required rate of return will be the discount rate for most cash flow models and affects all the relative valuation techniques. There is a difference in the discount rate when you are employing the present value of operating free cash flow technique because, as noted, it uses the weighted average cost of capital (WACC). Notably, the cost of equity is a critical input to estimating the firm’s WACC.

Recall that three factors influence an equity investor’s required rate of return (k):

1. The economy’s real risk-free rate (RRFR)
2. The expected rate of inflation (I)
3. A risk premium (RP)

The Economy’s Real Risk-Free Rate This is the absolute minimum rate that an investor should require. It depends on the real growth rate of the investor’s home economy because
The Expected Rate of Inflation

Investors are interested in real rates of return that will allow them to increase their rate of consumption. Therefore, if investors expect a given rate of inflation, they should increase their required nominal risk-free rate of return ($NRFR$) to reflect any expected inflation as follows:

$$NRFR = \left[\frac{1 + RRF}{1 + E(I)}\right] - 1$$

where:

$$E(I) = \text{expected rate of inflation}$$

The two factors that determine the $NRFR$ affect all investments, from U.S. government securities to highly speculative land deals. Investors who hope to calculate security values accurately must carefully estimate the expected rate of inflation. Not only does the $NRFR$ affect all investments, but also, as shown in Chapter 1, its extreme volatility due to changes in expected inflation makes its estimation difficult.

The Risk Premium

The risk premium ($RP$) causes differences in the required rates of return among alternative investments that range from government bonds to corporate bonds to common stocks. The $RP$ also explains the difference in the expected return among securities of the same type. For example, this is the reason corporate bonds with different ratings of Aaa, Aa, or A have different yields, and why different common stocks have widely varying $P/E$ ratios despite similar growth expectations.

In Chapter 1, we noted that investors demand a risk premium because of the uncertainty of returns expected from an investment. A measure of this uncertainty of returns was the dispersion of expected returns. We suggested several internal factors that influence a firm’s variability of returns, such as its business risk, financial risk, and liquidity risk. We noted that securities of foreign firms or of domestic companies with significant foreign sales and earnings (e.g., Coca-Cola and McDonald’s) have additional risk factors, including exchange rate risk and country (political) risk.

Changes in the Risk Premium

Because different securities (e.g., government bonds and common stocks) have different patterns of returns and different guarantees to investors, we expect their risk premiums to differ. In addition, a fact that is less recognized is that the risk premiums for the same securities can change over time. For example, Exhibit 11.4 shows the spread between the yields to maturity for Aaa-rated credit bonds and Baa-rated credit bonds from 1973 through 2010. This yield spread, or difference in yield, is a measure of the risk premium for investing in higher-risk bonds (Baa) compared to low-risk bonds (Aaa). As shown, the yield spread varied from 0.42 percent to 6.15 percent (from less than one-half of 1 percent to over 6 percent).

Exhibit 11.5 contains a plot of the ratio of the yields for the same period, which indicates the percentage risk premium of Baa bond yields compared to Aaa bond yields. We consider this because you might expect a larger difference in yield between Baa and Aaa bonds if Aaa bonds are yielding 12 percent rather than 6 percent. The yield ratio in Exhibit 11.5 adjusts for this size difference. This shows that even adjusting for the yield level difference, the risk premium varies from about 1.06 to 3.21—a 6 percent premium to a 221 percent premium over the base yield on Aaa bonds. This significant change in the credit risk premium over time occurs because either investors perceive a change in the level of risk of Baa bonds compared to Aaa bonds or there is a change in the amount of return that investors require to accept the same risk differential. In either case, this change in the risk premium for a set of
assets in either basis points or percent difference in yields implies a change in the slope of the security market line (SML), as demonstrated in Chapter 1.

In Chapter 12, we discuss the controversy regarding estimates of the equity market risk premium and possible changes in the long-run equity risk premium.

### 11.6.2 Estimating the Required Return for Foreign Securities

Our discussion of the required rate of return for investments has been limited to the domestic market. Although the basic valuation model and its variables are the same around the world, there are significant differences in the values for specific variables. This section points out where these differences occur.

**Foreign Real RFR** Because the RRFR in other countries should be determined by the real growth rate within the particular economy, the estimated rate can vary substantially among countries due to differences in an economy’s real growth rate. An example of differences in the real growth rate of gross domestic product (GDP) can be seen from growth expectations for 2011 real GDP contained in the *IMF World Economic Outlook*, as shown in Exhibit 11.6. There is a range of growth estimates for 2011 of about 2.2 percent (that is, 2.9 percent for the United States compared to only 0.7 percent for Japan). This difference in the expected growth rates of real GDP implies a substantial difference in the RRFR for these countries.  

**Inflation Rate** To estimate the NRFR for a country, you must also estimate its expected rate of inflation and adjust the NRFR for this expectation. Again, this rate of inflation typically

When investing globally, you also must estimate exchange rate risk, which is the additional uncertainty of returns caused by changes in the exchange rates for the currency of another country. This uncertainty can be small for a U.S. investor in a country such as Hong Kong because the currency is pegged to the U.S. dollar. In contrast, in some countries, substantial volatility in the exchange rate over time can mean significant differences in the domestic return for the country compared to the return in U.S. dollars.

The level of volatility for the exchange rate differs between countries. The greater the uncertainty (implied by the volatility) regarding future changes in the exchange rate, the larger the exchange rate risk for the country.

Recall that country risk arises from unexpected events in a country, such as upheavals in its political or economic environment. Examples of political disruptions occurred in several Middle Eastern countries (e.g., Libya, Syria) during 2011 when there was substantial turmoil about the political leadership in these countries. Such political unrest or a change in the economic environment creates uncertainties that increase the risk of investments in these countries. Before investing in such countries, investors must evaluate the additional returns they should require to accept this increased political and economic uncertainty. Thus, when estimating required rates of return on foreign investments, you must assign a unique risk premium for each country.

### 11.6.3 Expected Growth Rates

After arriving at a required rate of return, the investor must estimate the growth rate of sales, cash flows, earnings, and dividends because the alternative valuation models for common stock depend heavily on good estimates of growth ($g$) for these variables. The initial procedure we describe here is a brief summary of the presentation in Chapter 10, where we used financial ratios to measure a firm’s growth potential. Subsequently, we discuss the use of historical growth rates as an input to the estimate.

#### Estimating Growth from Fundamentals

The growth rate of dividends is determined by the growth rate of earnings and the proportion of earnings paid out in dividends (the payout ratio). Over the short run, dividends can grow faster or slower than earnings if the firm changes its payout ratio. Specifically, if a firm’s earnings grow at 6 percent a year and it pays out exactly 50 percent of earnings in dividends, then the firm’s dividends will likewise grow at 6 percent a year. Alternatively, if a firm’s earnings grow at 6 percent a year and the firm increases its payout, then during the period when the payout ratio increases, dividends will grow faster than earnings. In contrast, if the firm reduces its payout ratio, dividends will grow...

varies substantially among countries. The data show that the expected rate of inflation during 2011 varied from 0.2 percent in Japan to 3.9 percent in the United Kingdom. Assuming equal real growth, this inflation estimate implies a difference in the nominal required rate of return between Japan and the United Kingdom of 3.7 percent. Such a difference in $k$ can have a substantial impact on estimated values, as demonstrated earlier. Again, you must make a separate estimate for each individual country in which you are evaluating securities.

To demonstrate the combined impact of differences in real growth and expected inflation, Exhibit 11.6 shows the results of the following computation for four countries and the Euro Area based on the year 2011 estimates:

$$NRFR = [(1 + \text{Real Growth}) \times (1 + \text{Expected Inflation})] - 1$$

Given the differences between countries in the two components, the range in the $NRFR$ of 4.7 percent is not surprising (5.6 percent for the United Kingdom vs. 0.9 percent for Japan). As demonstrated earlier, such a difference in $k$ will have a significant impact on the value of an investment.

**Risk Premium** You must also derive an equity risk premium for the investments in each country. Again, the five risk components differ substantially between countries: business risk, financial risk, liquidity risk, exchange rate risk, and country risk. Business risk can vary because it is a function of the variability of economic activity within a country and of the operating leverage used by firms within the country. Firms in different countries assume significantly different financial risk, as well. For example, Japanese firms use substantially more financial leverage than U.S. or U.K. firms. Regarding liquidity risk, the U.S. capital markets are acknowledged to be the most liquid in the world, with Japan and the United Kingdom being close behind. In contrast, some emerging markets are quite illiquid, and in such cases investors need to add a significant liquidity risk premium.
slower than earnings for a period of time. Because there is a limit to how long such a difference in growth rates (faster or slower) can continue, most investors assume that the long-run dividend payout ratio is fairly stable. Therefore, our analysis of the growth rate of dividends concentrates on an analysis of the growth rate of equity earnings. Also, as will be shown in Chapter 14, equity earnings are the major factor driving the operating cash flows or the free cash flows for the firm.

When a firm retains earnings and acquires additional assets, if it earns some positive rate of return on these additional assets, the total earnings of the firm will increase because its asset base is larger. Therefore, as discussed earlier, how rapidly a firm’s earnings increase depends on: (1) the proportion of earnings it retains and reinvests in new assets, and (2) the rate of return it earns on these new assets. Specifically, the growth rate \( g \) of equity earnings (that is, earnings per share) without any external financing is equal to the percentage of net earnings retained (the retention rate, which equals 1 – the payout ratio) times the rate of return on equity capital.

\[
g = \text{Retention Rate} \times \text{Return on Equity}
\]

Therefore, a firm can increase its growth rate by increasing its retention rate (reducing its payout ratio) and investing these added funds at its historic ROE. Alternatively, the firm can maintain its retention rate but increase its ROE. For example, if a firm retains 50 percent of net earnings and consistently has a ROE of 10 percent, its net earnings will grow at the rate of 5 percent a year, as follows:

\[
g = 0.50 \times 0.10 = 0.05
\]

If, however, the firm increases its retention rate to 75 percent and is able to invest these additional funds in projects that likewise earn 10 percent, its growth rate will increase to 7.5 percent, as follows:

\[
g = 0.75 \times 0.10 = 0.075
\]

If, instead, the firm continues to reinvest 50 percent of its earnings but is able to earn a higher rate of return on these investments, say 15 percent, it can likewise increase its growth rate, as follows:

\[
g = 0.50 \times 0.15 = 0.075
\]

Breakdown of ROE

Although the retention rate is a management decision, changes in the firm’s ROE result from changes in its operating performance or its financial leverage. As discussed in Chapter 10, we can divide the ROE ratio into three components:

\[
\text{ROE} = \frac{\text{Net Income}}{\text{Sales}} \times \frac{\text{Sales}}{\text{Total Assets}} \times \frac{\text{Total Assets}}{\text{Equity}}
\]

\[
= \text{Profit Margin} \times \text{Total Asset Turnover} \times \text{Financial Leverage}
\]

This breakdown allows us to consider the three factors that determine a firm’s ROE. Because it is a multiplicative relationship, an increase in any of the three ratios will cause an increase in ROE.

You will recall from Chapter 10 (Exhibit 10.7) that it is possible to employ an extended DuPont system that involves eight ratios. For purposes of this discussion, the three ratios indicate the significant factors and differences among countries.

The arithmetic or geometric average technique involves computing the annual percentage change and then computing either the simple arithmetic average or the geometric average of these values for the alternative periods. As you will recall from the discussion in Chapter 3, the arithmetic average will always be a higher value than the geometric average (except when the annual values are constant) and the difference between the arithmetic and geometric average values will increase with volatility. As noted previously, we generally prefer the geometric mean because it provides the average annual compound growth rate.

The linear regression model goes well with the suggested time-series plot and is as follows:

\[ \text{EPS}_t = a + bt \]

where:

- \( \text{EPS}_t \) = earnings per period in Period \( t \) (where \( t \) goes from 1 to \( n \))
- \( b \) = the coefficient that indicates the average absolute change in the series during the period

It would be very informative to superimpose this regression line on the time-series plot because it would provide insights on changes in absolute growth.

The log-linear model considers that the series might be better described in terms of a constant growth rate. This model is as follows:

\[ \ln(\text{EPS}_t) = a + bt \]

where:

- \( \ln(\text{EPS}_t) \) = the natural logarithm of earnings per share in Period \( t \)
- \( b \) = the coefficient that indicates the average percentage change in the series during the period

The analysis of these historical growth rates both visually with the time-series graph and the alternative calculations should provide you with significant insights into the trend of the growth rates as well as the variability of the growth rates over time. As discussed in Chapter 10 and demonstrated in Appendix 10C, this could provide information on the unit’s business risk with the analysis of sales and EBIT growth.

11.6.4 Estimating Dividend Growth for Foreign Stocks

The underlying factors that determine the growth rates for foreign stocks are similar to those for U.S. stocks, but the value of the equation’s components may differ substantially from what is common in the United States. The differences in the retention rate or the components of ROE result from differences in accounting practices as well as alternative management performance or philosophy. Therefore, it is important to determine the different values for the ratios and the reasons for the differences.

Retention Rates

The retention rates for foreign corporations differ within countries, but differences also exist among countries due to differences in the countries’ investment opportunities. As an example, firms in Japan have a higher retention rate than firms in the United States, whereas the rate of retention in France is much lower. Therefore, you need to examine the retention rates for a number of firms in a country as a background for estimating the standard retention rate within a country.

Net Profit Margin

The net profit margin of foreign firms can differ because of different accounting conventions between countries. As noted in Chapter 10, foreign accounting rules allow firms to recognize revenue and allocate expenses differently from U.S. firms. For example, German firms are allowed to build up large reserves for various reasons. As a result, they report low earnings for tax purposes. Also, different foreign depreciation practices require adjustment of earnings and cash flows.

Estimating Growth Based on History

Although the authors have a strong bias in favor of using the fundamentals to estimate future growth, which involves estimating the components of ROE, we also believe in using all the information available to make this critical estimate. Therefore, we suggest that analysts also consider the historical growth rate of sales, earnings, cash flow, and dividends and consider not only the different rates of growth, but also the variability in the growth pattern over time for these series.

Although we demonstrate these computations for the market, for an industry, and for a company in subsequent chapters, the following discussion considers some suggestions on alternative calculations. In terms of the relevant period to consider, one is struck by the cliché “more is better” as long as you recognize that “recent is relevant.” Specifically, about 20 years of annual observations would be ideal, but it is important to consider subperiods as well as the total period—that is, 20 years, two 10-year periods, and four 5-year periods would indicate the overall growth rate but also would indicate if there were any changes in the growth rate during the critical recent periods.

The specific measurement can be done using one or more of three techniques: (1) arithmetic or geometric average of annual percentage changes, (2) linear regression models, and (3) log-linear regression models. Irrespective of the measurement techniques used, we strongly encourage a time-series plot of the annual percentage changes.

\[ \text{In Chapter 13, we discuss a study that analyzes why and how alternative industries differ regarding the return on assets and the two components of ROA.} \]
The arithmetic or geometric average technique involves computing the annual percentage change and then computing either the simple arithmetic average or the geometric average of these values for the alternative periods. As you will recall from the discussion in Chapter 3, the arithmetic average will always be a higher value than the geometric average (except when the annual values are constant) and the difference between the arithmetic and geometric average values will increase with volatility. As noted previously, we generally prefer the geometric mean because it provides the average annual compound growth rate.

The linear regression model goes well with the suggested time-series plot and is as follows:

\[ EPS_t = a + bt \]

where:
- \( EPS_t \) = earnings per period in Period \( t \)
- \( t \) = year \( t \) where \( t \) goes from 1 to \( n \)
- \( b \) = the coefficient that indicates the average absolute change in the series during the period

It would be very informative to superimpose this regression line on the time-series plot because it would provide insights on changes in absolute growth.

The log-linear model considers that the series might be better described in terms of a constant growth rate. This model is as follows:

\[ \ln(EPS_t) = a + bt \]

where:
- \( \ln(EPS_t) \) = the natural logarithm of earnings per share in Period \( t \)
- \( b \) = the coefficient that indicates the average percentage change in the series during the period

The analysis of these historical growth rates both visually with the time-series graph and the alternative calculations should provide you with significant insights into the trend of the growth rates as well as the variability of the growth rates over time. As discussed in Chapter 10 and demonstrated in Appendix 10C, this could provide information on the unit’s business risk with the analysis of sales and EBIT growth.

### 11.6.4 Estimating Dividend Growth for Foreign Stocks

The underlying factors that determine the growth rates for foreign stocks are similar to those for U.S. stocks, but the value of the equation’s components may differ substantially from what is common in the United States. The differences in the retention rate or the components of \( ROE \) result from differences in accounting practices as well as alternative management performance or philosophy. Therefore, it is important to determine the different values for the ratios and the reasons for the differences.

**Retention Rates** The retention rates for foreign corporations differ within countries, but differences also exist among countries due to differences in the countries’ investment opportunities. As an example, firms in Japan have a higher retention rate than firms in the United States, whereas the rate of retention in France is much lower. Therefore, you need to examine the retention rates for a number of firms in a country as a background for estimating the standard retention rate within a country.

**Net Profit Margin** The net profit margin of foreign firms can differ because of different accounting conventions between countries. As noted in Chapter 10, foreign accounting rules allow firms to recognize revenue and allocate expenses differently from U.S. firms. For example, German firms are allowed to build up large reserves for various reasons. As a result, they report low earnings for tax purposes. Also, different foreign depreciation practices require adjustment of earnings and cash flows.
Total Asset Turnover
Total asset turnover can likewise differ among countries because of different accounting conventions on the reporting of asset values at cost or market values. For example, in Japan, a large part of the market values for some firms comes from their real estate holdings and their common stock investments in other firms. These assets are reported at cost, which typically substantially understates their true value. This also means that the total asset turnover ratio for these firms is substantially overstated.

This ratio will also be impacted by leases that are not capitalized on the balance sheet—that is, if leases are not capitalized, both assets and liabilities are understated.

Total Asset/Equity Ratio
This ratio, a measure of financial leverage, differs among countries because of differences in economic environments, tax laws, management philosophies regarding corporate debt, and accounting conventions. In several countries, the attitude toward debt is much more liberal than in the United States. A prime example is Japan, where debt as a percentage of total assets is almost 50 percent higher than this ratio in the United States. Notably, most corporate debt in Japan entails borrowing from banks at fairly low rates of interest. Therefore, balance sheet debt ratios may be higher in Japan than in the United States or other countries; but, because of the lower interest rates in Japan, the fixed-charge coverage ratios, such as the times interest earned ratio, might be similar to those in other countries. The point is, it is important to consider the several cash flow financial risk ratios along with the balance sheet debt ratios.

Consequently, when analyzing a foreign stock market or an individual foreign stock that involves estimating the growth rate for earnings and dividends, you must consider the three components of the ROE just as you would for a U.S. stock but recognize that the financial ratios for foreign firms can differ from those of U.S. firms, as discussed in Chapter 10 references. Subsequent chapters on valuation applied to the aggregate market, to various industries, and to companies contain examples of these differences.

### SUMMARY

- As an investor, you want to select investments that will provide a rate of return that compensates you for your time, the expected rate of inflation, and the risk involved. To help you find these investments, this chapter considers the theory of valuation by which you derive the value of an investment using your required rate of return. We consider the two investment decision processes, which are the top-down, three-step approach and the bottom-up, stockpicking approach. Although either process can provide abnormal positive returns if the analyst is superior, we feel that a preferable approach is the top-down approach, in which you initially consider the aggregate economy and market, then examine alternative global industries, and finally analyze individual firms and their stocks.

- We apply the valuation theory to a range of investments, including bonds, preferred stock, and common stock. Because the valuation of common stock is more complex and difficult, we suggest two alternative approaches (the present value of cash flows and the relative valuation approach) and several techniques for each of these approaches. Notably, these are not competitive approaches, and we suggest that both approaches be used. Although we suggest using several different valuation models, the investment decision rule is always the same: If the estimated intrinsic value of the investment is greater than the market price, you should buy the investment or hold it if you own it; if the estimated intrinsic value of an investment is less than its market price, you should not invest in it and if you own it, you should sell it.

- We conclude with a review of factors that you need to consider when estimating the value of stock with either approach—your required rate of return on an investment and the growth rate of earnings, cash flow, and dividends. Finally, we consider some unique factors that affect the application of these valuation models to foreign stocks.
1. What is the value to you of a 9 percent coupon bond with a par value of $10,000 that matures in 10 years if you require a 7 percent return? Use semiannual compounding.

2. What would be the value of the bond in Problem 1 if you required an 11 percent rate of return?

3. The preferred stock of the Clarence Radiology Company has a par value of $100 and a $9 dividend rate. You require an 11 percent rate of return on this stock. What is the maximum price you would pay for it? Would you buy it at a market price of $96?

4. The Baron Basketball Company (BBC) earned $10 a share last year and paid a dividend of $6 a share. Next year, you expect BBC to earn $11 and continue its payout ratio. Assume that you expect to sell the stock for $132 a year from now. If you require 12 percent on this stock, how much would you be willing to pay for it?

5. Given the expected earnings and dividend payments in Problem 4, if you expect a selling price of $110 and require an 8 percent return on this investment, how much would you pay for the BBC stock?

6. Over the long run, you expect dividends for BBC in Problem 4 to grow at 8 percent and you require 11 percent on the stock. Using the infinite period DDM, how much would you pay for this stock?

7. Based on new information regarding the popularity of basketball, you revise your growth estimate for BBC to 9 percent. What is the maximum

8. The Shamrock Dogfood Company (SDC) has consistently paid out 40 percent of its earnings in dividends. The company’s return on equity is 16 percent. What would you estimate as its dividend growth rate?

9. Given the low risk in dog food, your required rate of return on SDC is 13 percent. What P/E ratio would you apply to the firm’s earnings?

10. What P/E ratio would you apply if you learned that SDC had decided to increase its payout to 50 percent? (Hint: This change in payout has multiple effects.)

11. Discuss three ways a firm can increase its ROE. Make up an example to illustrate your discussion.

12. It is widely known that grocery chains have low profit margins—on average, they earn about 1 percent on sales. How would you explain the fact that their ROE is about 12 percent? Does this seem logical?

13. Compute a recent five-year average of the following ratios for three companies of your choice (attempt to select diverse firms):

14. You have been reading about the Madison Computer Company (MCC), which currently retains 90 percent of its earnings ($5 a share this year). It earns an ROE of almost 30 percent.

15. Gentry Can Company’s (GCC) latest annual dividend of $1.25 a share was paid yesterday and maintained its historic 7 percent annual rate of growth. You plan to purchase the stock today because you believe that the dividend growth rate will increase to 8 percent

THOMSON REUTERS

Use the Thomson One—Business School Edition Online Database to answer the following questions.

1. Using Ford (F), General Electric (GE), McDonald’s (MCD), Nike (NKE), and Walgreens (WAG), find the five-year estimate for net income growth (LTG) dividend yield, P/E ratio, Price/Cash Flow ratio, and Price/Book Value ratio. Do a spreadsheet listing of each these values for each company, and briefly comment on the differences between each item.

2. Assume that the five-year estimates for net income growth for General Electric, McDonald’s, and Walgreens are the same as their dividend growth rates—that is, earnings and dividends grow at the same rate.
a. For each of these three firms, estimate the dollar amount of dividends per share over each of the next five years.
b. Find the present value of each dividend stream from Part a. Use a discount rate of 10 percent for each firm. (This is a simplification; in reality, we would need to estimate the required rate of return for each firm.)
c. For each firm, compare its current stock price with the estimated present value of its dividends over the next five years. Given our assumptions, what proportion of the stock price arises from cash flows beyond the next five years?

3. For each of the five firms, using the beta provided in the database, compute the stock’s required return on equity (k) using the following SML equation.

\[ E(R) = RFR + \beta_i (R_m - RFR) \]
\[ = 0.05 + \beta_i (0.09 - 0.05) \]

4. Knowing that a stock’s P/E ratio is mainly determined by k and g, show in a table the following for each of the five stocks:

<table>
<thead>
<tr>
<th>Stock</th>
<th>*Current Forward P/E</th>
<th>LTG</th>
<th>k</th>
</tr>
</thead>
</table>

*Forward P/E = \( \frac{\text{Current P}}{\text{EPS}_{t+1}} \)

Comment on the stocks that appear to be relatively high priced or low priced and why you labeled them as such.
Derivation of Constant-Growth Dividend Discount Model (DDM)

The basic model is:

\[ P_0 = \frac{D_1}{(1+k)} + \frac{D_2}{(1+k)^2} + \frac{D_3}{(1+k)^3} + \cdots + \frac{D_n}{(1+k)^n} \]

where:
- \( P_0 \) = current price
- \( D_i \) = expected dividend in Period \( i \)
- \( k \) = required rate of return on Asset \( j \)

If growth rate \( (g) \) is constant,

\[ P_0 = \frac{D_0(1+g)^1}{(1+k)} + \frac{D_0(1+g)^2}{(1+k)^2} + \cdots + \frac{D_0(1+g)^n}{(1+k)^n} \]

This can be written as:

\[ P_0 = D_0 \left[ \frac{(1+g)}{(1+k)} + \frac{(1+g)^2}{(1+k)^2} + \cdots + \frac{(1+g)^n}{(1+k)^n} \right] \]

Multiply both sides of the equation by \( \frac{1+k}{1+g} \)

\[ \frac{(1+k)}{(1+g)} P_0 = D_0 \left[ 1 + \frac{(1+g)}{(1+k)} + \frac{(1+g)^2}{(1+k)^2} + \cdots + \frac{(1+g)^n}{(1+k)^n} \right] \]

Subtract the previous equation from this equation:

\[ \left[ \frac{(1+k)}{(1+g)} - 1 \right] P_0 = D_0 \left[ 1 - \frac{(1+g)^n}{(1+k)^n} \right] \]

Assuming \( k > g \), as \( n \to \infty \), the term in brackets on the right side of the equation goes to 1, leaving:

\[ \left[ \frac{(1+k) - (1+g)}{(1+g)} \right] P_0 = D_0 \]

This simplifies to:

\[ \left[ \frac{(1+k-1-g)}{(1+g)} \right] P_0 = D_0 \]

which equals:

\[ \left[ \frac{k-g}{1+g} \right] P_0 = D_0 \]

This equals:

\( (k-g)P_0 = D_0(1+g) \)
\( D_0(1+g) = D_1 \)

so:

\[ (k-g)P_0 = D_1 \]
\[ P_0 = \frac{D_1}{k-g} \]

Remember, this model assumes:
- A constant growth rate
- An infinite time period
- The required return on the investment \( (k) \) is greater than the expected growth rate \( (g) \).
In Part 3, we considered the basic valuation principles and practices applied to all securities and how this was applied to the global asset allocation decision. In Part 4, we apply these same valuation principles and practices to the analysis and management of common stocks. The objective is to be in position to make the critical risk-return decision at the market-industry-company stock level.

Your will recall from Chapter 11 that successful investment requires several steps, beginning with a valuation of the aggregate economy and market and the examination of various industries and concluding with the analysis of individual companies and their securities. Globalization of the capital markets has definitely complicated this process wherein it is now necessary to consider markets on a worldwide basis, followed by the analysis of world industries that involve numerous, complex foreign companies.

In Chapter 12, we begin the three-step, top-down approach and discuss how to analyze the aggregate stock market using the two general valuation approaches introduced in Chapter 11— the present value of cash flow models and the relative valuation ratios. In Chapter 13, we again demonstrate these two approaches to the valuation of an industry.

Chapter 14 begins with a discussion of the difference between a company and its stock. In many instances, the common stock of a very fine company (possibly a true growth company) may not be a good investment, which is why we emphasize that company analysis and stock selection are two separate but dependent activities. Once again, the analysis procedure is built on the two valuation approaches employed for the market and alternative industries. We also consider other techniques, such as economic value added (EVA), that provide insights regarding the economic success of a firm and its management. The overall goal of this procedure is to select one of the best companies in a superior industry during a favorable market environment.

It was noted in Chapter 11 that it is not feasible to use the standard dividend discount model to value the stock of true growth companies. Therefore, in Chapter 14 we discuss several valuation models that have been specifically developed for the analysis and valuation of growth companies.

Throughout this section, we refer back to the semistrong efficient market hypothesis. Recall that, although many studies support this hypothesis, there is a growing literature dealing with anomalies related to this hypothesis. Therefore, in this section we provide a consistent and justifiable valuation process that can be used to find undervalued securities. You should never forget that the output of alternative valuation models is only as good as the estimated inputs and the superior analyst is the one who provides (1) the best estimates of the required rate of return on a security based upon its risks, and (2) the expected growth rate of future cash flows.

Chapter 15 deals with technical analysis, an alternative or supplement to the fundamental approach discussed in the prior chapters. Rather than estimating value based on fundamental variables, the technical analyst believes that it is possible to project future stock price movements based on past stock price changes or other stock market data. Various techniques used by technical analysts for U.S. and world markets are discussed and demonstrated.

Chapter 16 deals with equity portfolio management strategies. We begin with a general discussion of passive versus active management styles. This is followed by a specific discussion of indexing, including the selection of an appropriate benchmark index, and the various methods of index portfolio investing used in practice. The concept of tracking error is introduced as a means of assessing how well an investor has replicated the benchmark portfolio.

The overview of active equity portfolio management strategies includes a discussion of how one constructs a portfolio that reflects the client’s risk-return objectives and constraints from three different perspectives: fundamental analysis (e.g., asset class and sector rotation, stock under- and overvaluation), technical analysis (e.g., overreaction, price momentum), and anomaly and attribute analysis (e.g., earnings momentum, firm size). In this discussion, we pay special attention to the conceptual and practical differences between forming portfolios based on both value-oriented and growth-oriented investment styles. Notably, all of these approaches should consider global opportunities.

We conclude Chapter 16 with a discussion of how the equity portfolio management decision fits into the investor’s overall asset allocation strategy. After discussing the integrated approach to asset allocation, we examine strategic, tactical, and insured allocation strategies. Finally, we present the basic intuition for how investors can use derivative instruments (such as futures and option contracts) to alter the risk and return characteristics of their equity portfolios.

CHAPTER 12
Macroanalysis and Microvaluation of the Stock Market

After you read this chapter, you should be able to answer the following questions:

- What are the expected and the empirical relationships between economic activity and security markets?
- What is the macroeconomic approach to estimating future market returns?
- What are the major macroeconomic techniques used to project the securities market?
- What is the leading economic indicator approach? What are its uses and shortcomings?
- What are the expected and the empirical relationships between the growth of the money supply and stock prices?
- What is meant by excess liquidity, and how is it measured?
- What is the effect of monetary policy on stock prices in the United States and around the world?
- What are the expected and the empirical relationships among inflation, interest rates, and bond prices?
- What are the expected and the empirical relationships between inflation and stock prices?
- How do the basic valuation variables differ among countries?
- What factors should be considered when analyzing the outlook for a foreign economy and its stock and bond market?
- What is the asset allocation procedure for a global portfolio?
- For a world asset allocation, what is meant by normal weighting, underweighting, and over weighting?
- How do we apply the dividend discount model (DDM) to the valuation of the aggregate stock market?
- What would be the prevailing value of the market as represented by the S&P Industrials Index based upon the reduced form DDM?
- What would be the prevailing value of the aggregate stock market based upon the present value of free cash flow to equity (FCFE) model?
- What two components are involved in the two-part valuation procedure?
- Given the two components in the valuation procedure, which is more volatile?
- What steps are involved in estimating the earnings per share for an aggregate market series?
- What variables affect the aggregate operating profit margin, and how do they affect it?
- What variables determine the level and changes in the market earnings multiplier?
- What has happened to the values for the other relative valuation ratios—that is, the P/BV, P/CF, and P/S ratios?
- What additional factors must be considered when you apply this microanalysis approach to the valuation of stock markets around the world?

12.1 The Components of Market Analysis

In Chapter 11, we introduced the top-down, three-step market-industry-company investment process. This chapter is concerned with the market analysis portion of this process. In turn, this market analysis has two components: (1) the macroanalysis of the relationship between the aggregate securities markets and the aggregate economy, and (2) the specific microvaluation of the stock market employing the valuation approaches introduced in Chapter 11.

The macroanalysis is in response to the belief that security markets reflect what is expected to go on in the economy, because the value of an investment is determined by its expected cash
flows and its expected required rate of return (i.e., its discount rate). Clearly, both of these valuation factors are influenced by the aggregate economic environment. The objective is to consider what specific variables and economic series should be considered when attempting to project future market movements. This macroeconomy and market analysis provides important insights for our subsequent industry and company analysis.

The microanalysis builds on these macro insights by deriving a specific valuation for the market using the approaches discussed. The result is an estimated intrinsic value for a market indicator series, leading to the decision rule wherein this intrinsic value is compared to the current market value and an appropriate decision regarding the aggregate U.S. stock market. Specifically, the decision is how to weight the U.S. stock market in a global asset portfolio—that is, underweight, market weight, or overweight the U.S. stock market depending on whether it is currently overvalued, properly valued, or undervalued.

### 12.2 Macromarket Analysis

Fluctuations in security markets are related to changes in expectations for the aggregate economy. The prices of government and investment-grade corporate bonds are determined by the level of interest rates, which is influenced by overall economic activity and Federal Reserve policy. Aggregate stock prices reflect investor expectations about corporate performance in terms of earnings, cash flows, and the required rate of return by investors. All of these expectations are heavily impacted by the economic outlook.

Given the expected relationship between security markets and the economy, this section has four subsections: (1) documentation of the relationship between the economy and stock prices, (2) presentation of several economic series that provide specific insights related to the stock market, (3) specific discussion of the macroeconomic impact of inflation and interest rates on security prices, and (4) brief consideration of what additional factors should be analyzed when dealing with world security markets.

#### 12.2.1 Economic Activity and Security Markets

In its monitoring of business cycles, the National Bureau of Economic Research (NBER) has examined the relationship of alternative economic series to the behavior of the entire economy and has classified numerous economic series into three groups: leading, coincident, and lagging indicator series. Further, extensive analysis of the relationship between the economy and the stock market has shown that stock prices are one of the better leading indicator series.

The evidence by Moore and Cullity (1988) and Siegel (1991) not only has indicated a strong relationship between stock prices and the economy but also has shown that stock prices consistently turn before the economy does.

There are two possible reasons why stock prices lead the economy. One is that stock prices reflect expectations of earnings, dividends, and interest rates. As investors attempt to estimate these future variables, their stock price decisions reflect expectations for future economic activity, not past or current activity. A second possible reason is that the stock market reacts to various leading indicator series, the most important being corporate earnings, corporate profit margins, interest rates, and changes in the growth rate of the money supply. Because these series tend to lead the economy, when investors adjust stock prices to reflect these leading economic series, expectations for stock prices become a leading series as well.

Because stock prices lead the aggregate economy, our macroeconomic approach to market analysis concentrates on economic series that lead the economy by more than stock prices do. First, we discuss cyclical indicator approaches developed by various research groups. Next, we consider the money supply, as well as other measures of monetary liquidity and policy. Finally, we discuss the research related to a number of economic series expected to affect security returns (e.g., production, inflation, and risk premiums).
12.2.2 Economic Series and Stock Prices
As noted, because research has documented that peaks and troughs in stock prices tend to occur prior to peaks and troughs in the economy, our consideration of relevant economic series concentrates on two broad categories of economic series that likewise lead the economy and should provide some insights regarding the future trend of stocks. The first set are economic series suggested by the National Bureau of Economic Research. The second are alternative monetary series influenced by the Federal Reserve.

12.2.3 The Cyclical Indicator Approach
The cyclical indicator approach to monitoring and forecasting the economy is built on the belief that the aggregate economy experiences periods of expansion and contraction that can be identified by the movements in specific economic series.

Cyclical Indicator Categories The NBER examined the behavior of hundreds of economic time series in relation to past business cycles and grouped various economic series into three major categories based on their relationship to the business cycle.

The first category, leading indicators, includes economic series that usually reach peaks or troughs before corresponding peaks or troughs in aggregate economic activity. The group currently includes the 10 series shown in Exhibit 12.1 with their factor weights. Included are common stock prices, which have a median lead of four months at peaks and troughs, and

In addition to knowing that aggregate new orders are increasing, it is helpful to know whether 55 percent or 95 percent of the companies in the sample are reporting higher orders. This information on the pervasiveness of the increase in new orders would help you project the future length and strength of the increase and the impact on the expansion.

You also would want to know the prevailing trend for a diffusion index. The diffusion index for a series almost always reaches its peak or trough before the peak or trough in the corresponding aggregate series. Therefore, the trend of the diffusion index for a series helps predict the behavior of the series itself.

Besides diffusion indexes for individual series, a diffusion index that shows the percentage of the 10 leading indicators rising or falling is a widely used indicator of the future state of the economy.

### Rates of Change

Knowing whether a series is increasing is useful, but knowing that a 7 percent increase one month followed a 10 percent increase the previous month indicates the series is growing but at a declining rate. Similar to the diffusion index, the rate of change values for a series reaches peaks or troughs prior to the peak or trough in the aggregate series.

### Comparison with Previous Cycles

A set of tables and charts shows the movements of individual series during the current business cycle and compares these movements to previous cycles for the same economic series. This comparison reveals whether a given series is moving slower or faster than during prior cycles. This information can be useful because, typically, movements in the initial months of an expansion or contraction indicate their ultimate length and strength.

### Analytical Measures of Performance

Certain analytical measures have been suggested for examining behavior within an economic series.

#### Diffusion Indexes

As the name implies, diffusion indexes indicate how pervasive a given movement is in a series. Diffusion index values are measured by computing the percentage of reporting units in a series that indicate a given result. For example, if 100 companies constitute the sample reporting new orders for equipment, the diffusion index for this series would indicate what proportion of the 100 companies was reporting higher orders during an expansion.

1While the cyclical indicator approach and the placement of economic series into the three categories was done by the NBER beginning in the 1930s, the publication and maintenance of the database was transferred to the Conference Board in the late 1990s, so current references will be to The Conference Board.
Limitations of the Cyclical Indicator Approach

The Conference Board acknowledges the following limitations that are also discussed in Koenis and Emery (1991):

**False Signals**
This is when a series that is moving in one direction suddenly reverses and nullifies a prior signal or hesitates, which is difficult to interpret. High variability in a series causes this problem.

**Currency of the Data and Revisions**
Some data series take time to be reported, but a bigger problem are revisions in data especially if the revision changes the direction implied by the original data.

**Economic Sectors Not Represented**
Examples include the service sector, import-export data, and many international series.

**Other Leading Indicator Series**
The Center for International Business Conditions Research (CIBCR) at the Columbia Graduate School of Business has developed the following additional leading indicator series:

- **Long-Leading Index**
  - Intended to provide earlier signals of major turning points in the economy.

- **Leading Employment Index**
  - Meant to forecast changes in U.S. employment.

- **Leading Inflation Index**
  - Intended to forecast U.S. inflation.

**International Leading Indicator Series**
This is a set of composite leading indicators for eight other major industrial countries: Canada, Germany, France, the United Kingdom, Italy, Japan, Australia, and Taiwan (Republic of China). The series are comparable in data and analysis to the leading series for the United States.

**Surveys of Sentiment and Expectations**
Consumer expectations are considered relevant as the economy approaches cyclical turning points. Two surveys of consumer expectations are reported monthly. The University of Michigan Consumer Sentiment Index and the Conference Board Consumer Confidence Index both query a sample of households on their expectations. Although the two indexes deviate from month to month, over longer time periods they track each other fairly closely. Both indexes are meant to be leading indicators of the economy.

Other surveys of business expectations focus on firms’ capital spending or inventory investment plans. The problem with survey data is that individuals’ and firms’ reported plans may not come to fruition.

Economic statistics released by the government are another source of helpful information about current economic trends. Every Monday, *The Wall Street Journal* publishes the short commentary "Tracking the Economy." The feature reports statistics that will be released during the coming weeks, their previous values, and their consensus forecasts. As implied by our discussion of efficient markets, investors react to economic surprises wherein the actual results deviate from the consensus forecasts (expectations).

12.2.4 Monetary Variables, the Economy, and Stock Prices

Many academic and professional observers hypothesize a close relationship between stock prices and various monetary variables that are influenced by monetary policy. The best-known monetary variable is the money supply. You will recall from your economics course that there are numerous measures of the money supply and the Federal Reserve controls the money supply through various tools, the most useful of which is open market operations.

12.2.5 Money Supply and the Economy

In their classic work on the monetary history of the United States, Friedman and Schwartz (1963) thoroughly documented that declines in the rate of growth of the money supply have...
preceded business contractions, while increases in the growth rate of the money supply have consistently preceded economic expansions.

Friedman (1969) suggests a transmission mechanism through which changes in the growth rate of the money supply affect the aggregate economy. He hypothesizes that, to implement planned changes in monetary policy, the Federal Reserve engages in open market operations, buying or selling Treasury bonds to adjust bank reserves and, eventually, the money supply. Because the Fed deals in government bonds, the initial liquidity impact when the Fed buys bonds affects the government bond market, creating excess liquidity for those who sold bonds to the Fed. The result of the bond purchases is an increase in bond prices and lower interest rates. Rising government bond prices subsequently filter down to corporate bonds, and this change in liquidity eventually affects common stocks and then the real goods market. There is the opposite effect if the Fed sells bonds to reduce bank reserves and the money supply. The impact of changes in money supply growth on stock prices is really part of the transmission process whereby money supply affects the aggregate economy. This liquidity transmission scenario implies that the effect of a change in monetary policy initially appears in financial markets (bonds and stocks) and only later in the aggregate economy. This transmission discussion is consistent with the earlier observation that the stock market leads the economy.

12.2.6 Money Supply and Stock Prices
Numerous studies have tested the relationship suggested by this transmission mechanism. Specifically, do changes in the growth rate of the money supply precede changes in stock prices? The results of these studies have tended to change over time. The initial studies by Sprinkel (1971), Keran (1971), and Homa and Jaffe (1971) generally indicated a strong leading relationship between money supply changes and stock prices.

Subsequent studies by Cooper (1974) and Rozeff (1974) questioned these findings. Specifically, they found a relationship between the money supply and stock prices, but they found that changes in the growth rate of the money supply consistently lagged stock returns by about one to three months.

Davidson and Froyer (1982) and Hafer (1985) examined the relationship of stock returns to anticipated and unanticipated money supply growth and found that stock prices adjust very quickly to unexpected changes in money supply growth. This implies that to take advantage of this relationship it is necessary to forecast unanticipated changes in money supply growth.

12.2.7 Monetary Policy and Stock Returns
Following more than a decade of limited research on this topic, the subsequent focus has been on overall monetary policy rather than only money supply. Several studies by Jensen, Johnson, and Mercer (JJM) (1996, 1997, 1998, 2000) showed that the results of several earlier studies that examined the relationship between some economic or company variables and stock returns can be significantly affected by the prevailing monetary environment. Specifically, JJM showed that the business conditions proxies suggested by Fama and French (1989; i.e., the term spread, dividend yield, and the default spread) have a different effect on stock returns depending on the prevailing monetary policy. Notably, JJM contend that monetary policy is best identified by changes in the discount rate by the Federal Reserve (i.e., declining discount rates imply an easy monetary policy, while rising discount rates imply a restrictive policy). The JJM studies also show that the relationship between stock price returns and both size and the price-to-book value ratio that was found in studies by Fama and French (1995) and Fairfield (1994) only holds during periods of easy monetary policy. A subsequent study by Thorbecke (1997) that examined how stock returns respond to monetary policy shocks indicated that expansionary monetary policy increases ex-post stock returns. Patelis (1997) examined whether shifts in monetary policy affect the predictability of excess stock returns and found that monetary policy variables were significant predictors of future stock returns along with dividend yield.

Limitations of the Cyclical Indicator Approach The Conference Board acknowledges the following limitations that are also discussed in Koenis and Emery (1991):

12.2.8 Inflation, Interest Rates, and Security Prices

Because this chapter is concerned with the macroeconomic analysis of security markets, we should examine the macroeconomic impact of inflation and interest rates. We have noted throughout the book the critical role of expected inflation and nominal interest rates in determining the required rate of return used to derive the value of all investments. We would expect these variables, which are very important in microeconomic valuation, to also affect changes in the aggregate markets.

Inflation and Interest Rates

Exhibit 12.3 contains a plot of long-term interest rates (the 10-year Treasury note) and the year-to-year percentage change in the consumer price index (CPI, a measure of inflation). This graph demonstrates the relationship between inflation and interest rates. We contended in our earlier discussion that when investors anticipate an increase in the rate of inflation, we would expect them to increase their required rates of return by a similar amount to derive constant real rates of return. The time-series graph of the promised yield of Treasury bonds and the annual rate of inflation in Exhibit 12.3 confirms the expected relationship overall. If the relationship was perfect and investors were accurate in their predictions of future inflation, the difference between the interest rate and the inflation rate (the spread between them) would be fairly constant, reflecting the real return on Treasury bonds. Notably, the spread between these two curves changes over time as shown in Exhibit 12.4. Although the two curves generally move together, during 1983–1985 the real rates of return on these Treasury bonds were in the 8 to 9 percent range, which clearly exceeds what most investors would expect on zero credit risk bonds. In sharp contrast, during 2008, the real rate declines to almost minus 2 percent, which is likewise not reasonable, followed by a spike to almost 6 percent due to a temporary plunge in inflation.

The relationship among inflation, interest rates, and stock prices is not direct and consistent. The reason is that the expected cash flows from stocks can change along with inflation and interest rates, and we cannot be certain whether this change in cash flows will augment or offset the change in interest rates. To demonstrate this, consider the following potential scenarios following an increase in the rate of inflation and the effect of this on stock prices based on the DDM:

1. **The positive scenario.** Interest rates rise due to an increase in the rate of inflation, and corporate earnings likewise experience an increase in growth because firms are able to increase prices in line with cost increases. In this case, stock prices might be fairly stable because the negative effect of an increase in the required rate of return ($k$) is partially or wholly offset by the increase in the growth rate of earnings and dividends ($g$), which causes an increase in the value of stocks. As a result, the returns on stock increase in line with the rate of inflation—that is, stocks would be a good inflation hedge.

2. **Mildly negative scenario.** Interest rates and the required return $k$ increase due to inflation, but expected cash flows continue to grow at the prior rate assuming small increases in prices at rates below the increase in the inflation rate and cost increases. This would cause a decline in stock prices similar to what happens with a bond. The required rate of return ($k$) would increase, but the growth rate of dividends ($g$) would be constant. As a result, the $k - g$ spread discussed in Chapter 11 would widen and stock prices would decline.

3. **Very negative scenario.** Interest rates and the required return $k$ increase due to inflation, while the growth rate of cash flows declines because during the period of inflation the costs of production increase, but many firms are not able to increase prices at all, which causes a major decline in profit margins. Given this scenario, stock prices will experience a significant decline because $k$ will increase and $g$ will decline, causing a large increase in the $k - g$ spread.

In contrast to these scenarios, you can envision a comparable set of scenarios when inflation and interest rates decline. The relationship among inflation, interest rates, and stock prices is not as direct or consistent as the relationship between interest rates and bond prices. The point is, the effect of interest rate changes on stock prices will depend on what caused the change in interest rates and the effect of this event on the expected cash flows for alternative common stocks.

Notably, the actual relationship among inflation, interest rates, and stock prices is an empirical question and the effect varies over time and between alternative industries and stocks. Therefore, although there has generally been a significant negative relationship among inflation, interest rates, and the returns on stock, as shown in Chapter 3 (Exhibit 3.10), this is not always true as shown by Reilly (1975), Jaffee and Mandelker (1976), and Fama (1981). In addition, even when the negative relationship is true for the overall market, certain industries may have earnings, cash flows, and dividends that react positively to inflation and interest rate changes. In such an instance, their stock prices would be positively correlated with inflation and interest rates as demonstrated by Reilly, Wright, and Johnson (2005).

### 12.2.9 Analysis of World Security Markets

Although we have focused on the U.S. market to demonstrate the macroeconomic approach to forecasting movements in the securities markets, you must also consider a similar analysis for numerous foreign markets, including those in Japan, Canada, the United Kingdom, and Germany. While it is not feasible to consider the full macroanalysis, the following discussion considers some of the variables and economic series and some differences that will cause the macromarket analysis to imply a different outlook for alternative countries compared to the United States.

**Leading economic series** are available for virtually all the developed countries, and the empirical relationships to the economy are quite similar to those of the United States.

**Interest Rates and Bond Prices** The relationship between interest rates and bond prices is clearly negative because the only variable that changes in the valuation model is the discount factor. Specifically, the expected cash flows from a straight noncallable bond would not change, so an increase in interest rates will cause a decline in bond prices and a decline in interest rates will boost bond prices. For example, if you own a 10-year bond with a coupon of 10 percent, when interest rates increase from 10 percent to 12 percent, the price of this bond will decline from $1,000 (par) to $885. In contrast, if rates decline from 10 percent to 8 percent, the price of the bond will increase from $1,000 to $1,136.

The size of the price change will depend on the characteristics of the bond. As will be discussed in Chapter 18, a longer-term bond will experience a larger price change for a change in interest rates. Therefore, we can anticipate a negative relationship between inflation and the rates of return on bonds because inflation generally has a direct effect on interest rates; in turn, interest rates have an inverse effect on bond prices and rates of return. Empirical verification for this negative relationship is provided in Exhibit 3.10, which shows a correlation of $-0.14$ between inflation and rates of return on long-term investment-grade bonds during the period 1980–2010.
Inflation, Interest Rates, and Stock Prices

The relationship among inflation, interest rates, and stock prices is not direct and consistent. The reason is that the expected cash flows from stocks can change along with inflation and interest rates, and we cannot be certain whether this change in cash flows will augment or offset the change in interest rates. To demonstrate this, consider the following potential scenarios following an increase in the rate of inflation and the effect of this on stock prices based on the DDM:

2. **Mildly negative scenario.** Interest rates and the required return \( k \) increase due to inflation, but expected cash flows continue to grow at the prior rate assuming small increases in prices at rates below the increase in the inflation rate and cost increases. This would cause a decline in stock prices similar to what happens with a bond. The required rate of return \( k \) would increase, but the growth rate of dividends \( g \) would be constant. As a result, the \( k-g \) spread discussed in Chapter 11 would widen and stock prices would decline.

3. **Very negative scenario.** Interest rates and the required return \( k \) increase due to inflation, while the growth rate of cash flows declines because during the period of inflation the costs of production increase, but many firms are not able to increase prices at all, which causes a major decline in profit margins. Given this scenario, stock prices will experience a significant decline because \( k \) will increase and \( g \) will decline, causing a large increase in the \( k-g \) spread.

In contrast to these scenarios, you can envision a comparable set of scenarios when inflation and interest rates decline. 12.2.9 Analysis of World Security Markets

Although we have focused on the U.S. market to demonstrate the macroeconomic approach to forecasting movements in the securities markets, you must also consider a similar analysis for numerous foreign markets, including those in Japan, Canada, the United Kingdom, and Germany. While it is not feasible to consider the full macroanalysis, the following discussion considers some of the variables and economic series and some differences that will cause the macromarket analysis to imply a different outlook for alternative countries compared to the United States.

Leading economic series are available for virtually all the developed countries, and the empirical relationships to the economy are quite similar to those of the United States.
This model, which has been used extensively for the fundamental analysis of common stock, can also be used to value a stock market series. In the appendix to Chapter 11, it was shown that this model can be simplified to the following reduced form expression:

\[ V_j = P_j = D_1 - g \]

where:

- \( P_j \) = the price of stock \( j \)
- \( D_1 \) = dividend in Period 1, which is equal to \( D_0(1 + g) \)
- \( k \) = the required rate of return for stock \( j \)
- \( g \) = the constant growth rate of dividends

This model suggests that the parameters to be estimated are (1) the required rate of return (\( k \)) and (2) the expected growth rate of dividends (\( g \)). After estimating \( g \), it is simple to estimate \( D_1 \) because it is equal to the current dividend (\( D_0 \)) times (1 + \( g \)).

### Market Valuation Using the Reduced Form DDM

In this section, we will apply the model to the valuation of the S&P Industrials Index as of mid-2011. As noted, the critical estimates are the prevailing \( k \) and \( g \) for the U.S. equity market. The estimate of \( D_1 \) is the current \( D_0 \) for the latest 52-week period times (1 + \( g \)). As of mid-2011, the trailing 52-week dividend estimate in Barron’s was $34.16.

As discussed previously, the estimate of \( k \) is a function of the nominal risk-free rate (NRFR) plus a market risk premium. Because both of these components are subject to interpretation, we will consider a range of values.

#### The Nominal Risk-Free Rate

The alternatives for the NRFR are based upon the theoretical specifications that it should be a zero-coupon, default-free asset with a time to maturity that approximates the investor’s holding period. The point is that such an asset would provide the asset’s promised return (i.e., its yield to maturity) because there is no default risk, no reinvestment risk because it is a zero-coupon security, and no price risk because the asset matures at the end of the expected holding period. The range of suggested maturities goes from a three-month T-bill to an intermediate government bond (e.g., a 10-year Treasury bill), to the long-term government bond (e.g., a 30-year Treasury bond). As of mid-2011, these yields were:

- 1-year Treasury bill: 0.80%
- 10-year Treasury note: 3.20%
- 30-year Treasury bond: 4.30%

#### The Equity Risk Premium

The attitude toward the estimation of the equity risk premium has undergone significant changes during the 1990s. The initial empirical estimate of an equity risk premium was provided by the pioneering work of Ibbo tson and Sinquefield (1982) in their monograph for the Financial Analysts Research Foundation. They estimated the risk premium on common stock as the arithmetic mean of the difference in the annual rate of return from stocks minus the return on Treasury bills. Although the original estimate was for 1926–1981, this estimated risk premium has been updated annually in a yearbook provided by Ibbotson Associates (annual), now owned by Morningstar. For example, the equity risk premium as of 2011 for 1926–2010 was 8.2 percent, using the arithmetic mean of the annual values, and 6.3 percent, using the geometric mean of the annual values. The geometric mean is appropriate for long-run asset class comparisons, whereas the arithmetic mean is what you would use to estimate the premium for a given year (e.g., the expected performance next year). Because our application is to the long-term DDM model, the geometric mean value would probably be more appropriate, which implies using the 6.3 percent risk premium value.

An additional adjustment is suggested to reflect the belief that the typical investment horizon is longer than that implied by the T-bill rate. Assuming that most investors consider the intermediate time frame (5–10 years) a more appropriate investment horizon, the risk for this adjustment is reasonable given the historical trends during the past 17 years to help you become familiar with them so that you can use these relative valuation ratios in subsequent industry and company stock analysis. Specifically, you will want to compare the relative valuation ratios for an industry or company to the relative valuation ratios for the market. We finish the chapter with a discussion of unique factors that should be considered when applying these valuation techniques to foreign markets.

### 12.3 Microvaluation Analysis

In this section, building on the macroanalysis of the economy and the implications of this for the stock market, we estimate specific values for an aggregate stock market series using the various valuation models presented in Chapter 11. Therefore, this section has four subsections in which the four sets of valuation techniques are employed: (1) the dividend discount model (DDM), (2) the free cash flow to equity model (FCFE), (3) the earnings multiplier technique, and (4) the other relative valuation ratios. Note that the first two subsections consider two of the present value of cash flow approaches presented in Chapter 11, while the last two subsections employ the four relative valuation ratios from Chapter 11. Notably, we do not demonstrate the operating free cash flow model because of space constraints and the difficulty of estimating debt for the S&P industrials. Also, we do not use the other relative valuation ratios to derive a specific value of the market; rather, we discuss the trends for these ratios during the past 17 years to help you become familiar with them so that you can use these relative valuation ratios in subsequent industry and company stock analysis. Specifically, you will want to compare the relative valuation ratios for an industry or company to the relative valuation ratios for the market. We finish the chapter with a discussion of unique factors that should be considered when applying these valuation techniques to foreign markets.

#### 12.3.1 Applying the DDM Valuation Model to the Market

In Chapter 11, we employed the dividend discount model (DDM), which estimated the value of the stock (\( V_j \)) assuming a constant growth rate of dividends for an infinite period.

\[
12.1 \quad V_j = \frac{D_0(1 + g)}{(1 + k)} + \frac{D_0(1 + g)^2}{(1 + k)^2} + \cdots + \frac{D_0(1 + g)^n}{(1 + k)^n}
\]

where:

- \( V_j \) = the value of stock \( j \)
- \( D_0 \) = the dividend payment in the current period
- \( g \) = the constant growth rate of dividends
- \( k \) = the required rate of return on stock \( j \)
- \( n \) = the number of periods, which is assumed to be infinite
This model, which has been used extensively for the fundamental analysis of common stock, can also be used to value a stock market series. In the appendix to Chapter 11, it was shown that this model can be simplified to the following reduced form expression:

$$V_j = P_j = \frac{D_1}{k - g}$$

where:

- \(P_j\) = the price of stock \(j\)
- \(D_1\) = dividend in Period 1, which is equal to \(D_0(1 + g)\)
- \(k\) = the required rate of return for stock \(j\)
- \(g\) = the constant growth rate of dividends

This model suggests that the parameters to be estimated are (1) the required rate of return \(k\) and (2) the expected growth rate of dividends \(g\). After estimating \(g\), it is simple to estimate \(D_1\) because it is equal to the current dividend \((D_0)\) times \((1 + g)\).

**Market Valuation Using the Reduced Form DDM** In this section, we will apply the model to the valuation of the S&P Industrials Index as of mid-2011. As noted, the critical estimates are the prevailing \(k\) and \(g\) for the U.S. equity market. The estimate of \(D_1\) is the current \(D_0\) for the latest 52-week period times \((1 + g)\). As of mid-2011, the trailing 52-week dividend estimate in *Barron’s* was $34.16.

As discussed previously, the estimate of \(k\) is a function of the nominal risk-free rate (NRFR) plus a market risk premium. Because both of these components are subject to interpretation, we will consider a range of values.

**The Nominal Risk-Free Rate** The alternatives for the NRFR are based upon the theoretical specifications that it should be a zero-coupon, default-free asset with a time to maturity that approximates the investor’s holding period. The point is that such an asset would provide the asset’s promised return (i.e., its yield to maturity) because there is no default risk, no reinvestment risk because it is a zero-coupon security, and no price risk because the asset matures at the end of the expected holding period. The range of suggested maturities goes from a three-month T-bill to an intermediate government bond (e.g., a 10-year Treasury bill), to the long-term government bond (e.g., a 30-year Treasury bond). As of mid-2011, these yields were:

- 1-year Treasury bill: 0.80%
- 10-year Treasury note: 3.20%
- 30-year Treasury bond: 4.30%

**The Equity Risk Premium** The attitude toward the estimation of the equity risk premium has undergone significant changes during the 1990s. The initial empirical estimate of an equity risk premium was provided by the pioneering work of Ibbotson and Sinquefield (1982) in their monograph for the Financial Analysts Research Foundation. They estimated the risk premium on common stock as the arithmetic mean of the difference in the annual rate of return from stocks minus the return on Treasury bills. Although the original estimate was for 1926–1981, this estimated risk premium has been updated annually in a yearbook provided by Ibbotson Associates (annual), now owned by Morningstar. For example, the equity risk premium as of 2011 for 1926–2010 was 8.2 percent, using the arithmetic mean of the annual values, and 6.3 percent, using the geometric mean of the annual values. The geometric mean is appropriate for long-run asset class comparisons, whereas the arithmetic mean is what you would use to estimate the premium for a given year (e.g., the expected performance next year). Because our application is to the long-term DDM model, the geometric mean value would probably be more appropriate, which implies using the 6.3 percent risk premium value.

An additional adjustment is suggested to reflect the belief that the typical investment horizon is longer than that implied by the T-bill rate. Assuming that most investors consider the intermediate time frame (5–10 years) a more appropriate investment horizon, the risk
premium should be computed as the stock return less the return on intermediate government bonds. Given the typical upward-sloping yield curve, it is not surprising that this measure of the risk premium is about 1.8 percent less than the T-bill premium—that is, the arithmetic mean of the annual risk premiums relative to intermediate government bonds was 6.4 percent from 1926–2010 and the geometric mean of the annual risk premiums was 4.5 percent. In recent years, Ibbotson Associates has also provided a long-horizon risk premium estimate that employs the long-term government bond return. The arithmetic average for this series was 6.0 percent, and the geometric average was 4.40 percent. Therefore, because of the several possibilities, the long-term historical risk premium suggested is about 5.0 percent.

Several authors have contended that there are problems with this estimate in a dynamic real-world environment. The major criticism articulated by Rozell (1984) is that the time period is too long and causes the market risk premium to be almost a constant value. Given that we are dealing with an average value that encompasses almost 85 years, this technique will not reflect any changes over time. There are ways to adjust for this constant value problem, and other estimation approaches have been suggested.

The first suggestion to adjust for the constant value is to use a constant moving average period for the Ibbotson-Sinquefield technique—for example, instead of using a single mean value for the total period since 1926, employ a 20-year moving average of the series. This would reflect any trends in the series over time. The authors computed such a series employing a moving average and using the intermediate bond return as the risk-free asset. The time-series plots clearly demonstrated that the risk premium series was not stable since the 20-year moving average values varied from about 1 percent to 16 percent. Notably, given how the risk premium is computed, it increases during years when the market does well and declines during poor performing periods. This is clearly counterintuitive to expectations.

The paper by Rozell (1984) discusses the equity risk premium concept similar to the presentation in this book. This is followed by a review of alternative measures of the risk premium, including the Ibbotson-Sinquefield series, an estimate using the CAPM, and a brief consideration of the default risk premium (referred to as the credit risk series).

The credit risk premium concept has been referred to on several occasions in this book when discussing changes in the capital market risk premium. The notion is that changes in the absolute or percentage spread between the yield on BBB and AAA bonds indicate a change in the required rate of return by investors for accepting credit risk. Further, this change in the credit risk premium implies a change in the slope of the security market line (SML). The percent yield spread is considered a preferable measure because it adjusts for the level of yields. An advantage of the credit risk measure is that it is based on current market results and reflects prevailing investor attitudes. For a recent plot of this credit yield spread, see Exhibit 1.9, which indicates a very volatile series with peaks in late 1974, early 2003, and mid-2009.

An alternative estimate of the equity risk premium is suggested by Reichenstein and Rich (1993). They employ the Value Line forecast of dividends and capital gains. This estimated total market return less the short-term government bond yield is shown to provide better and more consistent results than an earnings price value or dividend yield although it provides consistently biased results, but it is possible to adjust for this.

A comparison used by Woolridge (1995) to justify a change in the equity risk premium is the relative volatility of stocks versus bonds. Woolridge argues that the risk premium for equity has declined from the 6 percent estimate based on the Ibbotson-Sinquefield data to about 2.5 percent because of the increase in bond market volatility relative to stock volatility. Specifically, the equity risk premium spread has declined, not because stocks have become less volatile but because bonds have become more volatile. Thus, the difference in risk between the two

---

3For an analysis of relative volatility of bonds versus stocks that is consistent with the Woolridge contention, see Reilly, Wright, and Chan (2000).
Therefore, to estimate the expected growth rate, you need to estimate changes in both the retention rate \( b \) and the return on equity \( \text{ROE} \). The plot in Exhibit 12.5 shows that the retention rate has become relatively high. Because the valuation model is a long-run model, you should estimate only relatively permanent changes, although short-run changes can affect expectations. Specifically, you should recognize that the annual retention rate, which has been volatile and generally increases (between 48 and 70 percent, excluding the extreme declines in 2001 and 2002), is heavily impacted by annual earnings changes (as will be discussed in the dividend payout section).

The second variable that affects \( g \) is changes in the return on equity \( \text{ROE} \). As discussed in Chapter 10, the \( \text{ROE} \) can be broken down using the three-component DuPont analysis as follows:

\[
\text{12.4 } \text{ROE} = \frac{\text{Net Income}}{\text{Equity}} = \frac{\text{Net Income}}{\text{Sales}} \times \frac{\text{Sales}}{\text{Total Assets}} \times \frac{\text{Total Assets}}{\text{Equity}}
\]

This equation shows that the \( \text{ROE} \) increases if either the total asset turnover or the profit margin increases. In addition, you can increase \( \text{ROE} \) by increasing financial leverage. Because the S&P Industrials series includes the required historical information only since 1993, we examine this three-component breakdown of \( \text{ROE} \) for the 17-year period 1993–2009 (2010 data).

As shown in Exhibit 12.6, the \( \text{ROE} \) for the S&P Industrials series during the period 1993–2009 experienced its lowest value during the recession in 2001–2002 and reached its peak in 1996. An analysis of the three components of \( \text{ROE} \) indicates what contributed to the changes over time. First, an analysis of Exhibits 12.6 and 12.7 shows that the profit margin over time was a major factor explaining the overall pattern of \( \text{ROE} \) since 1993. The second component, total asset turnover (Exhibit 12.8), experienced a peak of about 95 percent in 1996, a decline to about 85 percent in 2001, and another decline to 65 percent in 2002 and 2003. The third component, financial leverage, which also experienced a peak in 1996, was the least affected by the recession.

The matrix indicates a range of \( k \) from 0.028 (2.8 percent) to 0.103 (10.3 percent). The low required rate of return assumes investors have a very short-run horizon and a very small risk premium, while the high required return implies a long-run horizon and the very large long-run historical risk premium of Ibbotson-Sinquefield.

For purposes of our subsequent estimate, we will use the diagonal values from this cost of equity \( (k) \) matrix: 0.028, 0.072, and 0.103, which are equal to 2.8, 7.2, and 10.3 percent.

The Dividend Growth Rate

The earnings multiple that is applied to next year’s earnings must take into account the expected growth rate \( g \) for common dividends. There is a positive relationship between the earnings multiplier and the growth rate of earnings and dividends—the higher the expected growth rate, the higher the multiple. When estimating \( g \), you should consider the current expected rate of growth and estimate any changes in the expected growth rate. Such changes in expectations indicate a change in the relationship between \( k \) and \( g \) and will have a profound effect on the earnings multiplier.

As discussed in Chapters 10 and 11, a firm’s growth rate is equal to (1) the proportion of earnings retained and reinvested by the firm—that is, its retention rate \( (b) \)—times (2) the rate of return earned on investments \( (\text{ROE}) \). An increase in either or both of these variables causes an increase in the expected growth rate \( g \) and an increase in the earnings multiplier. Therefore, the expected growth rate can be stated as:

\[
\text{12.3 } g = f(b, \text{ROE})
\]

where:

\[
\begin{align*}
\text{expected growth rate} & = g \\
\text{the expected retention rate equal to } 1 - D/E & = b \\
\text{the expected return on equity investments} & = \text{ROE}
\end{align*}
\]

---

3You know that the \( g \) in the valuation model is the expected growth rate for dividends. In our discussion, we assume a relatively constant dividend-payout ratio (dividend/earnings), so the growth of dividends is dependent on the growth in earnings.

4A paper that specifically examines this relationship is Fairfield (1994).
Therefore, to estimate the expected growth rate, you need to estimate changes in both the retention rate \((h)\) and the return on equity \((ROE)\). The plot in Exhibit 12.5 shows that the retention rate has become relatively high. Because the valuation model is a long-run model, you should estimate only relatively permanent changes, although short-run changes can affect expectations. Specifically, you should recognize that the annual retention rate, which has been volatile and generally increases (between 48 and 70 percent, excluding the extreme declines in 2001 and 2002), is heavily impacted by annual earnings changes (as will be discussed in the dividend payout section).

The second variable that affects \(g\) is changes in the return on equity \((ROE)\). As discussed in Chapter 10, the \(ROE\) can be broken down using the three-component DuPont analysis as follows:

\[
12.4 \quad ROE = \frac{\text{Net Income}}{\text{Equity}} = \frac{\text{Net Income}}{\text{Sales}} \times \frac{\text{Sales}}{\text{Total Assets}} \times \frac{\text{Total Assets}}{\text{Equity}}
\]

\[
= \frac{\text{Net Profit Margin}}{\text{Total Asset Turnover}} \times \frac{\text{Financial Leverage}}{\text{Leverage}}
\]

This equation shows that the \(ROE\) increases if either the total asset turnover or the profit margin increases. In addition, you can increase \(ROE\) by increasing financial leverage. Because the S&P Industrials series includes the required historical information only since 1993, we examine this three-component breakdown of \(ROE\) for the 17-year period 1993–2009 (2010 data).

As shown in Exhibit 12.6, the \(ROE\) for the S&P Industrials series during the period 1993–2009 experienced its lowest value during the recession in 2001–2002 and reached its peak in 1996. An analysis of the three components of \(ROE\) indicates what contributed to the changes over time. First, an analysis of Exhibits 12.6 and 12.7 shows that the profit margin over time was a major factor explaining the overall pattern of \(ROE\) since 1993. The second component, total asset turnover (Exhibit 12.8), experienced a peak of about 95 percent in 1996, a decline to
a trough in 2002, and then an increase to finish at 81 percent in 2009. Combining these two variables (PM and TATO) equals return on total assets (ROTA; Exhibit 12.6) that experienced an overall increase from about 4 percent in 1993 to 5 percent in 2009. Finally, the total assets/equity ratio (in Exhibit 12.9) that reflects financial leverage experienced an almost constant
For convenience, we will use 7 percent as our estimate.

Combining the Estimates
If we combine the several estimates, they are as follows:

\[
D_0 = \$34.16, \quad k = 0.028, 0.072, \text{ or } 0.103; \quad g = 0.07
\]

\[
D_1 = 34.16 (1 + 0.07) = 36.55
\]

Using these inputs for the reduced form DDM indicates the following three estimates of market value:

1. \[
36.55 (0.028 - 0.070) = 36.55 - 0.042 = \text{Meaningless (} g > k \text{)}
\]

2. \[
36.55 (0.072 - 0.070) = 36.55 (0.002) = 18,275
\]

3. \[
36.55 (0.103 - 0.070) = 36.55 (0.033) = 1,108
\]

As noted, the first estimate is meaningless since the growth rate exceeds the required return \(k\).

The second estimate that has a \((k - g)\) spread of only 0.002 (which is likewise virtually meaningless) indicates a valuation of over 18,000, which exceeds the current market price of May 2011 of 1,770. Finally, the third estimate that has a \((k - g)\) spread of 0.033 indicates a value of 1,108, which is substantially below the current market price of 1,770. Assuming the dividend value of $36.55 is reasonable, one needs to consider what \(k - g\) spread is necessary to justify the prevailing market value. Consider the following values:

\[
\begin{align*}
36.55 (0.019) &= 1,924 \\
36.55 (0.020) &= 1,828 \\
36.55 (0.021) &= 1,740
\end{align*}
\]

It appears that the current market value implies (requires) a \(k - g\) spread very close to 2.0 percent, which means either a \(k\) below 0.090 or an expected growth rate above 0.070. Since the 7.0 percent long-run growth rate appears somewhat aggressive (optimistic), the most likely adjustment would be a \(k\) approaching 0.09, which is possible with a shorter investment horizon. A more conservative growth estimate would necessitate a lower required \(k\).

12.3.2 Market Valuation Using the Free Cash Flow to Equity (FCFE) Model

As indicated earlier, we will derive an estimate using this FCFE model under two scenarios: (1) a constant growth rate from the present, and (2) a two-stage growth rate assumption.

Decline over this period from about 3.6 times to 2.6 times. Therefore, the ROE started at about 15 percent and ended at about 13 percent, based upon an overall increase in the profit margin offset by a small decline in total asset turnover and a significant decline in financial leverage.

The point is, an investor needs to estimate the long-term outlook of ROE, which in turn requires a long-term estimate for each of the three components ratios. Once that is established, multiply this long-term of ROE by your estimate of \(b\), the retention rate, to calculate an estimate of the long-term growth rate \((g)\) of U.S. industrial firms. For example, if we are conservative and estimate a long-term retention rate of 55 percent (compared to an average without 2001 and
The Constant Growth FCFE Model

To begin, the FCFE is defined (measured) as follows:

\[
\text{Net Income} + \text{Depreciation expense} - \text{Capital expenditures} - \Delta \text{in working capital} - \text{Principal debt repayments} + \text{New debt issues}
\]

This technique attempts to determine the free cash flow that is available to the stockholders after payments to all other capital suppliers and after providing for the continued growth of the firm. The FCFE data for the S&P Industrials Index for the period 1994–2009 are contained in Exhibit 12.10.

Although there was overall growth in the FCFE series for the period 1994–2009, there was also substantial variation from a low point in 1994 to a peak of 101 in 2007. A major cause of the poor results in 2009 was the large working capital additions. Preliminary indications for 2010 point toward higher earnings, reasonable capital expenditures and small working capital increases, and a "best" estimate for FCFE of about 72.00. Therefore, for the constant growth version of the model, we will use the growth estimate used in the DDM as follows:

\[
g = 0.070
k = 0.072; 0.103
\]

\[
\begin{align*}
\text{FCFE}_0 &= 87,000 \\
\text{FCFE}_1 &= 87,000 \times (1 + 0.07) = 93,190
\end{align*}
\]

\section*{Combining the Estimates}

If we combine the several estimates, they are as follows:

\[
D_0 = 34.16 \\
k = 0.028, 0.072, \text{or 0.103} \\
g = 0.07 \\
D_1 = 34.16(1 + g) = 34.16(1.07) = 36.55
\]

Using these inputs for the reduced form DDM indicates the following three estimates of market value:

\[
\begin{align*}
1. \quad \frac{36.55}{0.028 - 0.070} &= \frac{36.55}{-0.042} = \text{Meaningless (g > k)} \\
2. \quad \frac{36.55}{0.072 - 0.070} &= \frac{36.55}{0.002} = 18,275 \\
3. \quad \frac{36.55}{0.103 - 0.070} &= \frac{36.55}{0.033} = 1,108
\end{align*}
\]

As noted, the first estimate is meaningless since the growth rate exceeds the required return \(k\). The second estimate that has a \((k - g)\) spread of only 0.002 (which is likewise virtually meaningless) indicates a valuation of over 18,000, which exceeds the current market price of May 2011 of 1,770. Finally, the third estimate that has a \((k - g)\) spread of 0.033 indicates a value of 1,108, which is substantially below the current market price of 1,770. Assuming the dividend value of $36.55 is reasonable, one needs to consider what \(k - g\) spread is necessary to justify the prevailing market value. Consider the following values:

\[
\begin{align*}
\frac{36.55}{0.019} &= 1,924 \\
\frac{36.55}{0.020} &= 1,828 \\
\frac{36.55}{0.021} &= 1,740
\end{align*}
\]

It appears that the current market value implies (requires) a \((k - g)\) spread very close to 2.0 percent, which means either a \(k\) below 0.090 or an expected growth rate above 0.070. Since the 7.0 percent long-run growth rate appears somewhat aggressive (optimistic), the most likely adjustment would be a \(k\) approaching 0.09, which is possible with a shorter investment horizon. A more conservative growth estimate would necessitate a lower required \(k\).

\section*{12.3.2 Market Valuation Using the Free Cash Flow to Equity (FCFE) Model}

As indicated earlier, we will derive an estimate using this FCFE model under two scenarios: (1) a constant growth rate from the present, and (2) a two-stage growth rate assumption.
Equity values:

\[ 77.040.072 - 0.070 = 38,520 \]

\[ 77.041.030 - 0.070 = 2,335 \]

In contrast to the DDM results, this model indicates that the market at its current price of about 1,770 is undervalued even if one assumes a cost of equity of 10.3 percent. Recall that this 10.3 percent is based on a long-term bond rate of 4.30 percent and an equity risk premium of 6.00 percent.

Alternatively, if we assume that FCFE does not grow by 7 percent in 2011 but only by 5 percent because of the sluggish recovery (to 75.60 = 72 × 1.05), and a lower perpetual growth rate of 6.5 percent, the values decline as follows:

\[ 75.600.072 - 0.065 = 10,800 \]

\[ 75.600.103 - 0.065 = 1,989 \]

Finally, if we assume the lower estimate of FCFE (75.60) and 6.0 percent perpetual growth, the values are:

\[ 75.600.072 - 0.060 = 6,300 \]

\[ 75.600.103 - 0.060 = 1,758 \]

Needless to say, the valuations and the investment decisions given the current market value of 1,770 are very sensitive to the estimate of \( k \) and \( g \) and the resulting spread.

The Two-Stage Growth FCFE Model

To demonstrate a two-stage model, we assume the following above-average growth rates during the next five years (the first stage) followed by a second stage of constant growth at 6 percent.

- 2011 — 8.5%
- 2012 — 8.0%
- 2013 — 7.5%
- 2014 — 7.0%
- 2015 — 6.5%
- 2016 onward — 6.0%

We assume a \( k \) of 9.0 percent, about midway between 0.072 and 0.103, which implies a risk premium of about 5 percent and a FCFE of $72.00 in 2010. The computations are as follows:

\[
g = 0.070 \\
k = 0.072; 0.103 \\
FCFE_0 = $72.00 \text{ (estimate for 2010)} \\
FCFE_1 = $72.00 \times (1.07) = $77.04 \text{ (estimate for 2011)}
\]

\(^5\text{For further discussion and detail, see Damodaran (1994).}\)
As can be seen, this set of assumptions indicates an intrinsic value that exceeds the current market price of (1,770), which implies the following: (1) the market is undervalued at this time, and (2) investors who acquire a diversified portfolio of U.S. stocks at these prices should derive a long-run annual rate of return in excess of 9.0 percent. It is also possible to approximate this market return using the estimate from the DDM as follows:

$$k = \frac{D + g}{P + g}$$

Combining the current dividend yield of about 1.8 percent and the expected long-run growth of 7.0 percent implies a return of 8.8 percent. Notably, this estimated return is higher than what is expected by Emmons (1999), who derives expected earnings growth based on the growth of nominal GDP of about 6 percent plus a dividend yield of 1.3 percent to arrive at a return estimate of about 7 percent (he stipulates a range of 5 to 7 percent).

The next section will discuss and demonstrate the four alternative relative valuation ratios as follows: (1) the price/earnings ratio (P/E), (2) the price/book value ratio (P/BV), (3) the price/cash flow ratio (P/CF), and (4) the price/sales ratio (P/S). We begin with the P/E ratio because it is the most well known and because it can be derived from the DDM. Also, this model can be used to derive a specific market value.

The Two-Stage Growth FCFE Model To demonstrate a two-stage model, we assume the following above-average growth rates during the next five years (the first stage) followed by a second stage of constant growth at 6 percent.

- 2011—8.5%
- 2012—8.0%
- 2013—7.5%
- 2014—7.0%
- 2015—6.5%
- 2016 onward—6.0%

We assume a $k$ of 9.0 percent, about midway between .072 and .103, which implies a risk premium of about 5 percent and a FCFE of $72.00 in 2010. The computations are as follows:

As can be seen, this set of assumptions indicates an intrinsic value that exceeds the current market price of (1770), which implies the following: (1) the market is undervalued at this time, and (2) investors who acquire a diversified portfolio of U.S. stocks at these prices should derive a long-run annual rate of return in excess of 9.0 percent. It is also possible to approximate this market return using the k estimate from the DDM as follows:

\[ k = \frac{D}{P} + g \]

Combining the current dividend yield of about 1.8 percent and the expected long-run g of 7.0 percent implies a return of 8.8 percent. Notably, this estimated return is higher than what is expected by Emmons (1999), who derives expected earnings growth based on the growth of nominal GDP of about 6 percent plus a dividend yield of 1.3 percent to arrive at a return estimate of about 7 percent (he stipulates a range of 5 to 7 percent).

We begin with the P/E ratio because it is the most well known and because it can be derived from the DDM. Also, this model can be used to derive a specific market value.

12.4 Valuation Using the Earnings Multiplier Approach

12.4.1 Two-Part Valuation Procedure

We use the earnings multiplier version of the dividend discount model to value the stock market because it is a theoretically correct model of value assuming a constant growth rate of dividends for an infinite time period. The point is, these are reasonable assumptions for the aggregate stock market.\(^6\) Also, this valuation technique is consistently used in practice.

Recall that k and g are independent variables because k depends heavily on risk, whereas g is a function of the retention rate and the ROE. Therefore, this spread between k and g can and does change over time. The following equations imply an estimate of this spread at a point in time equal to the prevailing dividend yield:

\[ P_j = \frac{D_i}{k - g} \]
\[ P_j/D_i = 1/(k - g) \]
\[ D_i/P_j = k - g \]

Although the dividend yield gives an estimate of the size of the prevailing spread, it does not indicate the values for the two individual components (k and g) or what caused the change in the spread. More important, it says nothing about what the spread should be, which is the critical value that must be determined based upon estimating the values for k and g.

12.4.2 Importance of Both Components of Value

The ultimate objective of this microanalysis is to estimate the intrinsic market value for a major stock market series, such as the S&P Industrials Index. This estimation process has two equally important steps:

\(^6\)Recall that these assumptions may be unrealistic for many stocks, especially for stocks of growth companies. We consider these problems for growth companies and discuss alternative growth company valuation models that consider such conditions in Chapter 14.
1. Estimating the future earnings per share for the stock market series
2. Estimating the appropriate earnings multiplier for the stock market series based on long-run estimates of \( k \) and \( g \).

Some analysts have concentrated on estimating the earnings for a market series with little consideration of changes in the earnings multiplier for the series. An investor who considers only the earnings for the series and ignores the earnings multiplier (i.e., the P/E ratio) assumes that the earnings multiplier will be relatively constant over time. If this were correct, stock prices would generally move in line with earnings. The fallacy of this assumption is obvious when one examines data for the two components during the period from 1993 to 2009, as shown in Exhibit 12.11.

The year-end stock price is the closing value for the S&P Industrials Index on the last trading day of the year. The next column is the percentage change in price for the year. The earnings figure is the earnings per share during the year for the S&P Industrials Index, and the next column shows the percentage change from the prior year. The fifth column is the historical earnings multiplier at the end of the year, which is equal to the year-end value for the S&P Industrials Index divided by the historical earnings for that year. As an example, at the end of 1993, the S&P Industrials Index was equal to $540.19, and the earnings per share for the firms that made up the series were $31.02 for the 12 months ending 12/31/93. This implies an earnings multiplier of 17.42 ($540.19/31.02). Although this may not be the ideal measure of the multiplier, it is consistent in its measurement and shows the changes in the relationship between stock prices and earnings over time. An alternative measure is the forward multiplier using next year’s earnings (i.e., stock price as of 12/31/93 vs. earnings for the 12 months ending 12/31/94). This forward P/E series likewise experiences substantial annual changes and is the multiple we will be estimating. Typically, it is a smaller value and less volatile than the historical multiple because it considers future earnings that are generally higher.

There have been numerous striking examples where annual stock price movements for the S&P Industrials Index were opposite to earnings changes during the same year as follows:

- 1998 profits decreased by almost 17 percent; stock prices increased almost 32 percent.
- 2000 profits increased almost 16 percent; stock prices declined over 17 percent.
- 2002 profits increased over 51 percent; stock prices declined over 24 percent.
- 2003 profits decreased over 12 percent; stock prices increased over 26 percent.
- 2007 profits decreased 9.45 percent; stock prices increased almost 11 percent.

During each of these years, the major influences on stock price movements came from changes in the forward earnings multiplier. The greater volatility of the multiplier series compared to the earnings per share series can be seen from the summary figures at the bottom of Exhibit 12.11 and from the graph of the forward earnings multiplier in Exhibit 12.12. The standard deviation of annual changes for the forward earnings multiplier series is much larger than the standard deviation of EPS changes (42.55 vs. 35.03). The same is true for the relative volatility measures of the coefficient of variability. Also, the standard deviation of the forward multiplier series without signs is larger than for the EPS series (31.77 vs. 26.32). Therefore, these figures show that given the two estimates required for market valuation, the forward earnings multiplier is the more volatile component.

The point of this discussion is not to reduce the importance of the earnings estimate but to note that the estimation of the intrinsic market value requires two separate estimates and both are important and necessary. Therefore, we initially consider a procedure for estimating aggregate earnings followed by the procedure for estimating the forward market earnings multiplier.

---

1Our emphasis will be on estimating future values for EPS, as well as estimating a forward earnings multiple using estimates of \( k \) and \( g \). We will show the relevant variables and provide a procedural framework, but the final estimate depends on the ability of the analyst.
The estimate of expected earnings per share for the market series will consider the outlook for the aggregate economy and for the corporate sector. This requires the following steps:

1. Estimate sales per share for a stock market series, such as the S&P Industrials Index. This estimate of sales involves estimating gross domestic product (GDP) because of the relationship between industrial firm sales and aggregate economic activity. Therefore, we will initially consider sources for an estimate of GDP.

2. Estimate the operating profit margin for the series, which equals operating profit divided by sales. Given the data available from Standard and Poor's, we define operating profit as earnings before interest and taxes (EBIT), similar to the specification in Chapter 10.

3. Estimate interest expense per share for the next year.

4. Estimate the corporate tax rate for the next year.

These steps will lead to an estimate of net earnings per share that will be combined with an estimate of the forward earnings multiplier to arrive at an estimate of the current intrinsic value for the stock market series.

12.5 Estimating Expected Earnings per Share

The estimate of expected earnings per share for the market series will consider the outlook for the aggregate economy and for the corporate sector. This requires the following steps:

1. Estimate sales per share for a stock market series, such as the S&P Industrials Index. This estimate of sales involves estimating gross domestic product (GDP) because of the relationship between industrial firm sales and aggregate economic activity. Therefore, we will initially consider sources for an estimate of GDP.

2. Estimate the operating profit margin for the series, which equals operating profit divided by sales. Given the data available from Standard and Poor’s, we define operating profit as earnings before interest and taxes (EBIT), similar to the specification in Chapter 10.

3. Estimate interest expense per share for the next year.

4. Estimate the corporate tax rate for the next year.

These steps will lead to an estimate of net earnings per share that will be combined with an estimate of the forward earnings multiplier to arrive at an estimate of the current intrinsic value for the stock market series.

12.5.1 Estimating Gross Domestic Product

GDP is a measure of aggregate economic output or activity. Therefore, one would expect aggregate corporate sales to be related to GDP. We begin our estimate of sales with a prediction of nominal GDP from one of several banks or financial service firms that regularly publish such estimates. We use this nominal GDP projection to estimate corporate sales based on the historical relationship between S&P Industrials Index sales per share and aggregate economic activity (GDP).3

3This would include projections by Standard & Poor’s appearing late in the year in the Outlook; and projections by several of the large investment firms, such as Goldman, Sachs, & Company (“The Pocket Chartroom”) or Morgan Stanley, as well as by banks. The Wall Street Journal publishes a survey of over 50 economists every six months that includes estimates of various interest rates, GDP, and inflation.
12.5.2 Estimating Sales per Share for a Market Series

As noted, we will use a sales figure for an existing stock market series—the S&P Industrials Index. Exhibit 12.13 contains the annual nominal GDP and sales per share for the S&P Industrials Index and yearly percent changes in the two series. Generally, a large proportion of the percentage changes in Industrial sales per share can be explained by percentage changes in nominal GDP. The relationship is not stronger because (1) the S&P Industrials Index sales series is more volatile than the GDP series, and (2) the nominal GDP series never experienced a decline until 2009. The equation for the least-squares regression line relating annual percentage changes (%Δ) in the two series as shown in the scatterplot in Exhibit 12.14 for the period 1993–2009 is:

\[
% \Delta \text{S&P Industrials Index Sales} = -0.059 + 2.072 \times (% \Delta \text{in Nominal GDP})
\]

\[
\text{Adj. } R^2 = 0.52
\]

These results indicate that about 52 percent of the variance in percentage changes in S&P Industrial sales can be explained by percentage changes in nominal GDP. Thus, given an estimate of the percentage change in nominal GDP for next year, we can estimate the percentage change in sales for the S&P Industrials Index series and therefore the sales per share. For example, the consensus estimate for economists is that during 2010 nominal GDP increased by approximately 4.1 percent (a 2.8 percent increase in real GDP plus 2.3 percent inflation).

Sales per share figures are available from 1993 in Standard & Poor’s Analysts’ Handbook (New York: Standard & Poor’s Corporation). Because the composite series include numerous companies of different sizes, all data are on a per-share basis. The book is updated annually.
The third method estimates an operating profit margin, defined as earnings before interest and taxes (EBIT), as a percentage of sales. Because this measure of operating earnings as a percentage of sales is not influenced by changes in interest expense or tax rates, it should be a more stable series compared to either the net profit margin or the net before tax margin series. We begin our analysis by estimating this operating profit margin series.

After estimating this operating profit margin, we multiply it by the sales estimate to derive a dollar estimate of operating earnings (EBIT). Subsequently, we will estimate interest expenses, which are subtracted from the EBIT to arrive at earnings before taxes (EBT). Finally, we estimate the expected tax rate (T) and multiply EBT times (1 − T) to get our estimate of net income. The following sections discuss the details of estimating earnings per share, beginning with the operating profit margin.

### 12.5.4 Estimating Aggregate Operating Profit Margin

Finkel and Tuttle (1971) hypothesized that the following four variables affected the aggregate profit margin:

1. Capacity utilization rate
2. Unit labor costs
3. Rate of inflation
4. Foreign competition

**Capacity Utilization Rate**

One would expect a positive relationship between the capacity utilization rate and the profit margin because if production increases as a proportion of total capacity, there is a decrease in per-unit fixed production costs and fixed financial costs. The relationship may not be completely linear at very high rates of capacity utilization because

This estimate, combined with the regression, implies the following increase in S&P Industrial sales for 2010:

\[ \% \Delta \text{S&P Industrials Index Sales} = -0.059 + 2.072 \times (0.041) \]

\[ = 0.0260 \]

\[ = 2.60\% \]

Using an estimate of 2.6 percent, our estimate of 2010 sales is 1,193.75 (we will use 1,194).

Given the continuing recovery in the economy during early 2011, we estimate that nominal GDP in 2011 will increase by 4.9 percent (2.5 percent real growth plus 2.3 percent inflation), which implies an S&P sales growth of about 5.0 percent. Notably, this is referred to as a point estimate of sales because it is based on a point estimate of GDP. Although we know there is actually a distribution of estimates for GDP, we have used the mean value, or expected value, as our point estimate. In actual practice, you would probably consider several estimates and assign probabilities to each of them.

### 12.5.3 Alternative Estimates of Corporate Net Profits

Once sales per share for the market series have been estimated, the difficult estimate is the profit margin. Exhibit 12.15 contains the data on the operating earnings components. Three alternative procedures are possible depending on the desired level of aggregation.

The first is a direct estimate of the net profit margin based on recent trends. As shown in Exhibit 12.15, the net profit margin series is quite volatile because of changes in operating earnings, interest, and the tax rate over time. As such, it is the most difficult series to estimate.

The second procedure would estimate the net before tax (NBT) profit margin. Once the NBT margin is derived, a separate estimate of the tax rate is obtained based on recent tax rates and current government tax pronouncements.
operating diseconomies are introduced as firms are forced to use marginal labor and/or older plant and equipment to reach the higher capacity. The figures in Exhibit 12.16 indicate that capacity utilization ranged from a peak of 84.0 percent in 1995 to a low of 66.2 percent in 2009 following the 2008–2009 recession.

Unit Labor Cost
The change in unit labor cost is a compound effect of two individual factors: (1) changes in wages per hour, and (2) changes in worker productivity. Wage costs per hour typically increase every year by varying amounts depending on the economic environment. As shown in Exhibit 12.16, the annual percentage increase in compensation per hour varied from 1.7 percent in 1994 to 7.2 percent in 2000. If workers did not become more productive, this increase in per-hour wage costs would be the increase in per-unit labor cost. Fortunately, because of advances in technology and greater mechanization, the output per hour (the measure of labor productivity) has increased over time—our labor force has become more productive. If wages per hour increase by 5 percent and labor productivity increases by 5 percent, there would be no increase in unit labor costs because the workers would offset wage increases by producing more. Therefore, the increase in per-unit labor cost is a function of the percentage change in hourly wages minus the increase in productivity during the period. The actual relationship is not this exact due to measurement problems, but it is close as indicated by the data in Exhibit 12.16. For example, during 2001, wage rates increased by 4.0 percent, productivity increased by only 2.5 percent because of the recession, and therefore unit labor costs increased by 1.5 percent. In contrast, during 2002 compensation increased by 3.6 percent but productivity increased by 7.3 percent because of the increased mechanization.

The third method estimates an operating profit margin, defined as earnings before interest and taxes (EBIT), as a percentage of sales. Because this measure of operating earnings as a percentage of sales is not influenced by changes in interest expense or tax rates, it should be a more stable series compared to either the net profit margin or the net before tax margin series. We begin our analysis by estimating this operating profit margin series.

After estimating this operating profit margin, we multiply it by the sales estimate to derive a dollar estimate of operating earnings (EBIT). Subsequently, we will estimate interest expenses, which are subtracted from the EBIT to arrive at earnings before taxes (EBT). Finally, we estimate the expected tax rate (T) and multiply EBT times (1 – T) to get our estimate of net income. The following sections discuss the details of estimating earnings per share, beginning with the operating profit margin.

12.5.4 Estimating Aggregate Operating Profit Margin
Finkel and Tuttle (1971) hypothesized that the following four variables affected the aggregate profit margin:

1. Capacity utilization rate
2. Unit labor costs
3. Rate of inflation
4. Foreign competition

Capacity Utilization Rate One would expect a positive relationship between the capacity utilization rate and the profit margin because if production increases as a proportion of total capacity, there is a decrease in per-unit fixed production costs and fixed financial costs. The relationship may not be completely linear at very high rates of capacity utilization because
operating diseconomies are introduced as firms are forced to use marginal labor and/or older plant and equipment to reach the higher capacity. The figures in Exhibit 12.16 indicate that capacity utilization ranged from a peak of 84.0 percent in 1995 to a low of 66.2 percent in 2009 following the 2008–2009 recession.

**Unit Labor Cost** The change in unit labor cost is a compound effect of two individual factors: (1) changes in wages per hour, and (2) changes in worker productivity. Wage costs per hour typically increase every year by varying amounts depending on the economic environment. As shown in Exhibit 12.16, the annual percentage increase in compensation per hour varied from 1.7 percent in 1994 to 7.2 percent in 2000. If workers did not become more productive, this increase in per-hour wage costs would be the increase in per-unit labor cost. Fortunately, because of advances in technology and greater mechanization, the output per hour (the measure of labor productivity) has increased over time—our labor force has become more productive. If wages per hour increase by 5 percent and labor productivity increases by 5 percent, there would be no increase in unit labor costs because the workers would offset wage increases by producing more. Therefore, the increase in *per-unit labor cost* is a function of the percentage change in hourly wages minus the increase in productivity during the period. The actual relationship is not this exact due to measurement problems, but it is close as indicated by the data in Exhibit 12.16. For example, during 2001, wage rates increased by 4.0 percent, productivity increased by only 2.5 percent because of the recession, and therefore unit labor costs increased by 1.5 percent. In contrast, during 2002 compensation increased by 3.6 percent but productivity

1 2007–2009 data are average of reported Q2 and Q4.

**Sources:** Federal Reserve and Bureau of Labor Statistics.
In contrast, following the peak of the business cycle, firms will be operating at full capacity, so there will be declines in capacity utilization. Also due to inflation, there will be large wage increases and small increases in labor productivity which will result in large increases in unit labor cost. Under these conditions, you should expect a major decline in the operating profit margin following the peak of a business cycle (i.e., a recession).

How do you use this information to estimate an operating profit margin? The most important estimate is the direction of the change from current levels. The size of the estimated change will depend on where the economy is in the business cycle and the direction and size of the expected changes in capacity utilization and unit labor cost.

After estimating the operating profit margin, you can calculate the dollar value of EBIT by applying this operating profit margin estimate to the estimated sales-per-share figure. The next step is to estimate interest expense.

12.5.5 Estimating Interest Expense

The estimate of interest expense should be based on an estimate of debt outstanding (will it grow and by how much?) and the level of interest rates (do you expect interest rates to increase or decline in the future?).

The point is, to estimate interest expense you need to estimate both of these components (the amount of debt outstanding and the cost of the debt) and determine the joint effect. The basic data are listed in Exhibit 12.17. The time-series plot of debt outstanding (Exhibit 12.18) shows an overall increase, but also an increase in the rate of growth during the recent period 2007–2009. Finally, a time-series plot of the average interest rate on debt in Exhibit 12.19 indicates an increase to about 8 percent in 2006, followed by a steady decline to about 6 percent in 2009. The combination of these two factors (the amount of the debt and the cost of the debt) produces the interest expense plot in Exhibit 12.20. Note the positive trend in the interest expense series from 2005 to 2008 consistent with the growth in debt outstanding but there was a decline in interest expense in 2009, because even though debt outstanding increased, interest rates experienced a significant decline during the year.

Under these conditions, you should expect a major decline in the operating profit margin following the peak of a business cycle (i.e., a recession).

Rate of Inflation The precise effect of inflation on the aggregate profit margin is unresolved. Finkel and Tuttle hypothesized a positive relationship between inflation and the profit margin. They contended that a higher level of inflation increases the ability of firms to pass higher costs on to the consumer and thereby raise their profit margin. Second, assuming the classic demand-pull inflation, the increase in prices would indicate an increase in general economic activity, which typically is accompanied by higher margins.

In contrast, many observers doubt that most businesses can consistently increase prices in line with rising costs. Assuming a 5 percent rate of inflation that impacts costs, the question is whether all firms can completely pass these cost increases along to their customers. If a firm increases prices at the same rate as cost increases, it will experience a constant profit margin, not an increase. Only if a firm can raise prices by more than cost increases can it increase its profit margin. Many firms are not able to raise prices in line with increased costs because of the elasticity of demand for their products, which will cause the profit margin to decline. Given the alternative scenarios, it is contended that virtually no firms will be able to increase their profit margins and very few firms will be able to hold profit margins constant during a period of inflation. Assuming this scenario, one would expect the aggregate profit margin to decline when there is an increase in the rate of inflation.

Given the contrasting expectations, one needs to consider the empirical evidence to determine the relationship between inflation and the operating profit margin.

Foreign Competition Finkel and Tuttle (1971) contend that export markets are more competitive than domestic markets, so export sales are made at a lower margin. This implies that lower exports by U.S. firms would increase profit margins. In contrast, Gray (1976) believed that only exports between independent firms should be considered and they should be examined relative to total output exported. Further, he felt that imports could have an important negative impact on the operating profit margin because they influence the selling price of all competing domestic products. Given these divergent expectations regarding the ultimate effect of foreign trade on the operating profit margin, this is likewise an empirical question.

Analysis of Effects Our analysis of the annual data for the period 1977 to 2009 confirmed that the relationship between the operating profit margin and the capacity utilization rate was always significant and positive. In addition, the expected relationship between the unit labor cost and the operating profit margin was likewise confirmed—it was always negative and significant. Alternatively, the rate of inflation and foreign trade variables were never significant in the multiple regression. Finally, the univariate correlation between the profit margin and inflation was consistently negative.

Therefore, given these empirical results, when estimating the operating profit margin, you should concentrate on the capacity utilization rate for the economy and the rate of change in unit labor cost. As an example, consider what will happen at two extremes of the business cycle. Coming out of a recession, capacity utilization will be increasing while unit labor costs will rise very slowly, due to increased labor productivity. Given this positive economic scenario, you should expect an increase in the operating profit margin.

---

10 An extreme example of this inability is regulated industries that may not be able to raise prices at all until after lengthy hearings before regulatory agencies. Even then, the increase in rates may not match the cost increase.
In contrast, following the peak of the business cycle, firms will be operating at full capacity, so there will be declines in capacity utilization. Also due to inflation, there will be large wage increases and small increases in labor productivity which will result in large increases in unit labor cost. Under these conditions, you should expect a major decline in the operating profit margin following the peak of a business cycle (i.e., a recession).

How do you use this information to estimate an operating profit margin? The most important estimate is the direction of the change from current levels. The size of the estimated change will depend on where the economy is in the business cycle and the direction and size of the expected changes in capacity utilization and unit labor cost.

After estimating the operating profit margin, you can calculate the dollar value of EBIT by applying this operating profit margin estimate to the estimated sales-per-share figure. The next step is to estimate interest expense.

### 12.5.5 Estimating Interest Expense

The estimate of interest expense should be based on an estimate of debt outstanding (will it grow and by how much?) and the level of interest rates (do you expect interest rates to increase or decline in the future?).

The point is, to estimate interest expense you need to estimate both of these components (the amount of debt outstanding and the average interest rate on this debt) and determine the joint effect. The basic data are listed in Exhibit 12.17. The time-series plot of debt outstanding (Exhibit 12.18) shows an overall increase, but also an increase in the rate of growth during the recent period 2007–2009. Finally, a time-series plot of the average interest rate on debt in Exhibit 12.19 indicates an increase to about 8 percent in 2006, followed by a steady decline to about 6 percent in 2009. The combination of these two factors (the amount of the debt and the cost of the debt) produces the interest expense plot in Exhibit 12.20. Note the positive trend in the interest expense series from 2005 to 2008 consistent with the growth in debt outstanding but there was a decline in interest expense in 2009, because even though debt outstanding increased, interest rates experienced a significant decline during the year.

12.5.6 Estimating the Tax Rate

This is the final step in estimating the earnings per share for the S&P Industrials Index series. As shown in Exhibit 12.15, the average tax rate during the 17-year period was about 35 percent, which is also consistent with the rate over the last 15 of 17 years to be between 30 and 40 percent.

Estimating the future tax rate is difficult because it depends on political action. You must evaluate the current tax rate and recent tax legislation that affects business firms (e.g., tax credits). Once you have estimated the tax rate ($T$), you multiply one minus this tax rate ($1 - T$) times the EBT per share figure to derive an estimate of the net income per share for the S&P Industrials Index series.

In the next section, we demonstrate this procedure by estimating S&P Industrial earnings per share for 2011.

12.5.7 Calculating Earnings per Share: An Example

The following demonstration emphasizes the procedure rather than the actual numbers. A practicing analyst would provide a long, detailed analysis. In this example, we estimate earnings per share for the S&P Industrials Index during 2011 using 2010 data (most of which is estimated).

Step 1

Estimate nominal GDP for 2010 and 2011. We made such an estimate earlier in the chapter using the data in Exhibit 12.13. It was envisioned that nominal economic growth in 2010 was sluggish coming out of the recession at 4.1 percent, and GDP would experience a small increase in growth during 2011 to 5.0 percent. Given GDP in 2009 of $14,119 billion, this implies a 2010 GDP estimate of $14,698 billion and an estimate of $15,492 billion for 2011.

Step 2

Estimate corporate sales for 2010 and 2011 based on GDP growth. Using the regression model derived from the data in Exhibit 12.13, corporate sales in 2010 are estimated to grow by 2.6 percent to 1,194, and to grow by 5.3 percent in 2011 to 1,257.

An estimate of debt outstanding requires two estimates: (1) the value of total assets for the firm based upon the firm’s expected total asset turnover, and (2) the expected capital structure based upon the average total debt to total asset ratio. Both of these ratios are included in Exhibit 12.17.

Notably, interest expense is a fixed expense that is impacted by corporate financing decisions and volatile changes in the cost of debt (i.e., interest rates). Therefore, interest expense as a percent of sales should not be used when estimating interest expense.

After you have estimated the interest expense figure (time-series plot in Exhibit 12.20), this value is subtracted from the EBIT per share value to arrive at an estimate of EBT.
**Step 3**

Estimate the operating profit margin for 2010 and 2011. Recall from Exhibit 12.15 that this margin declined sharply in 2008 to 9.40% and experienced a small recovery in 2009 to 10.75%. In 2010, we expect an increase in capacity utilization from the historic low value of 66.2 percent and a similar increase in 2011. We would likewise envision fairly low increases in unit labor costs for both years, because wage increases will be muted given the historically high unemployment rates that was in the 8–9 percent range, while percent productivity should become a small positive value in 2010 and increase in 2011. Because of these two positive factors (increases in capacity utilization and small increases in unit labor cost), we estimate an operating margin in 2010 of 11.50% and in 2011 of 12.50%, which implies operating earnings of 137.31 (0.1150 × 1,194) in 2010 and 157.13 (0.1250 × 1,257) in 2011.

**Step 4**

Interest expense experienced relatively steady increases over the period 2004–2008 because of increases in debt outstanding. In 2009, there was a small decline for interest expense due to lower interest rates. We envision another small decline in interest expenses during 2010 to about 19.0 because of a further decline in interest rates to about 5.50% caused by continued Federal Reserve easing. In 2011, we previously estimated sales of 1,257 and expect total asset turnover to return to about 0.85, which implies total assets in 2011 of 1,479 (1,257/0.85). In addition, the percent of debt to assets has increased to about 0.23, and assuming this rate of debt financing continues, it would indicate total debt of 340 (0.23 × 1,479). While interest rates have been declining, we envision stable rates in 2011, which implies an interest expense estimate of 18.7 (0.055 × 340) for 2011. Given this interest expense and the prior EBIT of 157.13 indicates an EBT value of 138.43 (157.13 − 18.70).

**Step 5**

The tax rate suggested by our earlier analysis was 35 percent. Using this rate for 2011 indicates net income for 2011 of $89.98 (138.43 × 0.65). For simplicity, we will round this to an EPS estimate of $90.

These estimates (rounded) can be summarized as follows:

<table>
<thead>
<tr>
<th>Sales</th>
<th>EBIT</th>
<th>Interest Expense</th>
<th>EBT</th>
<th>Taxes</th>
<th>Net Income (EPS)</th>

<td>19.0</td>
<td>138</td>
<td>48.8</td>
<td>$90.0</td>
</tr>
</tbody>
</table>

**12.5.6 Estimating the Tax Rate**

This is the final step in estimating the earnings per share for the S&P Industrials Index series. As shown in Exhibit 12.15, the average tax rate during the 17-year period was about 35 percent, which is also consistent with the rate over the last 15 of 17 years to be between 30 and 40 percent.

Estimating the future tax rate is difficult because it depends on political action. You must evaluate the current tax rate and recent tax legislation that affects business firms (e.g., tax credits). Once you have estimated the tax rate \( T \), you multiply one minus this tax rate \( (1 - T) \) times the EBT per share figure to derive an estimate of the net income per share for the S&P Industrials Index series.

In the next section, we demonstrate this procedure by estimating S&P Industrial earnings per share for 2011.

**12.5.7 Calculating Earnings per Share: An Example**

The following demonstration emphasizes the procedure rather than the actual numbers. A practicing analyst would provide a long, detailed analysis. In this example, we estimate earnings per share for the S&P Industrials Index during 2011 using 2010 data (most of which is estimated).

**Step 1** Estimate nominal GDP for 2010 and 2011. We made such an estimate earlier in the chapter using the data in Exhibit 12.13. It was envisioned that nominal economic growth in 2010 was sluggish coming out of the recession at 4.1 percent, and GDP would experience a small increase in growth during 2011 to 5.0 percent. Given GDP in 2009 of $14,119 billion, this implies a 2010 GDP estimate of $14,698 billion and an estimate of $15,492 billion for 2011.

**Step 2** Estimate corporate sales for 2010 and 2011 based on GDP growth. Using the regression model derived from the data in Exhibit 12.13, corporate sales in 2010 are estimated to grow by 2.6 percent to 1,194, and to grow by 5.3 percent in 2011 to 1,257.
12.6.1 Determinants of the Earnings Multiplier

Recall the variables that influence the earnings multiplier or the P/E ratio based on the dividend discount model:

\[ P = \frac{E}{D} \]

where:

- \( D_1 \) = dividends expected in Period 1, which is equal to \( D_0 \left(1 + g\right) \)
- \( E_1 \) = earnings expected in Period 1
- \( D_1 / E_1 \) = the dividend-payout ratio expected in Period 1
- \( k \) = the required rate of return on the stock
- \( g \) = the expected growth rate of dividends for the stock

Therefore, the major variables that affect the aggregate stock market earnings multiplier in a country are:

- The composite dividend-payout ratio for common stocks in a country
- The required rate of return on common stock in the country being analyzed
- The expected growth rate of dividends for the stocks in the country being analyzed

Because this equation is derived from the dividend discount model, it assumes constant growth for an infinite period. Also, the required rate of return is the long-term estimate. Thus, \( k \) and \( g \) projections are long-term estimates. Thus, although these variables can be impacted by near-term events, they should not experience major changes on a year-to-year basis.

It is easier to discuss the dividend-payout ratio after we have considered both \( k \) and \( g \). Therefore, we consider \( k \) and \( g \) before \( D_1 / E_1 \).

12.6.2 Estimating the Required Rate of Return (\( k \))

The multiplier equation indicates that the earnings multiplier is inversely related to the required rate of return. Earlier in the chapter, we discussed what determines \( k \), and we derived a range of estimates of \( k \) as follows:

<table>
<thead>
<tr>
<th>Description</th>
<th>NRFR</th>
<th>Risk Premium</th>

</tr>
<tr>
<td>Long-term RFR and historical risk premium</td>
<td>0.043</td>
<td>0.06</td>
</tr>
</tbody>
</table>

12.6.3 Estimating the Growth Rate of Dividends (\( g \))

Earlier, we discussed the estimated growth rate of earnings and dividends using Equation 12.4 as follows:

\[ g = b \times \text{ROE} \]

After discussing dividend payouts over the business cycle, we suggested using a long-run retention rate (\( b \)) of 55 percent. We estimated a long-run ROE based upon an analysis of the three components of the DuPont analysis of 13 percent. The combined result was:

\[ g = 0.071 = 7\% \]

For simplicity, we used \( g = 7\% \).

Step 5 The tax rate suggested by our earlier analysis was 35 percent. Using this rate for 2011 indicates net income for 2011 of $89.98 (138.43 x 0.65). For simplicity, we will round this to an EPS estimate of $90.

These estimates (rounded) can be summarized as follows:

12.6 Estimating the Stock Market Earnings Multiplier

Given our estimate of earnings per share, the next step is to estimate an earnings multiplier. A combination of the earnings per share estimate times the estimated forward earnings multiplier provides an estimate of the intrinsic value for the stock market series. Similar to the investment decision rule with the cash flow valuations, if the intrinsic value based on the forward P/E ratio and estimated EPS is greater than the current market price, we should overweight U.S. common stocks; if the value is below the market price we should underweight U.S. common stocks.

Our prior discussion of Exhibit 12.11 indicated that the earnings multiplier (i.e., P/E ratio) over time has been more volatile than the earnings per share series because the multiplier is very sensitive to changes in the spread between \( k \) and \( g \). We will examine each of the variables in the P/E ratio equation to determine why they change and demonstrate how an investor would estimate a value for the earnings multiplier.
12.6.4 Estimating the Dividend-Payout Ratio \( \left( \frac{D}{E} \right) \)

Based on the \( P/E \) equation, there is a positive relationship between the dividend-payout ratio and the \( P/E \) ratio. Therefore, if the \( k - g \) spread is constant and this dividend-payout ratio increases, there will be an increase in the earnings multiplier. Recall that the dividend-payout ratio is equal to one minus the earnings retention rate \( b \). Therefore, if the dividend-payout increases, there will be a decline in the earnings retention rate \( b \), which will cause a decline in the growth rate \( g \). Thus, there is a partial offset between changes in the dividend-payout rate and the expected growth rate \( g \).

In the discussion of the growth rate, we indicated that the retention rate was high in the 1970s, declined in the early 1980s, and has increased again since 1993. This increase in the retention rate implies that the payout ratio has declined recently.

Dividend Payout Rate — Active or Residual Decision?

When estimating the dividend payout for the aggregate market or an individual firm, you must consider whether the dividend payout rate is (1) an active decision of management (and the board of directors), or (2) a residual outcome because the active decision is the dividend payment. Obviously, if the dividend payout rate is the active decision, the dividend payment would vary over time in line with earnings. In contrast, if the dividend payment is the active decision, the dividend payout rate is a residual outcome. In this latter case, the dividend payments would be reasonably stable and show fairly steady increases, while the dividend-payout ratio would be very volatile because it would be dictated by the earnings. That is, the dividend payout rate would increase dramatically during periods of low earnings and decline significantly during periods of high earnings growth.

The time-series plots in Exhibits 12.21 and 12.22 support the residual payout theory because they show fairly constant changes in dividend payments (Exhibit 12.21) but high volatility for Exhibit 12.22.
Given these estimates of $k$, $g$, and dividend payout (1 minus the retention rate of 0.55), the following section discusses the estimation of the earnings multiples.

### 12.6.4 Estimating the Dividend-Payout Ratio ($D_1/E_1$)

Based on the $P/E$ equation, there is a positive relationship between the dividend-payout ratio and the $P/E$ ratio. Therefore, if the $k$–$g$ spread is constant and this dividend-payout ratio increases, there will be an increase in the earnings multiplier. Recall that the dividend-payout ratio is equal to one minus the earnings retention rate ($b$). Therefore, if the dividend-payout increases, there will be a decline in the earnings retention rate ($b$), which will cause a decline in the growth rate ($g$). Thus, there is a partial offset between changes in the dividend-payout rate and the expected growth rate ($g$).

In the discussion of the growth rate, we indicated that the retention rate was high in the 1970s, declined in the early 1980s, and has increased again since 1993. This increase in the retention rate implies that the payout ratio has declined recently.

**Dividend Payout Rate—Active or Residual Decision?** When estimating the dividend payout for the aggregate market or an individual firm, you must consider whether the dividend payout rate is (1) an active decision of management (and the board of directors), or (2) a residual outcome because the active decision is the dividend payment. Obviously, if the dividend payout rate is the active decision, the dividend payment would vary over time in line with earnings. In contrast, if the dividend payment is the active decision, the dividend payout rate is a residual outcome. In this latter case, the dividend payments would be reasonably stable and show fairly steady increases, while the dividend-payout ratio would be very volatile because it would be dictated by the earnings. That is, the dividend payout rate would increase dramatically during periods of low earnings and decline significantly during periods of high earnings growth.

The time-series plots in Exhibits 12.21 and 12.22 support the residual payout theory because they show fairly constant changes in dividend payments (Exhibit 12.21) but high volatility for

---

**Source:** Data from Standard & Poor’s Analysts’ Handbook.
The variables that must be estimated are:

1. Changes in the dividend-payout ratio
2. Changes in the real RFR
3. Changes in the rate of inflation
4. Changes in the risk premium for common stock
5. Changes in the earnings retention rate
6. Changes in the return on equity (ROE)

The changes envisioned for 2011 will be heavily impacted by the continuing sluggish recovery projected for 2011. The dividend-payout ratio declined in 2009 and probably declined again in 2010 with higher earnings. The earnings growth in 2011 is expected to be slightly higher than in 2010, so the payout ratio should be slightly lower than in 2010.

Given the three variables that affect the required rate of return on common stocks (k), we expect a small increase in the real RFR in 2011 consistent with the small increase in the real growth rate. The rate of inflation during 2010 was 2.7 percent and is expected to increase slightly in 2011. Finally, the equity risk premium is expected to increase in 2011 after a significant decrease during 2010. In summary, we envision a small increase in all three components: RFR, expected inflation, and the risk premium. Therefore, we expect an increase in k during 2011.

The last two factors in the earnings multiplier estimate relate to the growth rate. As discussed, we expect a lower payout rate, which implies higher retention rate. The outlook is for a small increase in the aggregate ROE during 2011. Specifically, both the profit margin and the total asset turnover are expected to increase given the continuing recovery in 2011. Finally, we envision a small decline in the financial leverage ratio as firms continue to reduce their financial risk given the memories of the financial crash. The overall result should be a small increase in the ROE during 2011. Therefore, with an increase in both the retention rate and in ROE, we envision a small increase in the expected growth rate. In summary, we expect:

- A decrease in the payout ratio
- A small increase in the required rate of return
- A small increase in the expected growth rate

Overall, this would imply a small increase or no change in the earnings multiplier. The forward earnings multiplier early in 2011 is about 14 times. This discussion indicates the estimated multiplier would be about 14 to 15 times during 2011.

### 12.6.5 Estimating an Earnings Multiplier: An Example

There are two ways to estimate the earnings multiplier. The first approach begins with the current earnings multiplier and estimates the direction and amount of change based on expected changes in the three major components.

The second approach estimates a specific value for the earnings multiplier based on specific estimates for the three components in the P/E ratio equation. This approach typically involves deriving several estimates based on optimistic or pessimistic scenarios.

**The Direction of Change Approach** Begin with the current earnings multiplier and estimate the direction and extent of change for the dividend payout and the variables that influence k and g. The direction of the change is more important than its size.
The variables that must be estimated are:

1. Changes in the dividend-payout ratio
2. Changes in the real \( RFR \)
3. Changes in the rate of inflation
4. Changes in the risk premium for common stock
5. Changes in the earnings retention rate
6. Changes in the return on equity (\( ROE \)) \{ \}
7. Changes in \( k \)
8. Changes in \( g \)

The changes envisioned for 2011 will be heavily impacted by the continuing sluggish recovery projected for 2011. The dividend-payout ratio declined in 2009 and probably declined again in 2010 with higher earnings. The earnings growth in 2011 is expected to be slightly higher than in 2010, so the payout ratio should be slightly lower than in 2010.

Given the three variables that affect the required rate of return on common stocks (\( k \)), we expect a small increase in the real \( RFR \) in 2011 consistent with the small increase in the real growth rate. The rate of inflation during 2010 was 2.7 percent and is expected to increase slightly in 2011. Finally, the equity risk premium is expected to increase in 2011 after a significant decrease during 2010. In summary, we envision a small increase in all three components: \( RFR \), expected inflation, and the risk premium. Therefore, we expect an increase in \( k \) during 2011.

The last two factors in the earnings multiplier estimate relate to the growth rate. As discussed, we expect a lower payout rate, which implies higher retention rate. The outlook is for a small increase in the aggregate \( ROE \) during 2011. Specifically, both the profit margin and the total asset turnover are expected to increase given the continuing recovery in 2011. Finally, we envision a small decline in the financial leverage ratio as firms continue to reduce their financial risk given the memories of the financial crash. The overall result should be a small increase in the \( ROE \) during 2011. Therefore, with an increase in both the retention rate and in \( ROE \), we envision a small increase in the expected growth rate. In summary, we expect:

- A decrease in the payout ratio
- A small increase in the required rate of return
- A small increase in the expected growth rate

Overall, this would imply a small increase or no change in the earnings multiplier. The forward earnings multiplier early in 2011 is about 14 times. This discussion indicates the estimated multiplier would be about 14 to 15 times during 2011.

### Specific Estimate Approach

This approach derives specific estimates for the earnings multiplier based on a range of estimates for the dividend payout (\( D/E \)), required rate of return (\( k \)), and expected growth (\( g \)). Although the payout ratio has fluctuated between 35 and 55 percent during the past 10 years, we expect it to be at midrange (45 percent) due to the small earnings increase envisioned for 2011 at the time of this writing.

As discussed, the required rate (\( k \)) can be estimated using the interest rate on government bonds plus a risk premium for common stocks between 2 and 6 percent. As noted before, in early 2011, the rate on T-bills was about 0.008 percent, the rate on 10-year government bonds was about 3.20 percent, and the rate on long-term bonds was 4.30 percent. Notably, these interest rates are at the low end of the range for the past 20 years, and most observers expect an increase during the year. Assuming an adjustment to reflect this, you could conceive of the following possibilities:
12.6.6 Calculating an Estimate of the Value for the Market Series

Previously, we estimated the earnings per share for Standard and Poor's Industrials Index of $90. Clearly, it would have been possible to derive additional earnings estimates. In our work with the P/E, we developed several estimates for the price/earnings multiplier that varied from about 15 to 25. At this point, we can combine these estimates of an earnings per share of $90 and the several earnings multipliers and calculate the following estimates of intrinsic value for Standard & Poor's Industrials Index series:

\[
\begin{align*}
15: & \quad 0 \times 90 = 1,350 \\
17:5 & \quad 5 \times 90 = 1,575 \\
20: & \quad 0 \times 90 = 1,800 \\
22:5 & \quad 5 \times 90 = 2,025 \\
25: & \quad 0 \times 90 = 2,250
\end{align*}
\]

You would compare these several intrinsic value estimates to the current price of the market, which is about 1,770—that is, two of the valuations indicate a clear overweight, one would indicate close to a market weight and two would suggest underweighting the U.S. market in a global portfolio. Alternatively, the current market is selling for a P/E of 19.67 (1,770/90), which is close to the midrange P/E estimate. Also, as indicated in Exhibit 12.23, the average forward P/E for the latest five years is 20.8 times.

This example is intended to help you understand the estimation procedure. The estimation of values for D/E, k, and g was not as extensive as the process used by professional analysts. In addition, we used a point estimate for earnings per share rather than a range of estimates (pessimistic, optimistic, most likely), which would have been preferable. Our discussion has provided the skeleton of the process that includes the theoretical background that forms the foundation for the fundamental analysis of stocks. It is important to understand the relevant variables and how they relate to the critical estimates of earnings per share.

By combining the more optimistic figures (with a positive k-g spread), we can derive a reasonably generous estimate. Using the pessimistic estimates, we can derive a fairly conservative estimate. The dividend-payout (D/E) figure should be consistent with the retention rate.

The fact is, it is not feasible to combine the maximum components because it would generate a negative k-g spread, which is undefined. The most reasonable spread is 2 percent, which provides the following result:

**High Estimate:** $D/E = 0.50$

\[
k = 0.09
\]

\[
g = 0.07 (0.50 \times 0.14)
\]

\[
P/E = \frac{0.50}{0.09 - 0.07} = \frac{0.50}{0.02} = 25 \text{ times}
\]

Obviously, if we assume a spread of only 1 percent, the estimated P/E would be 50 times, which is unrealistic for the aggregate stock market.

**Low Estimate:** $D/E = 0.60$

\[
k = 0.10
\]

\[
g = 0.06
\]

\[
P/E = \frac{0.60}{0.10 - 0.06} = \frac{0.60}{0.04} = 15 \text{ times}
\]

Therefore, these data imply a range of earnings multiplier from about 15 times to about 25 times with a midrange of about 20 times. The low estimate is consistent with the expectation of a P/E ratio range of 14–15 derived from the direction of change approach.
12.6.6 Calculating an Estimate of the Value of the Market Series

Previously, we estimated the earnings per share for Standard and Poor’s Industrials Index of $90. Clearly, it would have been possible to derive additional earnings estimates.

In our work with the P/E, we developed several estimates for the price/earnings multiplier that varied from about 15 to 25. At this point, we can combine these estimates of an earnings per share of $90 and the several earnings multipliers and calculate the following estimates of intrinsic value for Standard & Poor’s Industrials Index series:

\[
15.0 \times 90 = 1,350 \\
17.5 \times 90 = 1,575 \\
20.0 \times 90 = 1,800 \\
22.5 \times 90 = 2,025 \\
25.0 \times 90 = 2,250
\]

You would compare these several intrinsic value estimates to the current price of the market, which is about 1,770—that is, two of the valuations indicate a clear overweight, one would indicate close to a market weight and two would suggest underweighting the U.S. market in a global portfolio. Alternatively, the current market is selling for a P/E of 19.67 (1,770/90), which is close to the midrange P/E estimate. Also, as indicated in Exhibit 12.23, the average forward P/E for the latest five years is 20.8 times.

This example is intended to help you understand the estimation procedure. The estimation of values for $/E, k, and g was not as extensive as the process used by professional analysts. In addition, we used a point estimate for earnings per share rather than a range of estimates (pessimistic, optimistic, most likely), which would have been preferable. Our discussion has provided the skeleton of the process that includes the theoretical background that forms the foundation for the fundamental analysis of stocks. and the earnings multiplier. Notably, the two critical estimates that are necessary for both the present value of cash flow models and the earnings multiplier approach are $k$ and $g$—that is, the required rate of return discount rate and the expected growth rate of earnings, cash flow, and dividends.

### 12.6.7 Using Other Relative Valuation Ratios

In addition to the $P/E$ ratio, several other ratios are used by investors as indicators of relative value. Specifically, when doing an industry and company stock analysis, analysts compare these valuation ratios to similar ratios for the aggregate market, other industries, and other stocks in an industry. Therefore, it is important to become familiar with the computation and historical movements for these ratios. The other relative valuation ratios considered are:

- Price-to-book-value ratio ($P/BV$)
- Price-to-cash-flow ratio ($P/CF$)
- Price-to-sales ratio ($P/S$)

#### Calculation of Relative Valuation Ratios

The calculation of each of these ratios is generally straightforward with some differences in the measurement of the valuation variable (i.e., $BV$, $CF$, or $S$). Again, it is necessary to decide whether one uses historical data or forward values—that is, do you compare the current price to the historical valuation variable (e.g., cash flow for the prior year) or to the future expected variable (e.g., the expected cash flow for the industry or company). As before, the authors prefer forward valuation ratios.

The price-to-book-value ($P/BV$) ratio for current valuation purposes is equal to the current stock price divided by the equity book value per share of the entity. In the current case, because we are computing the relative valuation ratios for historical exposition purposes, we use the average price, which is equal to the average of the high and low prices for the year. Again, you must determine whether you want to use historical book value (i.e., compare the average stock price for Year $t$ to the book value at the end of Year $t$) or use future book value (i.e., average stock price for Year $t$ to estimated book value for Year $t + 1$). Similar to the $P/E$ ratio, when you compute a future ratio, the ratio will generally be lower and less volatile. Both sets of $P/BV$ ratios are contained in Exhibit 12.23 and plotted in Exhibit 12.24. The future ratios are computed using actual values for Period $t + 1$ except for the last year (2009) that would have required 2010 values that were not available.

The price-to-cash-flow ($P/CF$) ratio is equal to the average stock price for Year $t$ divided by either the historical or the estimated cash flow per share. Similar to most analysts, we use EBITDA for demonstration purposes, even though it is a very imperfect measure of cash flow. Again, we use actual EBITDA in Period $t + 1$ for the future ratio except for the final year. The data are in Exhibit 12.23 and plotted in Exhibit 12.25.

The price-to-sales ($P/S$) ratio is equal to the average stock price for Year $t$ divided by net sales per share during Year $t$ or an estimate of sales per share for Year $t + 1$. Again, for the future $P/S$ ratio, we use actual sales per share during Period $t + 1$ except for the final year. The results are in Exhibit 12.23 and plotted in Exhibit 12.26.

To understand why these valuation ratios generally were higher in 2009 than in 1993, it is necessary to consider what factors drive the particular valuation ratio and whether these factors have changed over time. In the case of the $P/E$ ratio, we know from DDM that the relevant variables are $k$ and $g$ for the economic unit. Therefore, when attempting to explain why the market $P/E$ ratio has gone from about 15 times to 19 times, you would consider what has happened to these two variables. Without going into detail, we know that $k$ has declined over time due to lower inflation and some evidence that the market risk premium has declined. In addition, the aggregate ROE has been fairly stable, so the expected growth rate has been constant. In summary, the $k$–$g$ spread has declined, so a higher $P/E$ is justified. How much higher
valuation variables because when investors buy a stock, they are buying future earnings, cash flows, book values, or sales. Therefore, you need to think in these terms when using these ratios for valuation. Similar to valuations using the $P/E$ ratio, you would almost certainly estimate these valuation variables (i.e., $BV$, $CF$, or sales per share) and then apply an appropriate future multiple to the valuation variable to derive an estimate of intrinsic value.

it should be is subject to estimation and debate. Subsequently, we will discuss the relevant factors for the other ratios.

The plots also show considerable consistency between the time series using historical and future expected data. Again, the authors have a definite preference for using the future
valuation variables because when investors buy a stock, they are buying future earnings, cash flows, book values, or sales. Therefore, you need to think in these terms when using these ratios for valuation. Similar to valuations using the P/E ratio, you would almost certainly estimate these valuation variables (i.e., BV, CF, or sales per share) and then apply an appropriate future multiple to the valuation variable to derive an estimate of intrinsic value.

**12.7 Microvaluation of World Markets**

Similar to our discussion at the end of the macroeconomic analysis of the market, we need to briefly consider some of the unique factors when deriving a microvaluation for markets outside the United States.

It is crucial to keep three important factors in mind. First, the basic valuation model and concepts apply globally. Specifically, value is still based on the discounted value of future cash flows whether you are in New York, London, Moscow, or Beijing. Also, the ultimate decision is still based on the relationship between estimated intrinsic value and the market price.

Second, while the models and concepts are the same, the input values can and will vary dramatically across countries, which means that values will differ and opportunities will differ—for example, when stocks appear overpriced in the United States, they may be undervalued in Japan or Australia, which provides an opportunity to adjust your global asset allocations.

Third, the valuation of nondomestic markets will almost certainly be more onerous because of several additional variables or constraints that must be considered. The most obvious is that you must estimate a value in the local currency but also estimate potential changes in the value of the foreign currency relative to the U.S. dollar. The difficulty of estimating these changes or attempting to hedge this currency risk (if it is possible) becomes an added risk factor discussed in Chapter 1—exchange rate risk.

It is also necessary to consider country or political risk, which can be very significant in many countries. This risk generally cannot be hedged away. Notably, investors in U.S. stocks generally do not think about this risk even during elections. The only change has been terrorist
Finally, because we know it is necessary to do a similar analysis for non-U.S. markets, we discussed some of the additional factors involved in non-U.S. market analysis. Following this aggregate market analysis, the next step is industry analysis, which is considered in the following chapter.

QUESTIONS

1. Why would you expect a relationship between economic activity and stock price movements?
2. At a lunch with some business associates, you discuss the reason for the relationship between the economy and the stock market. One of your associates contends that she has heard that stock prices typically turn before the economy does. How would you explain this phenomenon?
3. Explain the following statements: (a) There is a strong, consistent relationship between money supply changes and stock prices. (b) Money supply changes cannot be used to predict stock price movements.
4. The current rate of inflation is 3 percent, and long-term Treasury bonds are yielding 7 percent. You estimate that the rate of inflation will increase to 6 percent. What do you expect to happen to long-term bond yields? Compute the effect of this estimated change in inflation on the price of a 15-year, 10 percent coupon bond with a current yield to maturity of 8 percent.
5. Some observers contend that it is harder to estimate the effect of a change in interest rates on common stocks than on bonds. Discuss this contention.
6. An investor is convinced that the stock market will experience a substantial increase next year because corporate earnings are expected to rise by at least 12 percent. Do you agree or disagree? Why or why not?
7. Find at least three sources of historical information on nominal and real GDP. Find two sources of an annual estimate of nominal GDP.
8. To arrive at an estimate of the net profit margin, why would you spend time estimating the operating profit margin and work down?
9. You are convinced that capacity utilization next year will decline from 82 percent to about 79 percent. Explain what effect that only this change will have on the operating profit margin.
10. You see an estimate that hourly wage rates will increase by 6 percent next year. What other information do you need to determine the effect of this wage rate increase on the operating profit margin, and why do you need it?
11. It is estimated that next year hourly wage rates will increase by 7 percent and productivity will increase by 5 percent. What would you expect to happen to unit labor cost?

SUMMARY

In earlier chapters, we emphasized the importance of analyzing the aggregate markets before any industry or company analysis. You must assess the economic and security market outlooks and their implications regarding the bond, stock, and cash components of your portfolio. Then you proceed to consider the best industry or company.

- Two techniques are used to make the market decision: (1) the macroeconomic technique, which is based on the relationship between the aggregate economy and the stock market; and (2) the microeconomic technique, which determines future market values by applying the two valuation approaches discussed in Chapter 11 to the aggregate stock market.
- The economy and the stock market have a strong, consistent relationship, but the stock market generally turns before the economy does. Therefore, the best macroeconomic projection techniques use economic series that likewise lead the economy, and possibly the stock market. The Conference Board leading indicator series (which includes stock prices) is one possibility.
- The money supply has been suggested as a predictor of aggregate market behavior based on its relationship to the economy. Some early studies indicated a strong relationship and suggested that money supply changes turned before stock prices. Subsequent studies confirmed the link between money supply and stock prices, but indicated that stock prices turn with or before money supply changes. Recent studies show that the monetary policy environment has an important impact on security market returns and also affects how stocks relate to other variables.
- Our microanalysis of the U.S. equity market considered both approaches to equity analysis—the present value of cash flow techniques and the relative valuation ratio techniques. The cash flow techniques provided a range of estimates which indicated that the rates of return on common stock in the near term will be similar to the long-run historical returns.
- We considered four relative valuation ratios, including the earnings multiple (P/E) approach, where we discussed a two-step approach (that included estimating EPS and the P/E ratio) and generated a specific intrinsic market value. The other three ratios (P/BV, P/CF, and P/S) were defined and explained in anticipation of using them during industry and company analysis, where the relative valuation technique compares an industry to the market and relates a company to both its industry and the aggregate market. The goal is to evaluate the relative value position of an industry or a stock. This initial analysis of the valuation ratios demonstrated the computations involved. Subsequent analysis will consider what variables drive these relative valuation ratios and evaluate whether these variables have changed in a way that justifies current values.
Finally, because we know it is necessary to do a similar analysis for non-U.S. markets, we discussed some of the additional factors involved in non-U.S. market analysis.

- Following this aggregate market analysis, the next step is industry analysis, which is considered in the following chapter.

11. It is estimated that next year hourly wage rates will increase by 7 percent and productivity will increase by 5 percent. What would you expect to happen to unit labor cost?
Discuss how this unit labor cost estimate would influence your estimate of the operating profit margin.

12. Assume that each of the following changes is independent (i.e., except for this change, all other factors remain unchanged). In each case, indicate what will happen to the earnings multiplier and explain why.
   a. The return on equity increases
   b. The aggregate debt-equity ratio declines
   c. Overall productivity of capital increases
   d. The dividend-payout ratio declines

PROBLEMS

1. Prepare a table showing the percentage change for each of the last 10 years in (a) the Consumer Price Index (all items), (b) nominal GDP, (c) real GDP (in constant dollars), and (d) the GDP deflator. Discuss how much of nominal growth was due to real growth and how much was due to inflation.

2. There has been considerable growth in recent years in the use of economic analysis in investment management. Further significant expansion may lie ahead as financial analysts develop greater skills in economic analysis and these analyses are integrated more into the investment decision-making process. The following questions address the use of economic analysis in the investment decision-making process:
   a. (1) Differentiate among leading, lagging, and coincident indicators of economic activity, and give an example of each.
      (2) Indicate whether the leading indicators are useful for achieving above-average investment results. Briefly justify your conclusion.
   b. Interest rate projections are used in investment management for a variety of purposes. Identify three significant reasons why interest rate forecasts may be important in reaching investment conclusions.
   c. Assume you are a fundamental research analyst following the automobile industry for a large brokerage firm. Identify and briefly explain the relevance of three major economic time series, economic indicators, or economic data items that would be significant to automotive industry and company research.

3. You are told that nominal GDP will increase by about 10 percent next year. Using Exhibit 12.13 and the regression equation, what increase would you expect in corporate sales?

4. Currently, the dividend-payout ratio \( \frac{D}{E} \) for the aggregate market is 60 percent, the required return \( (k) \) is 11 percent, and the expected growth rate for dividends \( (g) \) is 5 percent.
   a. Compute the current earnings multiplier.
   b. You expect the \( \frac{D}{E} \) payout ratio to decline to 50 percent, but you assume there will be no other changes. What will be the \( P/E \)?
   c. Starting with the initial conditions, you expect the dividend-payout ratio to be constant, the rate of inflation to increase by 3 percent, and the growth rate to increase by 2 percent. Compute the expected \( P/E \).
   d. Starting with the initial conditions, you expect the dividend-payout ratio to be constant, the rate of inflation to decline by 3 percent, and the growth rate to decline by 1 percent. Compute the expected \( P/E \).

5. As an analyst for Charlotte and Chelle Capital, you are forecasting the market \( P/E \) ratio using the dividend discount model. Because the economy has been expanding for 9 years, you expect the dividend-payout ratio will be at its low of 40 percent and that long-term government bond rates will rise to 7 percent. Because investors are becoming less risk averse, the equity risk premium will decline to 3 percent. As a result, investors will require a 10 percent return, and the return on equity will be 12 percent.
   a. What is the expected growth rate?
   b. What is your expectation of the market \( P/E \) ratio?
c. What will be the value for the market index if the expectation is for earnings per share of $95?

You are also informed that the estimated operating profit (EBIT) margin is 12 percent and the tax rate is 32 percent.

a. Compute the estimated EPS for 2013.
b. Assume that a member of the research committee for your firm feels that it is important to consider a range of operating profit margin (OPM) estimates. Therefore, you are asked to derive both optimistic and pessimistic EPS estimates using 11 and 13 percent for the OPM and holding everything else constant.

b. Assume that there is a 1 percent increase in the rate of inflation—what would be the market’s value, and how would you weight the U.S. market? State your assumptions.
We acknowledge the importance of industry analysis as a component of the three-step fundamental analysis procedure initiated in Chapter 11. Industry analysis is the second step as we progress toward selecting specific firms and stocks for our investment portfolio. In Chapter 12, we did a macroanalysis and valuation of the stock market to decide whether the expected rate of return from investing in common stocks was equal to or greater than our required rate of return—that is, should we overweight, market weight, or underweight stocks? In this chapter, we analyze different industries to determine if the intrinsic value of an industry is equal to or greater than its market price. Based on this relationship, we decide how to weight the industry in our stock portfolio. In Chapter 14, we analyze the individual companies and stocks within alternative industries.

In the first section, we discuss the results of several studies that identify the benefits and uses of industry analysis. Similar to the market analysis that considered both macroeconomic factors and microvaluation, we consider several industry macroanalysis topics, such as the differential impact of the business cycle on alternative industries, how various structural economic changes affect different industries, understanding an industry’s life cycle, and evaluating the competitive environment in an industry. This macroanalysis is crucial to an overall understanding of what factors determine risk and return in an industry.

Following this, the bulk of the chapter considers the microvaluation of the retail industry including a demonstration of both the cash flow models and the relative valuation ratios introduced earlier in Chapter 11. We conclude the chapter with a discussion of global industry analysis, because many industries transcend U.S. borders and compete on a worldwide basis.

13.1 Why Do Industry Analysis?

Investment practitioners perform industry analysis because they believe it helps them isolate investment opportunities that have favorable return-risk characteristics. We likewise have recommended it as part of our three-step, top-down investment analysis approach. What exactly do we learn from an industry analysis? Can we spot trends in industries that make them good investments? Are there unique patterns in the rates of return and risk measures over time in different industries? In this section, we survey the results of studies that addressed the following set of questions designed to pinpoint the benefits and limitations of industry analysis:

- Is there a difference between the returns for alternative industries during specific time periods? What is the implication of these results for industry analysis?
- Is there consistency in the returns for individual industries over time? What do these results imply regarding industry analysis?
- Is the performance for firms within an industry consistent? What is the implication of these results for industry and company analysis?
- Is there a difference in risk among industries? What are the implications of these results for industry analysis?
- What happens to risk for individual industries over time? What does this imply for industry analysis?
- What are the stages in the industrial life cycle, and how does the stage in an industry’s life cycle affect the sales estimate for an industry?
- What are the five basic competitive forces that determine the intensity of competition in an industry and, thus, its rate of return on capital?
- How does an analyst determine the value of an industry using the DDM, assuming constant growth or two-stage growth?
- How does an analyst determine the value of an industry using the free cash flow to equity (FCFE) model, assuming constant growth or two-stage growth?
- What are the steps involved in estimating earnings per share for an industry?
- How does the procedure for estimating the operating profit margin differ for the aggregate market versus an industry?
- What is involved in a macroanalysis of the industry earnings multiplier?
- What are the steps in the microanalysis of an industry earnings multiplier?
- How do you determine if an industry’s estimated multiplier is relatively high or low?
- How do analysts compare relative valuation ratios such as P/BV, P/CF, and P/S to comparable market ratios?
- How do industries differ in terms of what dictates their return on assets?
- What are some of the unique factors that must be considered in global industry analysis?

When asked about his or her job, a securities analyst typically will reply that he or she is an oil analyst, a retail analyst, or a computer analyst. A widely read trade publication, The Institutional Investor, selects an All-American analyst team each year based on industry groups. Investment managers talk about being in or out of the metals, the autos, or the utilities. This constant reference to industry groups is because most professional investors are extremely conscious of differences among alternative industries and organize their analyses and portfolio decisions according to industry groups.

- Will an industry that performs well in one period continue to perform well in the future? That is, can we use past relationships between the market and an individual industry to predict future trends for the industry?
- Is the performance of firms within an industry consistent over time?

Several studies also considered questions related to risk:

- Is there a difference in the risk for alternative industries?
- Does the risk for individual industries vary, or does it remain relatively constant over time?

Based on the results of these studies, we come to some general conclusions about the value of industry analysis. In addition, this assessment helps us interpret the results of our subsequent industry valuation.
13.1.1 Cross-Sectional Industry Performance

To find out if the rates of return among different industries varied during a given period (e.g., during the year 2012), researchers compared the performance of alternative industries during a specific time period. Similar performance during specific time periods for different industries would indicate that industry analysis is not necessary. For example, assume that during 2012, the aggregate stock market experienced a rate of return of 10 percent and the returns for all industries were bunched between 9 percent and 11 percent. If this similarity in performance persisted over time, you might question whether it was worthwhile to do industry analysis to find an industry that would return 11 percent when random selection would provide a return of about 10 percent (the average return).

Studies of the annual performance by numerous industries found that different industries have consistently shown wide dispersion in their rates of return. A specific example is the year 2010. As shown in Exhibit 13.1, although the aggregate stock market (the S&P 500) experienced a percent price change of about 12.78, the industry performance ranged from 90.51 percent (Platinum and Precious Metals) to −18.82 percent (Renewable Energy Equipment). The consistency of these wide-ranging results is confirmed in Exhibit 13.2 for the recent 11 years—the

average high industry change is over 89 percent and the average low change is almost –43 percent. These results imply that industry analysis is important and necessary to uncover these substantial performance differences—that is, industry analysis helps identify both unprofitable and profitable opportunities.

13.1.2 Industry Performance over Time
Another set of studies questioned whether industries that perform well in one time period would perform well in subsequent time periods, or outperform the aggregate market in the later time period. Investigators found almost no association in industry performance year to year or over sequential rising or falling markets.

These time-series studies imply that past performance alone does not project future industry performance. The results do not, however, negate the usefulness of industry analysis. They simply confirm that variables that affect industry performance change over time, and each year you must estimate the current intrinsic value for each industry based on future estimates of relevant variables and compare this to its current market price.

13.1.3 Performance of the Companies within an Industry
Other studies examined whether there is consistency in the performance of companies within an industry. If all the firms within an industry performed consistently during a specified time period, you would not need to do company analysis. Specifically, industry analysis alone would be enough because given a profitable industry you would know that all the stocks in that industry would do well.

These studies typically have found wide dispersion in the performance among companies in most industries. Studies by Meyers (1973) and Livingston (1977) provided evidence of a stronger industry effect in specific industries, such as oil or autos, but also showed that the industry effect has been declining over time.

Implication of Dispersion within Industries Some observers have contended that industry analysis is useless because all firms in an industry do not move together. Obviously, consistent firm performance in an industry would be ideal, as noted, because you would not need to do company analysis. For industries that have a strong, consistent industry influence, such as oil, gold, steel, autos, and railroads, company analysis is less critical than industry analysis.

The fact that there is not a strong industry influence across firms in most industries means that a thorough company analysis is necessary. Still, industry analysis is valuable because it is much easier to select a superior company from a good industry than to find a good company in a poor industry. By selecting the best stocks within a strong industry, you avoid the risk that your analysis and selection of the best company in the industry will be offset by poor industry performance.

13.1.4 Differences in Industry Risk
Although numerous studies have examined industry returns, few studies have examined industry risk measures. The studies on industry risk investigated two questions: (1) Does risk differ among industries during a given time period? (2) Are industry risk measures stable over time? The studies of risk dispersion found a wide range of risk among different industries and the differences in industry risk typically widened during rising and falling markets. The results on risk stability were positive—the risk measures for individual industries over time were reasonably stable.

Therefore, although risk measures for different industries showed substantial dispersion during a period of time, individual industries’ risk measures are stable over time. Hence, the dispersion means that the analysis of industry risk is necessary, but this analysis of risk is useful when estimating the future risk for an industry.
13.1.5 Summary of Research on Industry Analysis

The conclusions of the studies dealing with industry analysis are:

- During any time period, the returns for different industries vary within a wide range, which means that industry analysis is an important part of the investment process.
- The rates of return for individual industries vary over time, so we cannot simply extrapolate past industry performance into the future.
- The rates of return of firms within industries also vary, so analysis of individual companies in an industry is a necessary follow-up to industry analysis.
- During any time period, different industries’ risk levels vary within wide ranges, so we must examine and estimate the risk factors for alternative industries.
- Risk measures for different industries remain fairly constant over time, so the historical risk analysis is useful when estimating future risk.

13.1.6 Industry Analysis Process

An important question is: How should you structure your industry analysis? In our previous analysis of the economy and the aggregate equity market, we contended that it is necessary to examine the macroeconomy for two related reasons. First, although the security markets tend to move ahead of the aggregate economy, we know that security markets reflect the strength or weakness of the economy. Second, most of the variables that determine value for the security markets are macrovariables such as interest rates, GDP growth, and corporate earnings. Therefore, our analysis of the aggregate equity market contained two components—one dealing with macrovariables such as leading indicators and monetary policy, and a second facet being microanalysis of specific variables that affect market valuation.

The point is, the industry analysis process is similar—first is a macroanalysis of the industry to determine how this industry relates to the business cycle and what economic variables drive this industry. This macroanalysis will make the microvaluation easier when we use the several valuation techniques introduced earlier. As noted, macroanalysis of the industry will make the estimation of the major valuation inputs (a discount rate and the expected growth for earnings and cash flows) easier and more accurate.

The specific macroanalysis topics are:

1. The business cycle and industry sectors
2. Structural economic changes and alternative industries
3. Evaluating an industry’s life cycle
4. Analysis of the competitive environment in an industry

13.2 The Business Cycle and Industry Sectors

Economic trends can and do affect industry performance. Our objective is to monitor the economy and gauge how any new information on our economic outlook will impact the short-run and long-run valuation of our industry. Recall that in order to beat the market on a risk-adjusted basis, our forecasts must differ from the market consensus and we must be correct more often than not.

Economic trends can take two basic forms: cyclical changes that arise from the ups and downs of the business cycle, and structural changes that occur when the economy is undergoing a major change in how it functions. For example, excess labor or capital may exist in some sectors, whereas shortages of labor and capital exist elsewhere. The “downsizing” of corporate America during the 1990s, transitions from socialist to market economies in Eastern Europe, and the transition in the United States from a manufacturing to a service economy are all
Traditionally, toward the business cycle peak, inflation increases as demand starts to outstrip supply. Basic materials industries such as oil, metals, and timber, which transform raw materials into finished products, become investor favorites. Because inflation has little influence on the cost of extracting these products and the firms in these industries can increase prices, these industries experience higher profit margins.

During a recession, some industries do better than others. Consumer staples, such as pharmaceuticals, food, and beverages, outperform other sectors during a recession because, although overall spending may decline, people still spend money on necessities so these "defensive" industries generally maintain their values—that is, they will experience minimal declines. Similarly, if a weak domestic economy causes a weak currency, industries that export to growing economies benefit because their goods become more cost competitive.

We have identified certain industries that are typically attractive investments over the business cycle. Remember, you should not invest based only upon the current economic environment because the efficient market has already incorporated current economic news into security prices. Rather, you must forecast important economic variables and invest accordingly. The following subsections consider how changes in several important economic variables may affect different industries.

13.2.1 Inflation

As noted in several chapters, higher inflation is generally negative for stocks because it causes higher market interest rates and more uncertainty about future prices and costs, and it harms firms that cannot pass through cost increases. Although these adverse effects are true for most industries, there are some industries that benefit from inflation. Natural resource industries benefit if their production costs do not rise with inflation, because their output will likely sell at higher prices. Industries with high operating leverage benefit because many of their costs are fixed in nominal (current dollar) terms, whereas revenues increase with inflation. Industries with high financial leverage may also gain, because their debts are repaid in cheaper dollars.

13.2.2 Interest Rates

Financial institutions, including banks, are typically adversely impacted by higher rates because they find it difficult to pass on these higher rates to customers (i.e., lagged adjustment). High interest rates clearly harm the housing and the construction industry, but they might benefit industries that supply the do-it-yourselfer. High interest rates also benefit retirees whose income is dependent on interest income. A study by Reilly, Wright, and Johnson (2007) examines the interest rate sensitivity of a large cross-section of industries and types of stocks.

13.2.3 International Economics

Both domestic and international events affect the value of the U.S. dollar. A weaker U.S. dollar helps U.S. industries because their exports become comparatively cheaper in overseas markets, while the goods of foreign competitors become more expensive in the United States. A stronger dollar has an opposite effect. Economic growth in world regions or specific countries benefits industries that have a large presence in those areas. The creation of free trade zones, such as the European Community and the North American Free Trade Zone, assist industries that produce goods and services that previously faced quotas or tariffs in partner countries.

13.2.4 Consumer Sentiment

Because it comprises about two-thirds of GDP, consumption spending has a large impact on the economy. Optimistic consumers are more willing to spend and borrow money for expensive goods, such as houses, cars, new clothes, and furniture. Therefore, the performance of consumer cyclical industries will be affected by changes in consumer sentiment and by consumers’ willingness and ability to borrow and spend money.

1An excellent discussion of structural changes in the U.S. economy and the implications of these changes for the business cycle, the stock market, and some specific industries is contained in Dudley and McKelvey (1997).

2As discussed in Chapter 1, operating leverage arises from the existence of fixed costs in a firm’s operating structure. Industries with large fixed expenses will have high degrees of operating leverage. This means a small percentage change in sales can result in a large percentage change in operating income.

3As noted in Chapter 10, financial leverage arises from fixed financial costs (that is, interest expense) in a firm’s capital structure. Industries that have extensive debt financing (such as banks or utilities) will have net income that is sensitive to small changes in operating income.
Traditionally, toward the business cycle peak, inflation increases as demand starts to outstrip supply. Basic materials industries such as oil, metals, and timber, which transform raw materials into finished products, become investor favorites. Because inflation has little influence on the cost of extracting these products and the firms in these industries can increase prices, these industries experience higher profit margins.

Remember, you should not invest based only upon the current economic environment because the efficient market has already incorporated current economic news into security prices. Rather, you must forecast important economic variables and invest accordingly. The following subsections consider how changes in several important economic variables may affect different industries.

13.3.1 Inflation
As noted in several chapters, higher inflation is generally negative for stocks because it causes higher market interest rates and more uncertainty about future prices and costs, and it harms firms that cannot pass through cost increases. Although these adverse effects are true for most industries, there are some industries that benefit from inflation. Natural resource industries benefit if their production costs do not rise with inflation, because their output will likely sell at higher prices. A stronger dollar has an opposite effect. Economic growth in world regions or specific countries benefits industries that have a large presence in those areas. Because it comprises about two-thirds of GDP, consumption spending has a large impact on the economy. Optimistic consumers are more willing to spend and borrow money for expensive goods, such as houses, cars, new clothes, and furniture. Therefore, the performance of consumer cyclical industries will be affected by changes in consumer sentiment and by consumers’ willingness and ability to borrow and spend money.
13.3 Structural Economic Changes and Alternative Industries

Influences other than the economy are part of the business environment. Demographics, changes in technology, and political and regulatory environments also can have a significant effect on the cash flow and risk prospects of different industries.

13.3.1 Demographics

In the past 50 years, the United States has had a baby boom and a baby bust and is now enjoying a baby boomerlet as members of the baby boom generation (those born between the end of World War II and the early 1960s) have children. The influx of the baby boom and the “graying of the baby boom” have had a large impact on U.S. consumption, from advertising strategies to house construction to concerns over social security and health care. The study of demographics includes much more than population growth and age distributions. Demographics also includes the geographical distribution of people, the changing ethnic mix in a society, and changes in income distribution. Therefore, industry analysts need to carefully study demographic trends and project their effect on different industries.

During the period from 1990 to 2011, the fastest-growing age groups in the United States were teens, those in their forties and fifties, and those over 70; among the declining groups were those between ages 18 and 24. As of the early 2000s, more than one in eight Americans are 65 years of age or older. The changing age profile of Americans has implications for resource availability, namely, a possible shortage of entry-level workers leading to an increase in labor costs and difficulty in finding qualified persons to replace the retiring baby boomers. The aging U.S. population also affects U.S. savings patterns, because people in the 40 to 60 age bracket usually save more than younger people. This is good for the financial services industry, which offers assistance to those who want to invest their savings. Alternatively, fewer younger workers and more “saving seniors” may have a negative impact on some industries, such as the retailing industry.

13.3.2 Lifestyles

Lifestyles deal with how people live, work, form households, consume, enjoy leisure, and educate themselves. Consumer behavior is affected by trends and fads. The rise and fall of designer jeans, chinos, and other styles in clothes illustrate the sensitivity of some markets to changes in consumer tastes. The increase in divorce rates, dual-career families, population shifts away from cities, and computer-based education and entertainment have influenced numerous industries, including housing, restaurants, automobiles, catalog shopping, services, and home entertainment. From an international perspective, some U.S.-brand goods—from blue jeans to movies—have a high demand overseas. They are perceived to be more in style and perhaps higher quality than items produced domestically. Several industries have benefited from this positive brand reputation.

13.3.3 Technology

Technology can affect numerous industry factors, including the product or service and how it is produced and delivered. There are numerous examples of changes due to technological innovations. For example, demand has fallen for carburetors on cars because of electronic fuel-injection technology. The engineering process has changed because of the advent of computer-aided design and manufacturing. Perpetual improvement of designs in the semiconductor and microprocessor industry has made that industry a difficult one to evaluate.
Innovations in process technology allowed steel minimills to grow at the expense of large steel producers. Advances in technology allow some plant sites and buildings to generate their own electricity, bypassing their need for power from the local electric utility. Trucks have reduced railroads’ market share in the long-distance carrier industry. The information superhighway is becoming a reality and encouraging linkages between telecommunications and cable television systems. Changes in technology have spurred capital spending in technological equipment as a way for firms to gain competitive advantages. The future effects of the Internet will be astronomical.

The retailing industry is a wonderful example of how an industry can use new technology. Some forecasters envision relationship merchandising, in which customer databases will allow closer links between retail stores and customer needs. Rather than market research on aggregate consumer trends, specialized retailers offer products that consumers desire in preferred locations. Technology allows retailers to become more organizationally decentralized and geographically diversified. Major retailers use barcode scanning, which speeds the checkout process and allows the firm to track inventory and customer preferences. Credit cards allow firms to track customer purchases and send customized sales announcements. Electronic data interchange (EDI) allows the retailer to electronically communicate with suppliers to order new inventory and pay accounts payable. Electronic funds transfer allows retailers to move funds quickly and easily between local banks and headquarters.

It is essential for an analyst to become aware of how technology can be a benefit or a threat to an industry.

13.3.4 Politics and Regulations

Because political change reflects social values, today’s social trend may be tomorrow’s law, regulation, or tax. The industry analyst needs to project and assess political changes relevant to the industry under study.

Some regulations and laws are based on economic reasoning. Due to utilities’ positions as natural monopolies, their rates must be reviewed and approved by a regulatory body. Some regulation involves social ends. For example, the Food and Drug Administration protects consumers by reviewing new drugs. Public and worker safety concerns spurred creation of the Consumer Product Safety Commission, the Environmental Protection Agency, and OSHA. Notably, heavy regulation of an industry can increase a firm’s costs but also can restrict entry into the industry.

Regulatory changes have affected numerous industries. An example is the numerous regulations and inspections introduced to protect against terrorist attacks. Changing regulations and technology are bringing participants in the financial services industry—banking, insurance, investment banking, and investment services—together.

Regulations and laws affect international commerce. International tax laws, tariffs, quotas, embargoes, and other trade barriers have a significant effect on some industries and global commerce.

Again, an interesting example is how the retail industry is affected by numerous regulatory factors. First, the minimum-wage law impacts many retail employees. A second factor is employer-paid health insurance, which dramatically impacts the labor costs of service industries, such as retailing. Third, because goods must first be delivered to the stores, regulations that affect the cost of shipping by airplane, ship, or truck will affect retailers’ costs. Finally, lower tariffs and quotas will allow retailers to offer imported goods at lower prices (e.g., Walmart), which will expand their international production (outsourcing).

---

*Technology can change natural monopolies. We mentioned earlier how some firms are generating their own electrical power. Another example is that, currently, numerous states are allowing electric utilities to compete for customers.*
13.4 Evaluating the Industry Life Cycle

An insightful analysis when predicting industry sales and trends in profitability is to view the industry over time and divide its development into stages similar to those that humans progress through: birth, adolescence, adulthood, middle age, old age. The number of stages in this industry life cycle analysis can vary based on how much detail you want. A five-stage model would include:

1. Pioneering development
2. Rapid accelerating growth
3. Mature growth
4. Stabilization and market maturity
5. Deceleration of growth and decline

Exhibit 13.4 shows the growth path of sales during each stage. The vertical scale in logs reflects rates of growth, whereas the arithmetic horizontal scale has different widths representing different, unequal time periods. To estimate industry sales, you must predict the length of time for each stage. This requires answers to such questions as: How long will an industry grow at an accelerating rate (Stage 2)? How long will it be in a mature growth phase (Stage 3) before its sales growth stabilizes (Stage 4) and then declines (Stage 5)?

Besides being useful when estimating sales, this industry life cycle analysis also provides insights into profit margins and earnings growth, although these profit measures may not parallel the sales growth. The profit margin series typically peaks very early in the total cycle and then levels off and declines as competition is attracted by the early success of the industry.

---

**Exhibit 13.4 Life Cycle of an Industry**

[Graph showing the life cycle stages with labels: Stage 1 - Pioneering Development, Stage 2 - Rapid Accelerating Growth, Stage 3 - Mature Growth, Stage 4 - Stabilization and Market Maturity, Stage 5 - Deceleration of Growth and Decline.]
The following is a brief description of how these stages affect sales growth and profits:

1. **Pioneering development.** During this start-up stage, the industry experiences modest sales growth and very small or negative profits. The market for the industry’s product or service during this stage is small, and the firms incur major development costs.

2. **Rapid accelerating growth.** During this rapid growth stage, a market develops for the product or service and demand becomes substantial. The limited number of firms in the industry face little competition, and firms can experience substantial backlogs and very high profit margins. The industry builds its productive capacity as sales grow at an increasing rate and the industry attempts to meet excess demand. High sales growth and high profit margins that increase as firms become more efficient cause industry and firm profits to explode (i.e., profits can grow at over 100 percent a year because of the low earnings base and the rapid growth of sales and margins).

3. **Mature growth.** The success in Stage 2 has satisfied most of the demand for the industry goods or service. Thus, future sales growth may be above normal, but it no longer accelerates. For example, if the overall economy is growing at 8 percent, sales for this industry might grow at an above normal rate of 15 percent to 20 percent a year. Also, the rapid growth of sales and the high profit margins attract competitors to the industry, causing an increase in supply and lower prices, which means that the profit margins begin to decline to normal levels.

4. **Stabilization and market maturity.** During this stage, which is probably the longest phase, the industry growth rate declines to the growth rate of the aggregate economy or its industry segment. During this stage, investors can estimate growth easily because sales correlate highly with an economic series. Although sales grow in line with the economy, profit growth varies by industry because the competitive structure varies by industry, and by individual firms within the industry because the ability to control costs differs among companies. Competition produces tight profit margins, and the rates of return on capital (e.g., return on assets, return on equity) eventually become equal to or slightly below the competitive level.

5. **Deceleration of growth and decline.** At this stage of maturity, the industry’s sales growth declines because of shifts in demand or growth of substitutes. Profit margins continue to be squeezed, and some firms experience low profits or even losses. Firms that remain profitable may show very low rates of return on capital. Finally, investors begin thinking about alternative uses for the capital tied up in this industry.

Although these are general descriptions of the alternative life cycle stages, they should help you identify the stage your industry is in, which in turn should help you estimate its potential sales growth and profit margin. Obviously, everyone is looking for an industry in the early phases of Stage 2 and hopes to avoid industries in Stage 4 or Stage 5. Comparing the sales and earnings growth of an industry to similar growth in the economy should help you identify the industry’s stage within the industrial life cycle.

### 13.5 Analysis of Industry Competition

Similar to the sales forecast that can be enhanced by the analysis of the industrial life cycle, an industry earnings forecast should be preceded by the analyses of the competitive structure for the industry. Specifically, a critical factor affecting the profit potential of an industry is the intensity of competition in the industry, as Porter (1980a, 1980b, 1985) has discussed.

#### 13.5.1 Competition and Expected Industry Returns

Porter’s concept of **competitive strategy** is described as the search by a firm for a favorable competitive position in an industry. To create a profitable competitive strategy, a firm must...
first examine the basic competitive structure of its industry because the potential profitability of a firm is heavily influenced by the profitability of its industry. After determining the competitive structure of the industry, you examine the factors that determine the relative competitive position of a firm within its industry. In this section, we consider the competitive forces that determine the competitive structure of the industry. In the next chapter, our discussion of company analysis considers the factors that determine the relative competitive position of a firm within its industry.

**Basic Competitive Forces** Porter believes that the competitive environment of an industry (the intensity of competition among the firms in that industry) determines the ability of the firms to sustain above-average rates of return on invested capital. As shown in Exhibit 13.5, he suggests that five competitive forces determine the intensity of competition and that the relative effect of each of these five factors can vary dramatically among industries.

1. **Rivalry among the existing competitors.** For each industry analyzed, you must judge if the rivalry among firms is currently intense and growing, or polite and stable. Rivalry increases when many firms of relatively equal size compete in an industry. When estimating the number and size of firms, be sure to include foreign competitors. Further, slow growth causes competitors to fight for market share and increases competition. High fixed costs stimulate the desire to sell at the full capacity, which can lead to price cutting and greater competition. Finally, look for exit barriers, such as specialized facilities or labor agreements. These can keep firms in the industry despite below-average or negative rates of return.

   Beyond these general conditions that impact competition, the following four factors will likewise affect the competitive environment within an industry:

   **Exhibit 13.5 Forces Driving Industry Competition**

   **Source:** Reprinted with the permission of The Free Press, an imprint of Simon & Schuster, Inc., from *Competitive Strategy: Techniques for Analyzing Industries and Competitors* by Michael E. Porter. Copyright © 1980, 1998 by The Free Press. All rights reserved.
2. **Threat of new entrants.** Although an industry may have few competitors, you must determine the likelihood of firms entering the industry and increasing competition. *High barriers to entry,* such as low current prices relative to costs, keep the threat of new entrants low. Other barriers to entry include the need to invest large financial resources to compete as well as the availability of capital. Also, substantial economies of scale give a current industry member an advantage over a new firm. Further, entrants might be discouraged if success in the industry requires extensive distribution channels that are hard to build because of exclusive distribution contracts. Similarly, high costs of switching products or brands, such as those required to change a computer or telephone system, keep competition low. Finally, government policy can restrict entry by imposing licensing requirements or limiting access to materials (lumber, coal). Without some of these barriers, it might be very easy for competitors to enter an industry, increasing the competition and driving down potential profit margins and rates of return.

3. **Threat of substitute products.** Substitute products limit the profit potential of an industry because they limit the prices firms in an industry can charge. Although almost everything has a substitute, you must determine how close the substitute is in price and function to the product in your industry. As an example, the threat of substitute glass containers hurt the metal container industry. Glass containers kept declining in price, forcing metal container prices and profits down. In the food industry, consumers constantly substitute between beef, pork, chicken, and fish. The more commodity-like the product, the greater the competition and the lower the profit margins.

4. **Bargaining power of buyers.** Buyers can influence the profitability of an industry because they bid down prices or demand higher quality or more services by showing a propensity to switch among competitors. Buyers become powerful when they purchase a large volume relative to the sales of a supplier (e.g., Walmart, Home Depot). The most vulnerable firm is a one-customer firm that supplies a single large manufacturer, as is common for auto parts manufacturers or software developers. Buyers will be more conscious of the costs of items that represent a significant percentage of the firm’s total costs. This consciousness increases if the buying firm is feeling cost pressure from its customers. Also, buyers who know a lot about the costs of supplying an industry will bargain more intensely—for example, when the buying firm supplies some of its own needs and buys from the outside.

5. **Bargaining power of suppliers.** Suppliers can alter future industry returns if they increase prices or reduce the quality of the product or the services they provide. The suppliers are more powerful if there are few of them and if they are more concentrated than the industry to which they sell. Their power increases if they supply critical inputs to several industries for which few, if any, substitutes exist. In this instance, the suppliers are free to change prices and services they supply to the firms in an industry. When analyzing supplier bargaining power, be sure to consider labor’s power within each industry.

An investor needs to analyze these competitive forces to determine the intensity of the competition in an industry and assess the effect of this competition on the industry’s long-run profit potential. You should examine each of these factors and develop a relative competitive profile for each industry. It is important to consistently update this analysis of an industry’s competitive environment over time because an industry’s competitive structure can and will change over time.

### 13.6 Estimating Industry Rates of Return

At this point, we have determined that industry analysis helps an investor select profitable investment opportunities, and we have completed a thorough macroanalysis of the industry. Our next question is: How do we go about valuing an industry? Again, we consider the two equity
valuation approaches introduced in Chapter 11—the present value of cash flows and the relative valuation ratios.

Although our investment decision is always the same, the form of the comparison depends on which valuation approach is being used. In the case of the present value of cash flow techniques, we compare the present value of the specified cash flow and the prevailing value of the index and determine if we should underweight, equal weight, or overweight this global industry in our portfolio.

When we value the industry using the alternative valuation ratios, an important addition to the analysis is that we also need to compare our industry ratios to the market ratios presented in Chapter 12.

To demonstrate industry analysis, we use Standard and Poor’s retailing index to represent industry-wide data. This retailing index (hereinafter referred to as the RET industry) contains about 30 individual companies from several retailing sectors including two drugstores. Therefore, it should be reasonably familiar to most observers, and it is consistent with the subsequent company analysis of Walgreens.

### 13.6.1 Valuation Using the Reduced Form DDM

Recall that the reduced form DDM is:

\[
P_t = \frac{D_1}{k - g}
\]

where:

- \( P_t \) = the price of Industry \( i \) at Time \( t \)
- \( D_1 \) = expected dividend for Industry \( i \) in Period 1 equal to \( D_0(1 + g) \)
- \( k \) = the required rate of return on the equity for Industry \( i \)
- \( g \) = the expected long-run growth rate of earnings and dividend for Industry \( i \)

As always, the two major estimates for any valuation model are \( k \) and \( g \). We will discuss each of these at this point and also use these estimates subsequently when applying the two-step price/earnings ratio technique for valuation.

**Estimating the Required Rate of Return (k)** Because the required rate of return (\( k \)) on all investments is influenced by the risk-free rate and the expected inflation rate, the differentiating factor in this case is the risk premium for the retailing industry versus the market. In turn, we discussed the risk premium in terms of fundamental factors, including business risk (\( BR \)), financial risk (\( FR \)), liquidity risk (\( LR \)), exchange rate risk (\( ERR \)), and country (political) risk (\( CR \)). Alternatively, you can estimate the risk premium based on the CAPM, which implies that the risk premium is a function of the systematic risk (beta) of the asset. Therefore, to derive an estimate of the industry's risk premium, you should examine the \( BR, FR, LR, ERR, \) and \( CR \) for the industry and compare these industry risk factors to those of the aggregate market. Alternatively, you can compute the systematic risk (beta) for the industry and compare this to the market beta of 1.0. Prior to calculating an industry beta, we briefly discuss the industry’s fundamental risk factors.

**Business risk** is a function of relative sales volatility and operating leverage. As we will see when we examine the sales and earnings for the industry, the annual percentage changes in retailing sales were less volatile than aggregate sales as represented by PCE. Also, the \( OPM \) (operating profit margin) for retail stores was less volatile than for the S&P Industrials Index. Therefore, because both the sales and the \( OPM \) for the retailing industry have been less volatile than the market, operating profits are substantially less volatile. This implies that the business risk for the retailing industry is below average.
The financial risk for this industry is difficult to judge because of widespread use of operating leases for stores in the industry that are not included on the balance sheet. As a result, the reported data on debt to total capital or interest coverage ratios indicate that the FR for this industry is substantially below the market. Assuming substantial use of long-term lease contracts, when these are capitalized the retailing industry probably has financial risk about equal to the market. While data are not available to capitalize leases for the industry, we showed how to do this in Chapter 10 and will demonstrate it for a company in Chapter 14.

To evaluate an industry’s market liquidity risk, you must estimate the liquidity risk for all the firms in the industry, and derive a composite view. The fact is, there is substantial variation in market liquidity among the firms in this industry, ranging from Walgreens and Walmart, which are fairly liquid to small specialty retail chains, which are relatively illiquid. A conservative view is that the industry has above-average liquidity risk.

Exchange rate risk (ERR) is the uncertainty of earnings due to changes in exchange rates faced by firms in this industry that sell outside the United States. The amount of ERR is determined by what proportion of sales is non-U.S., how these sales are distributed among countries, and the exchange rate volatility for these countries. This risk could range from an industry with very limited international sales (e.g., a service industry that is not involved overseas) to a global industry (e.g., the chemical or pharmaceutical industry). For a truly global industry, you need to examine the distribution of sales among specific countries because the exchange rate risk varies among countries based on the volatility of exchange rates with the U.S. dollar. The ERR for the retailing industry would be relatively low because sales and earnings for most retailing firms are attributable to activity within the United States.

The existence of country risk (CR) is likewise a function of the proportion of foreign sales, the specific foreign countries involved, and the stability of the political/economic system in these countries. As noted, there is very little CR in the United Kingdom and Japan, but there can be substantial CR in China, Russia, and South Africa. Again, for the retailing industry, country risk would be relatively low because of limited foreign sales.

In summary, for the retailing industry business risk is definitely below average, financial risk is at best equal to the market, liquidity risk is above average, and exchange rate risk and country risk are fairly low for most retail firms. The consensus is that the fundamental risk for the RET industry should be slightly lower than for the aggregate market.

The systematic risk for the retailing industry is computed using the market model as follows:

\[ \% \Delta \text{RET}_t = \alpha_t + \beta_{\text{RET}} \left( \% \Delta \text{S&P 500}_t \right) \]

where:

- \% \Delta \text{RET}_t = the percentage price change in the retailing (RET) index during month \( t \)
- \( \alpha_t = the \ regression \ intercept \ for \ the \ RET \ industry \)
- \( \beta_{\text{RET}} = the \ systematic \ risk \ measure \ for \ the \ RET \ industry \ equal \ to \ \frac{\text{Cov}_{t,m}}{\sigma_m^2} \)

To derive an estimate for the RET industry, the model specified was run with monthly data for the five-year period of 2006 to 2010. The results for this regression are as follows:

- \( \alpha_t = 0.008 \)
- \( R^2 = 0.69 \)
- \( \beta_{\text{RET}} = 1.10 \)
- \( DW = 1.86 \)
- \( t\text{-value} = 5.45 \)
- \( F = 68.50 \)

The systematic risk (\( \beta = 1.10 \)) for the RET industry is a little above unity, indicating an above market risk industry (i.e., risk slightly above the market). These results suggest that the systematic risk for this industry is a little above the prior estimate of fundamental risk factors (\( BR, FR, LR, ERR, CR \)).
Translating this systematic risk into a required rate of return estimate \( k \) calls for using the security market line model as follows:

\[
k_i = RFR + \beta_i (R_m - RFR)
\]

Recall that in Chapter 12 we derived three estimates for the required market rate of return based on alternative risk premiums \((0.048 - 0.085 - 0.108)\). For our purposes here, it seems that the midpoint is reasonable—that is, a nominal \( RFR \) of 0.032 and an \( R_m \) of 0.072. This, combined with a beta for the industry at 1.10, indicates the following:

\[
k = 0.032 + 1.10(0.04) \\
= 0.032 + 0.044 \\
= 0.076 = 7.60\%
\]

For ease of computation, we will use a \( k \) of 8.0%. The fundamental risk analysis indicates risk slightly below the market and the CAPM estimate implies risk slightly above average. We prefer the 8 percent estimate for \( k \) in an environment of historically low Treasury rates.

**Estimating the Expected Growth Rate (g)** Recall that earnings and dividend growth are determined by the retention rate and the return on equity:

\[
g = f \text{ (Retention Rate and Return on Equity)}
\]

Again, we employ the three components of ROE:

\[
\frac{\text{Net Profit}}{\text{Equity}} = \frac{\text{Net Income}}{\text{Sales}} \times \frac{\text{Sales}}{\text{Total Assets}} \times \frac{\text{Total Assets}}{\text{Equity}} \\
= \frac{\text{Profit}}{\text{Margin}} \times \frac{\text{Total Asset}}{\text{Financial Turnover}} \times \frac{\text{Leverage}}{\text{Leverage}}
\]

We examine each of these variables in Exhibit 13.6 to determine if they imply a different expected growth rate for RET versus the aggregate market (S&P Industrials Index).

**Earnings Retention Rate** The data in Exhibit 13.6 indicate that the RET industry has a higher retention rate than the market (78 percent versus 63 percent), which implies a potentially higher growth rate, all else being the same (i.e., equal ROE).

**Return on Equity** Because the return on equity is a function of the net profit margin, total asset turnover, and financial leverage, these three variables are examined individually.

Historically, the data in Exhibit 13.6 show that the net profit margin for the S&P Industrials Index series has been consistently higher than the margin for the RET industry. This is not surprising because retail firms typically have lower profit margins but higher asset turnover.

As expected, the total asset turnover \( (TAT) \) for the RET industry was higher than the average industrial company. In Exhibit 13.6, the average \( TAT \) for the S&P Industrials Index was 0.86 versus 1.74 for the RET industry. Beyond the overall difference, as shown in Exhibits 13.6 and 13.7, the spread between the two series increased over the period because the industrials \( TAT \) experienced an overall decline, while the \( TAT \) for the RET industry experienced an overall increase. Multiplying the PM by the \( TAT \) indicates the industry’s return on total assets \( (ROA) \).

\[
\frac{\text{Net Income}}{\text{Sales}} \times \frac{\text{Sales}}{\text{Total Assets}} = \frac{\text{Net Income}}{\text{Total Assets}}
\]

The results in Exhibit 13.6 indicate that the return on total assets \( (ROA) \) for the S&P Industrials Index series went from 3.27 percent in 1993 to 5.12 percent in 2009 and averaged

---

5The reader is encouraged to read Appendix 13B to this chapter, which contains a discussion of an article by Selling and Stickney (1989), wherein they analyze the components of ROA and relate this to an industry’s economics and its strategy.
4.72 percent, whereas the ROTA for the RET industry went from 4.07 percent to 5.73 percent and averaged 6.02 percent. Clearly, the industry ROTA results were superior on average to S&P Industrial results.

The final component is the financial leverage multiplier (total assets/equity). As shown in Exhibits 13.6 and 13.8, both leverage multipliers experienced declines over the 17-year period.

*Recent five-year average.
**Total period average.

Given the decrease in g for the industry when we consider the recent results, it is probably appropriate to use a growth estimate for the RET industry that is below the long-run historical estimate—that is, we will assume a near-term growth rate of 11 percent.

Combining the Estimates

At this point, we have the following estimates:

\[
\begin{align*}
\kappa & = 0.080 \\
g & = 0.11 \\
D_0 & = \$6.28 \quad \text{(Estimated 2010 Dividends)} \\
D_1 & = \$6.28 \times 1.11 = \$6.97 \quad \text{(Estimated Dividend for 2011)}
\end{align*}
\]

Because of the inequality between \(k\) and \(g\) (this \(g\) is above \(k\) and above the long-run market norm of about 7 percent and probably cannot be sustained), we need to evaluate this industry using the temporary growth company model discussed in Chapter 12. We will assume the following growth pattern:

- 2011–2013: 0.11
- 2014–2016: 0.09
- 2017–2019: 0.07
- 2020–onward: 0.06

Using these estimates of \(k\) and this growth pattern, the computation of value for the industry using the DDM is contained in Exhibit 13.10.

the industrials by 27 percent and the RET industry by 30 percent. Although the higher financial leverage multiplier implies greater financial risk for the S&P Industrials Index series, recall that the financial leverage for the RET industry is understated because the widely used leases are not capitalized.

This final value of ROE in Exhibits 13.6 and 13.9 indicate that the best annual ROE varied by year until the last seven years when the RET industry was higher, except for 2008 when its profit margin experienced a large decline. The average annual ROEs were quite close—15.31 percent for the industrials, 15.76 percent for the RET industry. These average percentages are quite consistent with what would be derived from multiplying the averages of the components from Exhibit 13.6 as follows:

Although examining the long-term historical trends and the averages for each of the components is important, you should not forget that expectations of future performance will determine the ROE value for the industry, and these expectations probably will be heavily influenced by the recent years. To get more information regarding recent performance, it is insightful to examine the results for the recent five-year period (2005–2009) as follows:

Given the decrease in \( g \) for the industry when we consider the recent results, it is probably appropriate to use a growth estimate for the RET industry that is below the long-run historical estimate—that is, we will assume a near-term growth rate of 11 percent.

Combining the Estimates At this point, we have the following estimates:

\[
\begin{align*}
  k &= 0.080 \\
  g &= 0.11 \\
  D_0 &= $6.28 \text{ (Estimated 2010 Dividends)} \\
  D_1 &= $6.28 \times 1.11 = $6.97 \text{ (Estimated Dividend for 2011)}
\end{align*}
\]

Because of the inequality between \( k \) and \( g \) (this \( g \) is above \( k \) and above the long-run market norm of about 7 percent and probably cannot be sustained), we need to evaluate this industry using the temporary growth company model discussed in Chapter 12. We will assume the following growth pattern:

*Constant Growth Rate = 7%

Continuing Value: \( D_1 = \frac{13.62(1.06)}{0.08 - 0.06} = \frac{14.44}{0.02} = 722 \)
These computations imply a value of $449.34, compared to the stock price for the industry index of about $430 in early 2011. Therefore, according to this valuation model and these \( k \) and \( g \) estimates, this industry is currently about 4 percent undervalued. As will be shown, a fairly small change in the \( k - g \) spread can have a large effect on the estimated value.

If we assumed a constant growth rate of 6 percent from the beginning and a \( D_1 \) of $6.97, the value would be as follows:

\[
P = \frac{6.97}{(0.08 - 0.06)} = \frac{6.97}{0.02} = $348.50
\]

Notably, this valuation likewise implies the industry is overvalued, even though it is a low estimate of value since it assumes the base growth rate of 6 percent from the beginning. The point is, the industry is undervalued assuming strong growth in the next few years, but also overvalued assuming basic economic growth. Clearly, both valuations are dependent on the growth estimate.

### 13.6.2 Industry Valuation Using the Free Cash Flow to Equity (FCFE) Model

We initially define the FCFE series and present the series for the recent 17-year period, along with an estimate for 2010 in Exhibit 13.11. Given these data, we consider the historical growth rates for the components and for the final FCFE series as inputs to estimating future growth for the valuation models. You will recall that FCFE is defined (measured) as follows:

Net Income
- Depreciation expense
- Capital expenditures
- Change in working capital
- Principal debt repayments
+ New debt issues

As noted, the FCFE data inputs and final annual value of FCFE for the RET industry for the period 1993–2010 is contained in Exhibit 13.11, along with 5-year and 10-year growth rates of the components. Using this data, we derive an estimate using the FCFE model under two scenarios: (1) a constant growth rate from the present, and (2) a two-stage growth rate assumption.

**The Constant Growth Rate FCFE Model** We know that the constant growth rate model requires that the growth rate \( g \) be lower than the required rate of return \( k \), which we have specified as 8.00 percent. In the current case, this is difficult because the 10-year growth rate exceeds this. Still, in order to use the model, we assume a 10 percent growth in 2011 and 6 percent long-run growth in subsequent years. The result is as follows:

\[
g = 0.06 \text{ (Long-Run Growth Beginning in 2012)}
\]
\[
k = 0.080
\]
\[
FCFE (2010) = $21.83
\]
\[
FCFE (2011) = $21.83(1.10) = $24.01 = FCFE_{2011}
\]
\[
V = \frac{FCFE_{2011}}{k - g}
\]
\[
= \frac{24.01(1.06)}{0.080 - 0.060} = \frac{24.01}{0.02} = $1,200
\]
Notably, the alternative present value of cash flow models have generated the following intrinsic values:

Source: Adapted from the Standard and Poor’s Analysts’ Handbook.

This $1,200 value exceeds the industry stock price of $430 that prevailed in early 2011. This implies that the industry is substantially undervalued and should be overweighted in the portfolio. Notably, even if we assumed the long-run growth rate was only 5 percent, the estimated value would be $800, which would still imply that the industry is undervalued.

**The Two-Stage Growth FCFE Model** As before, we assume a period of above-average growth for several years followed by a second period of constant growth at 6 percent. The period of above-average growth will be as follows based on an estimated initial 9 percent growth rate of FCFE, which is lower than what was used for dividends because the FCFE series has been fairly erratic over the past 17 years, including several years when the FCFE was negative.

- 2011: 9%
- 2012: 9%
- 2013: 8%
- 2014: 8%
- 2015: 7%
- 2016: 7%
- 2017–onward: 6%

If we assume a k of 8.0 percent and an FCFE of $21.83 in 2010, $23.79 in 2011, and $25.93 in 2012, the value for the industry is as shown in Exhibit 13.12. These results are very encouraging for the industry because the computed value of $1,368 is substantially above the recent market price of about $430. This apparent undervaluation would indicate that the industry should be overweighted in the portfolio.
Recall that the macroanalysis of the industry included the following: (1) how the industry is impacted by the business cycle, (2) what structural changes have occurred within the industry, and (3) where the industry is in its life cycle. Based on this, the analyst would have a strong start regarding an industry sales estimate. We consider two general estimation techniques (time series and input-output analysis) and a primary technique that should be used for almost all industries (i.e., a specific analysis of the industry-economy relationship).

**Time-Series Analysis**

A simple time-series plot of the sales for an industry can be very informative regarding the pattern and the rate of growth for industry sales. Analyzing this series with an overlay of business cycle periods (expansions and recessions) and notations regarding major events will provide further insights. Finally, for many industries, you can extrapolate the time series to derive an estimate of sales. For industries that have experienced consistent growth, this can be an important estimate, especially if it is a new industry that has not yet developed a history with the economy. If the sales growth has been at a constant rate, you should use a semi-log scale where the constant growth shows as a straight line.

**Input-Output Analysis**

Input-output analysis provides useful insights regarding the outlook for an industry by identifying the industry’s suppliers and customers. This will indicate (1) the future demand from customers, and (2) the ability of suppliers to provide the goods and services required by the industry. The goal is to determine the long-run sales outlook for the industry’s suppliers and its major customers. In the case of global industries, you must include worldwide suppliers and customers.

**Industry-Economy Relationships**

The most rigorous and useful analysis involves comparing sales for an industry with one or several economic series that are related to the goods and services produced by the industry. The specific question is: What economic variables influence the demand for this industry? You should think about numerous factors that impact industry sales, how these economic variables will impact demand, and how they might interact. The following example demonstrates this industry-economy technique for the retailing industry (RET).

### Demonstrating a Sales Forecast

The RET industry includes retailers of basic necessities, including pharmaceuticals, medical supplies, and nonmedical products, such as food and clothing. Therefore, we want a series that (1) reflects broad consumption expenditures, and (2) gives weight to food and clothing. The economic series we consider are personal consumption expenditures (PCE) and PCE food, clothing, and shoes. Exhibit 13.13 contains the aggregate and per-capita values for these two series.

These time-series data indicate that personal consumption expenditures (PCE) have experienced reasonably steady growth of about 7.7 percent a year during this period, while PCE food, clothing, and shoes has grown at a slower rate of about 4.6 percent. As a result, food, clothing, and shoes as a percentage of all PCE has declined from 14.1 percent in 1993 to only 11.0 percent in 2009. Obviously, as an analyst, you would be encouraged because even though sales of food, clothing, and shoes have grown slower than overall PCE, retail sales have grown faster than both of them at about 14.5 percent.

The scatterplot in Exhibit 13.14 indicates a strong linear relationship between retail sales per share and sales of food, clothing, and shoes. Although not shown, there also is a good relationship with PCE. Therefore, if you can accurately estimate changes in these economic series, you should be able to estimate sales for RET.

As the industry being analyzed becomes more specialized, you need a more unique economic series that reflects the demand for the industry’s unique product. The selection of several appropriate economic series demonstrates an analyst’s knowledge and innovation. Also, industry sales are often dependent on several components of the economy, and in such a case you should consider a multivariate model that would include two or more economic series. For example, if you are analyzing the tire industry, you would need to consider new-car production, new-truck production, and a series that would reflect the replacement tire demand for both cars and trucks.

### 13.7 Industry Analysis Using the Relative Valuation Approach

This section contains a discussion and demonstration of the relative valuation ratio techniques: (1) price/earnings ratios \((P/E)\), (2) the price to book value ratios \((P/BV)\), (3) price to cash flow ratios \((P/CF)\), and (4) price to sales ratios \((P/S)\). We begin with the detailed demonstration of the \(P/E\) ratio approach, which provides a specific intrinsic value that equals an estimate of future earnings per share and an industry multiple.

The analysis of the other relative valuation ratios is also more meaningful because we can compare the industry valuation ratios to the market valuation ratios while considering what factors affect the specific valuation ratios.

#### 13.7.1 The Earnings Multiple Technique

Again, the earnings multiple technique involves (1) a detailed estimation of future earnings per share, and (2) an estimate of an appropriate earnings multiplier \((P/E)\) ratio based on a consideration of \(P/E\) determinants derived from the DDM.

**Estimating Earnings per Share**

To estimate earnings per share, you must start by estimating sales per share. We initially describe three techniques that provide help and insights for the sales estimate. Next, we derive an estimate of earnings per share, which implies a net profit margin for the industry. As in Chapter 12, we begin the \(EPS\) estimate by estimating the operating profit margin and operating profits. Then we subtract estimates of interest expense and then apply a tax rate to arrive at an estimate of earnings per share.
You also should consider per-capita personal consumption expenditures. Although aggregate PCE increases each year, there also is an increase in the aggregate population, so the increase in PCE per capita (the average PCE for each adult and child) will be less than for the aggregate series. For example, during 2007, aggregate PCE increased about 5.2 percent, but per-capita PCE

Forecasting Sales per Share Recall that the macroanalysis of the industry included the following: (1) how the industry is impacted by the business cycle, (2) what structural changes have occurred within the industry, and (3) where the industry is in its life cycle. Based on this, the analyst would have a strong start regarding an industry sales estimate. We consider two general estimation techniques (time series and input-output analysis) and a primary technique that should be used for almost all industries (i.e., a specific analysis of the industry-economy relationship).

Time-Series Analysis A simple time-series plot of the sales for an industry can be very informative regarding the pattern and the rate of growth for industry sales. Analyzing this series with an overlay of business cycle periods (expansions and recessions) and notations regarding major events will provide further insights. Finally, for many industries, you can extrapolate the time series to derive an estimate of sales. For industries that have experienced consistent growth, this can be an important estimate, especially if it is a new industry that has not yet developed a history with the economy. If the sales growth has been at a constant rate, you should use a semi-log scale where the constant growth shows as a straight line.

Input-Output Analysis Input-output analysis provides useful insights regarding the outlook for an industry by identifying an industry’s suppliers and customers. This will indicate (1) the future demand from customers, and (2) the ability of suppliers to provide the goods and services required by the industry. The goal is to determine the long-run sales outlook for the industry’s suppliers and its major customers. In the case of global industries, you must include worldwide suppliers and customers.

Industry-Economy Relationships The most rigorous and useful analysis involves comparing sales for an industry with one or several economic series that are related to the goods and services produced by the industry. The specific question is: What economic variables influence the demand for this industry? You should think about numerous factors that impact industry sales, how these economic variables will impact demand, and how they might interact. The following example demonstrates this industry-economy technique for the retailing industry (RET).

Demonstrating a Sales Forecast The RET industry includes retailers of basic necessities, including pharmaceuticals, medical supplies, and nonmedical products, such as food and clothing. Therefore, we want a series that (1) reflects broad consumption expenditures, and (2) gives weight to food and clothing. The economic series we consider are personal consumption expenditures (PCE) and PCE food, clothing, and shoes. Exhibit 13.13 contains the aggregate and per-capita values for these two series.

These time-series data indicate that personal consumption expenditures (PCE) have experienced reasonably steady growth of about 7.7 percent a year during this period, while PCE food, clothing, and shoes has grown at a slower rate of about 4.6 percent. As a result, food, clothing, and shoes as a percentage of all PCE has declined from 14.1 percent in 1993 to only 11.0 percent in 2009. Obviously, as an analyst, you would be encouraged because even though sales of food, clothing, and shoes have grown slower than overall PCE, retail sales have grown faster than both of them at about 14.5 percent.

The scatterplot in Exhibit 13.14 indicates a strong linear relationship between retail sales per share and sales of food, clothing, and shoes. Although not shown, there also is a good relationship with PCE. Therefore, if you can accurately estimate changes in these economic series, you should be able to estimate sales for RET.

As the industry being analyzed becomes more specialized, you need a more unique economic series that reflects the demand for the industry’s unique product. The selection of several appropriate economic series demonstrates an analyst’s knowledge and innovation. Also, industry sales are often dependent on several components of the economy, and in such a case you should consider a multivariate model that would include two or more economic series. For example, if you are analyzing the tire industry, you would need to consider new-car production, new-truck production, and a series that would reflect the replacement tire demand for both cars and trucks.
increased only 1.0 percent. Finally, an analysis of the relationship between percent change in an economic variable and percent changes in industry sales will indicate how the two series move together and would be sensitive to any changes in the relationship. Using annual percentage changes provides the following regression model:

\[ \frac{\Delta \text{Industry Sales}}{} = \alpha_i + \beta_i \left( \frac{\Delta \text{in Economic Series}}{} \right) \]

The size of the \( \beta_i \) coefficient should indicate how closely the two series move together. Assuming the intercept (\( \alpha_i \)) is close to zero, a slope (\( \beta_i \)) value of 1.00 would indicate relatively equal percent changes (e.g., a 10 percent increase in PCE typically is associated with a 10 percent increase in industry sales). A \( \beta_i \) larger than unity would imply that industry sales are more volatile than the economy is. This analysis and the levels relationship reflected in Exhibit 13.14 would help you find an economic series that closely reflects the demand for the industry's products; it also would indicate the form of the relationship.

As indicated, there was a good relationship between retail sales and PCE—Food, Clothing, and Shoes. The specific regression relationship was:

\[ \frac{\Delta \text{Retail Sales}}{} = -0.05 + 2.52 \left( \frac{\Delta \text{PCE—Food, Clothing, and Shoes}}{} \right) \]

\[ r^2 = 0.37 \]

Given the regression results, the specific sales forecast begins with an estimate of aggregate PCE growth for the years in question (i.e., 2010 and 2011). Because of the importance of PCE as a component of the economy, several estimates of PCE are available. The next step is to estimate the proportion of PCE spent on food, clothing, and shoes that has declined from 14.11 percent to 11 percent. You apply an estimate of this proportion to the PCE estimate and derive an estimate of the percent change in PCE—Food, Clothing, and Shoes that is used in the retail store sales regression model.

To demonstrate this process, we examined several economic sources that indicated that nominal PCE increased by 5.1 percent in 2010 (to $10,511 billion) and the projection was for an increase in 2011 of 6.3 percent to $11,173 billion. Regarding the percent of PCE spent on food, clothing, and shoes, we expect this proportion to increase slightly with the slow recovery of the economy—we estimate 11.02 percent in 2010 and 11.04 percent in 2011. This implies values for PCE—Food, Clothing, and Shoes of $1,158 billion in 2010 and $1,233 billion in 2011, which implies growth in this series of 5.3 percent in 2010 and 6.5 percent in 2011. Using these percentages in the Equation 13.5 regression provides an estimate of retail stores sales growth of 8.4 percent for 2010 ($627) and 11.38 percent for 2011 ($698). These sales growth rates are conservative relative to the long-run results in this industry (which was over 14 percent a year), but reflect the sluggish economic recovery in 2010 and 2011.

## Forecasting Earnings per Share
After the sales forecast, it is necessary to estimate the industry’s profitability based on an analysis of the industry income statement. An analyst should also benefit from the prior macroanalysis that considered where the industry is in its life cycle, which impacts its profitability. How does this industry relate to the business cycle, and what does this imply regarding profit margins at this point in the cycle? Most important, what did you conclude regarding the competitive environment in the industry, and what does this mean for the profitability of sales?

### Industry Profit Margin Forecast
Similar to the aggregate market, the net profit margin is the most volatile and the hardest margin to estimate directly. Alternatively, it is suggested that you begin with the operating profit margin (\( \frac{\text{EBIT}}{\text{Sales}} \)) and then estimate interest expense and the tax rate.

### The Industry’s Operating Profit Margin
Recall that in the market analysis, we analyzed the factors that should influence the economy’s operating profit margin, including capacity utilization, 438 Part 4: Analysis and Management of Common Stocks

### Exhibit 13.14 Scatterplot of Retail Sales per Share and PCE—Food, Clothing, and Shoes: 1993–2009

You also should consider per-capita personal consumption expenditures. Although aggregate PCE increases each year, there also is an increase in the aggregate population, so the increase in PCE per capita (the average PCE for each adult and child) will be less than for the aggregate series. For example, during 2007, aggregate PCE increased about 5.2 percent, but per-capita PCE
increased only 1.0 percent. Finally, an analysis of the relationship between percent change in an economic variable and percent changes in industry sales will indicate how the two series move together and would be sensitive to any changes in the relationship. Using annual percentage changes provides the following regression model:

\[ \%\Delta \text{ Industry Sales} = \alpha_i + \beta_i(\%\Delta \text{ in Economic Series}) \]

The size of the \( \beta_i \) coefficient should indicate how closely the two series move together. Assuming the intercept (\( \alpha_i \)) is close to zero, a slope (\( \beta_i \)) value of 1.00 would indicate relatively equal percent changes (e.g., a 10 percent increase in PCE typically is associated with a 10 percent increase in industry sales). A \( \beta_i \) larger than unity would imply that industry sales are more volatile than the economy is. This analysis and the levels relationship reflected in Exhibit 13.14 would help you find an economic series that closely reflects the demand for the industry’s products; it also would indicate the form of the relationship.

As indicated, there was a good relationship between retail sales and PCE—Food, Clothing, and Shoes. The specific regression relationship was:

\[ \%\Delta \text{ Retail Sales} = -0.05 + 2.52(\%\Delta \text{ PCE—Food, Clothing, and Shoes}) \]

\[ r^2 = 0.37 \]

Given the regression results, the specific sales forecast begins with an estimate of aggregate PCE growth for the years in question (i.e., 2010 and 2011). Because of the importance of PCE as a component of the economy, several estimates of PCE are available. The next step is to estimate the proportion of PCE spent on food, clothing, and shoes that has declined from 14.11 percent to 11 percent. You apply an estimate of this proportion to the PCE estimate and derive an estimate of the percent change in PCE—Food, Clothing, and Shoes that is used in the retail store sales regression model.

To demonstrate this process, we examined several economic sources that indicated that nominal PCE increased by 5.1 percent in 2010 (to $10,511 billion) and the projection was for an increase in 2011 of 6.3 percent to $11,173 billion. Regarding the percent of PCE spent on food, clothing, and shoes, we expect this proportion to increase slightly with the slow recovery of the economy—we estimate 11.02 percent in 2010 and 11.04 percent in 2011. This implies values for PCE—Food, Clothing, and Shoes of $1,158 billion in 2010 and $1,233 billion in 2011, which implies growth in this series of 5.3 percent in 2010 and 6.5 percent in 2011. Using these percentages in the Equation 13.5 regression provides an estimate of retail stores sales growth of 8.4 percent for 2010 ($627) and 11.38 percent for 2011 ($698). These sales growth rates are conservative relative to the long-run results in this industry (which was over 14 percent a year), but reflect the sluggish economic recovery in 2010 and 2011.

**Forecasting Earnings per Share** After the sales forecast, it is necessary to estimate the industry’s profitability based on an analysis of the industry income statement. An analyst should also benefit from the prior macroanalysis that considered where the industry is in its life cycle, which impacts its profitability. How does this industry relate to the business cycle, and what does this imply regarding profit margins at this point in the cycle? Most important, what did you conclude regarding the competitive environment in the industry, and what does this mean for the profitability of sales?

**Industry Profit Margin Forecast** Similar to the aggregate market, the net profit margin is the most volatile and the hardest margin to estimate directly. Alternatively, it is suggested that you begin with the operating profit margin (\( EBIT/\text{Sales} \)) and then estimate interest expense and the tax rate.

**The Industry’s Operating Profit Margin** Recall that in the market analysis, we analyzed the factors that should influence the economy’s operating profit margin, including capacity utilization,
unit labor cost, inflation, and net exports. The most important variables were capacity utilization and unit labor cost. We cannot do such an analysis for most industries because these variables (capacity utilization and unit labor cost) typically are not available for individual industries. As an alternative, we can assume that movements in these industry profit margin variables are related to movements in similar economic variables. For example, if we assume an increase in capacity utilization for the aggregate economies, there is probably a comparable increase in utilization for the auto industry or the chemical industry. The same could be true for unit labor cost. If there is a stable relationship between these variables for the industry and the economy, we would expect a relationship to exist between the profit margins for the industry and the economy. Although it is not necessary that the relationship be completely linear, it is important for the relationship (whatever it is) to be generally stable.

The operating profit margin (OPM) for the S&P Industrials Index and the RET industry is presented in Exhibit 13.15. The time-series plot in Exhibit 13.16 indicates that the S&P Industrials Index OPM experienced a steady increase from 1993 through 2000, followed by a decline during the recession year 2001. The margins slowly recovered from 2002 through 2007, but had small declines during the recession in 2008–2009. The RET industry OPM likewise experienced a fairly steady increase that peaked in 1999, followed by small declines in 2000 and 2001, a recovery in 2002 to a peak in 2005, gradual declines through 2008, and a small recovery in 2009. The regression analysis of the relationship between the OPM for the market and industry was not useful, so it is not discussed. Apparently, the best estimate for the RET industry is the OPM time-series plot using what we know about the changing competitive environment and profit trends in the retail business. The point is, any quantitative analysis should be a supplement to the macroanalysis of the competitive environment for the industry.

Regression analysis and the time-series analysis are both useful tools, but neither technique should be applied mechanically. You should be aware of any unique factors affecting the industry, such as price wars, contract negotiations, building plans, or foreign competition. These unique events can significantly impact an estimate of the gross profit margin or a range of industry profit margins (optimistic, pessimistic, most likely).

Beyond this estimation of the near-term OPM, it is important to consider the long-term profitability of the industry based on its competitive structure.

**Industry Interest Expense** An industry’s interest expense will be a function of its financial leverage and interest rates. As shown in Exhibit 13.17, interest expense for the RET industry has always been relatively low and stable compared to the S&P Industrials Index. Because there is not a relationship between the two interest expense series, an analyst would need to derive his/her own estimate based on two separate estimates: (1) changes in the amount of debt outstanding for this industry, and (2) the trend in interest rates (will they increase or decline?).

**Estimating Interest Expense** The historical data needed to estimate interest expense are in Exhibit 13.17, and we can use the following steps:

1. Estimate the annual total asset turnover (TAT) for the RET industry.
2. Use your 2011 sales and TAT forecasts to estimate total assets.
3. Estimate the long-term (interest-bearing) debt as a percentage of total assets for the RET industry.
4. Based on your estimate of total assets and the percent of long-term debt to total assets, estimate the dollar value of long-term debt.
5. Estimate the annual interest cost as a percentage of long-term debt based upon prior estimates of market yields.
6. Estimate interest expense based on the following:

\[
\text{(Estimated Interest Cost of Debt)} \times \text{(Estimated Long-Term Debt)}
\]

**Source:** Standard and Poor’s Analysts’ Handbook.
Based on the declines in market interest rates during 2010 and early 2011, we would estimate a debt rate of 4.50 percent. This interest rate estimate combined with our long-term debt estimate of $85.60 implies interest expense of $3.85 (0.045 × $85.60).

Industry Tax Rate

As you might expect, tax rates differ between industries. An extreme example would be the oil industry, in which heavy depletion allowances cause lower taxes. Generally, you can assume that tax law changes are consistent across industries. To see if this is valid, you need to examine the relationship of tax rates over time for your industry and the aggregate market to determine if you can use regression analysis in your estimation process. Alternatively, a time-series plot could provide a useful estimate.

Exhibit 13.19 indicates that the RET industry tax rate has been between 31 and 35 percent and has been at or below the lower boundary in recent years. Therefore, we would use 32 percent, although you still need to consider pending national legislation and unique industry tax factors. Using this estimated tax rate, you multiply the EBT per share value by (1 − 0.32) to get your estimate of earnings per share (EPS).

In addition to estimating EPS, you also should examine the industry’s net profit margin as a check on your EPS estimate. A time-series plot of the net profit margin series for the industry and the S&P Industrials Index is contained in Exhibit 13.20. Notably, both series experienced an overall increase of about 2 percent, but the RET industry has been less volatile.

An Industry Earnings Estimate Example

To help you understand the procedure, the following is an estimate of earnings per share for the RET industry. A practicing analyst would use this example as an initial estimate that would be modified based on his or her industry knowledge, current events, and expectations of unique factors.

Given that the best relationship was between RET industry sales and PCE—Food, Clothing, and Shoes, we estimated PCE and PCE—Food, Clothing, and Shoes as a percent of PCE and derived a RET sales estimate of $698 per share.

For example, our sales estimate of $698 and a TAT that has averaged about 1.63 over the recent years imply total assets of $428 next year. Long-term interest-bearing debt has averaged about 20 percent of total assets for the RET industry recently, so we will use that percent for 2011, which implies debt of $85.60 (0.20 × $428). In turn, interest expense as a percentage of long-term debt
As noted earlier, the OPM for the RET industry recovered from the recession in 2002 and experienced strong performance during 2003 through 2007. Following a decline during the 2008 recession, the margin recovered to almost 6 percent in 2009. We estimate a further recovery to 6.50 percent in 2010 and 7.00 percent in 2011, which implies operating profits in 2011 of $48.86 (0.07 × $698).

Exhibit 13.20 Time-Series Plot of the Net Profit Margin for the Industrials and Retail Industry: 1993–2009

The industry’s approximate debt cost during the recent period has been between 4 and 5 percent. Based on the declines in market interest rates during 2010 and early 2011, we would estimate a debt rate of 4.50 percent. This interest rate estimate combined with our long-term debt estimate of $85.60 implies interest expense of $3.85 (0.045 × $85.60).

**Industry Tax Rate** As you might expect, tax rates differ between industries. An extreme example would be the oil industry, in which heavy depletion allowances cause lower taxes. Generally, you can assume that tax law changes are consistent across industries. To see if this is valid, you need to examine the relationship of tax rates over time for your industry and the aggregate market to determine if you can use regression analysis in your estimation process. Alternatively, a time-series plot could provide a useful estimate.

Exhibit 13.19 indicates that the RET industry tax rate has been between 31 and 35 percent and has been at or below the lower boundary in recent years. Therefore, we would use 32 percent, although you still need to consider pending national legislation and unique industry tax factors. Using this estimated tax rate, you multiply the EBT per share value by (1 − 0.32) to get your estimate of earnings per share (EPS).

In addition to estimating EPS, you also should examine the industry’s net profit margin as a check on your EPS estimate. A time-series plot of the net profit margin series for the industry and the S&P Industrials Index is contained in Exhibit 13.20. Notably, both series experienced an overall increase of about 2 percent, but the RET industry has been less volatile.

**An Industry Earnings Estimate Example** To help you understand the procedure, the following is an estimate of earnings per share for the RET industry. A practicing analyst would use this example as an initial estimate that would be modified based on his or her industry knowledge, current events, and expectations of unique factors.

Given that the best relationship was between RET industry sales and PCE—Food, Clothing, and Shoes, we estimated PCE and PCE—Food, Clothing, and Shoes as a percent of PCE and derived a RET sales estimate of $698 per share.
Given the declining yields during 2010 and the flat interest rates envisioned during 2011, our estimate of interest expense was $3.85 in 2011. Thus, EBT would be $45.01 (48.86 - 3.85).

As noted earlier, the tax rate for the RET industry has consistently been in the 31–35 percent range in recent years, and 32 percent seems appropriate for 2011. This implies net income of $30.61 (45.01 × 0.68) and a net profit margin for the RET industry of 4.39 percent (30.61/698), which is similar to the 2007 margin.

Given an estimate of the industry’s net income per share (for simplicity, we will round the EPS estimate to $31 per share), the next step is to estimate the earnings multiplier for this industry.

**Estimating an Industry Earnings Multiplier** In this section, we discuss how to estimate an industry earnings multiplier using two alternative techniques: macroanalysis and microanalysis. In macroanalysis, you examine the relationship between the multiplier for the industry and the market. In microanalysis, you estimate the multiplier by examining the specific variables that influence it: (1) the dividend-payout ratio, (2) the required rate of return for the industry \( (k) \), and (3) the expected growth rate of earnings and dividends for the industry \( (g) \).

**Macroanalysis of an Industry Multiplier: Why a Relationship?** This subsection considers the relationship between the earnings multiplier \( (P/E \text{ ratio}) \) for an industry to the \( P/E \) for the aggregate market. We expect a relationship based on the variables that influence the multiplier—the required rate of return, the expected growth rate of earnings and dividends, and the dividend-payout ratio. Specifically, as discussed, the required rate of return \( (k) \) is a function of the nominal risk-free rate (which is the same for all investments) plus a risk premium, which is the major reason for differences in \( k \). Also, while the risk premium may differ between the market and an industry, any changes in the risk premium for the market and the industry are probably related.

Clearly, the rate of growth \( (g) \) for an industry may differ from that of the market and is a major reason for the difference in the level of the \( P/E \) ratio. Still, changes in the growth expectations for many industries are related to changes in \( g \) for the market and other industries because all of these growth rates are driven by macroeconomic growth factors that affect the overall market and most industries. Therefore, changes in the \( P/E \) ratio for the aggregate market and for alternative industries are caused by changes in the \( k – g \) spread. Because, these two variables have several components that move together, we expect an overall (macro) relationship between changes in an industry’s \( P/E \) and the market \( P/E \) ratio.

An examination of the relationship between the \( P/E \) ratios for 71 S&P industries and the S&P Industrials Index by Reilly and Zeller (1974) indicated a significant positive relationship between percentage changes in \( P/E \) ratios for most industries examined. Notably, because the significance of the relationship differed between alternative industries and the market, it is necessary to evaluate the quality of the relationship between the \( P/E \) ratios for a specific industry and the market before using this technique.

The results in Exhibits 13.6 and 13.21 for the RET industry indicate a relatively close relationship between the \( P/Es \) for the market and the RET industry. In fact, the \( P/E \) ratios have been very similar during six of the last seven years. Still, a crucial question is: Why has the RET industry multiplier been so similar to the market and should this similarity continue? The following microanalysis should help us answer this question.

**Microanalysis of an Industry Multiplier** In Chapter 12, we estimated a future market earnings multiplier by estimating a range of values for the three variables (i.e., dividend payout, \( k \), and \( g \)) that determine the multiplier and derived a range of \( P/E \) ratios that were used with our EPS estimate to compute a range of intrinsic values for the market index.

For the industry multiplier, we want to take advantage of the prior work on the stock market multiplier. Because the variables that affect the multipliers are the same, we can compare
our outlook for the three variables that determine the industry and market earnings multiplier. Hence, we can determine whether the industry earnings multiplier should be above, below, or equal to the market multiplier and can estimate a specific industry P/E ratio.

**Industry Multiplier versus the Market Multiplier** Recall from Exhibit 13.21 that the P/E ratios for the RET industry and the market generally moved together during the recent seven years, except for 2007. An analysis of the earnings multiplier factors should help us determine if this is an appropriate relationship.

**Comparing Dividend-Payout Ratios** The data in Exhibit 13.6 indicate that the retention rate for retail stores has consistently been higher than for the market (over 78 percent vs. about 63 percent). This indicates a higher dividend payout for the S&P Industrials Index, which alone implies a higher multiplier for the S&P Industrials Index.

**Comparing the Required Rates of Return** Earlier, we estimated the industry’s required rate of return \( (k) \) assuming a beta of 1.10 for the RET industry. Notably, this was not consistent with the fundamental risk characteristics of the industry that indicated slightly below average risk. In turn, this SML beta implied a \( k \) of 7.60 percent that we rounded to 8.00 percent, which compares to the stock market \( k \) derived in Chapter 12 of 8.00 percent. This specific variable indicates that the industry and market P/E should be approximately the same.

**Comparing the Expected Growth Rate (\( g \))** Previously, we estimated an industry growth rate in connection with the present value of cash flow models. Using the relationship:

\[
g = \text{Retention Rate} \times \text{Return on Equity (ROE)}
\]

\[
= (b) \times (\text{ROE})
\]

we estimated a \( g \) of over 11 percent based on historical and recent results.

This 11 percent growth rate estimate compares to the growth rates for the S&P Industrials Index of between 10 and 11 percent (using the long-run retention rate or the recent five-year
retention rate). Notably, the growth rates implied for both the industry (11 percent) and the market (10–11 percent) appear too high for any long-term period—that is, we typically use continuing growth rates of 5 to 6 percent. Therefore, while we would not use the higher growth rates for long-run estimates, the comparison appears valid for our purposes here. Specifically, the industry has a slightly higher g than the market, which implies that based on this specific variable alone that the industry multiple would be a little higher than the market multiple.

In summary, a comparison of the dividend-payout ratios indicates that the market \( P/E \) ratio should be higher. The required returns are approximately equal and the growth rate comparison barely favors the industry multiple. Therefore, overall the analysis suggests that the industry multiple should be similar to the market, which is consistent with the recent relationship. The discussion in Chapter 12 concluded that the forward market multiple should be about 20 times, which implies an industry multiplier in the 18 to 22 range.

**Estimate of Industry Value** Based upon an earlier estimate of industry earnings per share ($31.00) and an estimate for an industry earnings multiple in the 18 to 22 range imply a range of intrinsic values as follows:

\[
\begin{align*}
\text{Optimistic Multiple:} & \quad 22 \times 31.00 = $682 \\
\text{Expected Multiple:} & \quad 20 \times 31.00 = $620 \\
\text{Pessimistic Multiple:} & \quad 18 \times 31.00 = $558
\end{align*}
\]

Given a current market price for the industry index of about $430, all of these results indicate the industry is underpriced. Put another way, while we envisioned \( P/Es \) of between 18 and 22, the RET industry is currently priced at about 14 times.

## 13.8 Other Relative Valuation Ratios

Now we need to consider the other three relative valuation ratios (\( P/BV \), \( P/CF \), and \( P/S \)) and compare their performance over time relative to similar ratios for the aggregate stock market (the S&P Industrials Index).

Again, the calculations employ the average annual price and future book value, cash flow, and sales. The input data derived for the industry and the S&P Industrials Index (from Chapter 12) with 10-year growth rates for each of these variables are contained in Exhibit 13.22. Notably, the subsequent comparison indicates that the compound growth rate for every RET industry variable is higher than the growth rate for the same aggregate market variable.

Exhibit 13.23 contains the four relative valuation ratios for the RET industry and for the S&P Industrials Index, along with the ratio of the annual industry valuation ratio divided by the market valuation ratio. For each valuation ratio, you should examine the long-run industry-market relationship, including any changes in this relationship. Subsequently, the goal is to explain the overall relationship and consider any changes that have occurred and whether these changes in the relationship can be explained based upon the factors that should determine the relative valuation ratio. The comparative \( P/E \) ratios will not be discussed again because we previously concluded they should be approximately equal.

### 13.8.1 The Price/Book Value Ratio

Exhibit 13.24 shows the overall increase in the price/book value ratio experienced by both the market and the industry to a peak of about five times in 1999 followed by a brief trough in 2003, after which they are virtually equal. Notably, the relationship between the industry and the market has typically shown the market \( P/BV \) ratio larger than or equal to the RET industry ratio. The ratios were equal in 2008 at the lowest values since 1993.

The relationship of generally equal ratios is reasonable because the P/BV ratio should reflect the ability of the market or an industry to earn a ROE that exceeds its cost of equity. During the last five years, the ROE for the industry has been larger than for the market, but the cost of equity for the industry is also higher (β = 1.10). This consistency between ROE and risk implies that the P/BV ratio for the industry should be similar to the market.

13.8.2 The Price/Cash Flow Ratio

As shown in Exhibit 13.23 and Exhibit 13.25, the P/CF ratios peaked in the late 1990s, then declined to about 11 times; both series ended with their lowest values since 1993, with the industry multiple a little larger. The P/CF ratio is similar to the P/E ratio because it is driven by the growth rate and the stability of the cash flow series. As shown in Exhibit 13.22, the growth rate of the industry CF has consistently been higher than the market CF (i.e., over 14 percent versus about 5 percent). Also, the growth of the industry CF series was more consistent than the market's growth. Therefore, the P/CF ratio relationship is in the right direction (the industry ratio is larger), and the difference in the P/CF ratio of about 38 percent seems justified by the substantial difference in the growth rate of CF and its consistency.

13.8.3 The Price/Sales Ratio

As shown in Exhibits 13.23 and 13.26, the P/S ratio for the aggregate market has always been substantially higher in terms of the mean values (0.72 vs. 1.30), during the final year (0.55 vs. 0.99), or the mean industry/market ratio (0.57). The P/S ratio should be impacted by three factors: (1) sales growth rate, (2) the uncertainty (risk) of sales growth, and (3) the profitability of sales (i.e., the net profit margin). The results indicate the following: (1) The industry experienced a higher rate of growth for sales during the recent 10-year period; (2) both the industry and the market experienced relatively low volatility in sales growth; and (3) the profit margin (PM).

The relationship of generally equal ratios is reasonable because the P/BV ratio should reflect the ability of the market or an industry to earn a ROE that exceeds its cost of equity. During the last five years, the ROE for the industry has been larger than for the market, but the cost of equity for the industry is also higher ($β = 1.10$). This consistency between ROE and risk implies that the P/BV ratio for the industry should be similar to the market.

### 13.8.2 The Price/Cash Flow Ratio

As shown in Exhibit 13.23 and Exhibit 13.25, the P/CF ratios peaked in the late 1990s, then declined to about 11 times; both series ended with their lowest values since 1993, with the industry multiple a little larger. The P/CF ratio is similar to the P/E ratio because it is driven by the growth rate and the stability of the cash flow series. As shown in Exhibit 13.22, the growth rate of the industry CF has consistently been higher than the market CF (i.e., over 14 percent versus about 5 percent). Also, the growth of the industry CF series was more consistent than the market’s growth. Therefore, the P/CF ratio relationship is in the right direction (the industry ratio is larger), and the difference in the P/CF ratio of about 38 percent seems justified by the substantial difference in the growth rate of CF and its consistency.

### 13.8.3 The Price/Sales Ratio

As shown in Exhibits 13.23 and 13.26, the P/S ratio for the aggregate market has always been substantially higher in terms of the mean values (0.72 vs. 1.30), during the final year (0.55 vs. 0.99), or the mean industry/market ratio (0.57). The P/S ratio should be impacted by three factors: (1) sales growth rate, (2) the uncertainty (risk) of sales growth, and (3) the profitability of sales (i.e., the net profit margin). The results indicate the following: (1) The industry experienced a higher rate of growth for sales during the recent 10-year period; (2) both the industry and the market experienced relatively low volatility in sales growth; and (3) the profit margin (PM)
13.8.4 Summary of Industry/Market Ratios

Exhibit 13.27 contains the four industry-market ratios for each of the valuation ratios. These results indicate that investors’ assessment of this industry relative to the market has declined slightly over time because all the industry-market relative ratios have declined. Only the price/FCF ratio for the industry is above the market. Given that the industry has higher growth rates for all of these variables and generally lower risk characteristics, this indicates that possibly the industry is undervalued relative to the aggregate stock market.

13.9 Global Industry Analysis

Because so many firms are active in foreign markets and because the proportion of foreign sales is growing for many firms, it is necessary to consider the effects of foreign firms on industry returns. To see why this is so, consider the auto industry. Besides Ford and General Motors, the auto industry for a global investor includes numerous firms from Japan, Germany, Italy, and Korea, among others. Thus, we must extend our analysis to include global factors.

While space does not permit an example, the following major factors need to be analyzed in this context:

1. The macroenvironment in the major producing and consuming countries for an industry. This will impact demand from these countries.
2. An overall analysis of the significant global companies in the industry, the products they produce, and how successful they are in terms of the DuPont three-component analysis.
3. Regarding company analysis, what are the accounting differences by country and how do these differences impact the relative valuation ratios? Because of accounting differences, it is typically not possible to directly compare many ratios across countries but only to

has always been higher for the market, but the difference in profit margins has declined in recent years. Therefore, the direction of difference is appropriate (the market should be higher because of the difference in the important PM), but one might question whether the size of the difference is too much.
13.8.4 Summary of Industry/Market Ratios
Exhibit 13.27 contains the four industry-market ratios for each of the valuation ratios. These results indicate that investors’ assessment of this industry relative to the market has declined slightly over time because all the industry-market relative ratios have declined. Only the price/CF ratio for the industry is above the market. Given that the industry has higher growth rates for all of these variables and generally lower risk characteristics, this indicates that possibly the industry is undervalued relative to the aggregate stock market.

13.9 Global Industry Analysis
Because so many firms are active in foreign markets and because the proportion of foreign sales is growing for many firms, it is necessary to consider the effects of foreign firms on industry returns. To see why this is so, consider the auto industry. Besides Ford and General Motors, the auto industry for a global investor includes numerous firms from Japan, Germany, Italy, and Korea, among others. Thus, we must extend our analysis to include global factors.

While space does not permit an example, the following major factors need to be analyzed in this context:

- The macroenvironment in the major producing and consuming countries for an industry. This will impact demand from these countries.
- An overall analysis of the significant global companies in the industry, the products they produce, and how successful they are in terms of the DuPont three-component analysis.
- Regarding company analysis, what are the accounting differences by country and how do these differences impact the relative valuation ratios? Because of accounting differences, it is typically not possible to directly compare many ratios across countries but only to
examine them over time within a country. This problem should be reduced as the use of international accounting standards grows, as discussed in Chapter 10.

- What is the effect of currency exchange rate trends for the major countries? Significant currency changes can affect the demand for U.S. products from specific countries and also impact costs, assuming U.S. firms receive inputs from foreign firms.

Global industry analysis is growing in importance as documented by Cavaglia, Brightman, and Aked (2000). Specifically, prior research showed that country factors dominated industry factors in terms of explaining equity returns, but the Cavaglia et al. (2000) study presented evidence that industry factors have been growing in importance and currently dominate country factors. In summary, it is important to carry out industry analysis on a global scale.

**SUMMARY**

- Several studies examined industry performance and risk. They found wide dispersion in the performance of alternative industries during specified time periods, implying that industry analysis can help identify superior investments. They also showed inconsistent industry performance over time, implying that looking at only past performance of an industry has little value in projecting future performance. Also, the performance by firms within industries typically is not very consistent, so you must analyze the individual companies in an industry following the industry analysis.
- The analysis of industry risk indicated wide dispersion in the measures of risk for different industries but strong consistency in the risk measure over time for individual industries. These results imply that risk analysis and measurement are useful and necessary. The good news is that past risk measures are useful when estimating future risk.
- We discussed and demonstrated both approaches to the valuation of the RET industry. The present value of cash flow models indicated a fairly wide range of values.
- The four relative valuation ratio techniques also provided a range of results, including the two-step earnings multiple technique where the multiple results surrounded the current market price. All of the relative valuation ratios declined over time relative to the market.
- Industry analysis needs to be carried out on a global scale and must evaluate the effects of world supply, demand, and cost components for an industry but also different valuation levels due to accounting conventions. Finally, you must consider the impact of exchange rates on the total industry and the firms within it.

**SUGGESTED READINGS**

The following are proceedings from industry analysis seminars sponsored by the Association for Investment Management and Research (AIMR):

QUESTIONS

1. Briefly describe the results of studies that examined the performance of alternative industries during specific time periods, and discuss their implications for industry analysis.
2. Briefly describe the results of the studies that examined industry performance over time. Do these results complicate or simplify industry analysis?
3. Assume all the firms in a particular industry have consistently experienced similar rates of return. Discuss what this implies regarding the importance of industry and company analysis for this industry.
4. Discuss the contention that differences in the performance of various firms within an industry limit the usefulness of industry analysis.
5. Several studies have examined the difference in risk for alternative industries during a specified time period. Describe the results of these studies, and discuss their implications for industry analysis.
6. What were the results when industry risk was examined during successive time periods? Discuss the implication of these results for industry analysis.
7. Assume the industry you are analyzing is in the fourth stage of the industrial life cycle. How would you react if your industry-economic analysis predicted that sales per share for this industry would increase by 20 percent? Discuss your reasoning.
8. Discuss at what stage in the industrial life cycle you would like to discover an industry. Justify your decision.
9. Give an example of an industry in Stage 2 of the industrial life cycle. Discuss your reasoning for putting the industry in Stage 2 and any evidence that caused you to select this stage for the industry.
10. Discuss the impact of substitute products on the steel industry’s profitability.
11. Discuss the two variables that must be considered whether you are using the present value of cash flow approach or the relative valuation ratio approach to valuation. Why are these variables relevant for either valuation approach?
12. List the three variables that are relevant when attempting to determine whether the earnings multiple (P/E ratio) for an industry should be higher, equal to, or lower than the market multiple.
13. Discuss when you would use the two-stage growth FCFE model rather than the constant growth model.
14. You are examining the P/CF ratio for an industry compared to the market and find that the industry ratio has always been at a discount to the market—for example, the industry-market ratio of ratios is about 0.80. Discuss the variable(s) you would examine to explain this difference or to justify an increase in the industry-market ratio.

PROBLEMS

1. Select three industries from Standard and Poor’s Analysts’ Handbook, or some other source of industry data with different demand factors. For each industry, indicate what economic series you would use to predict the growth for the industry. Discuss why the economic series selected is relevant for this industry.
2. Prepare a scatterplot for one of the industries in Problem 1 of industry sales per share and observations from the economic series you suggested for this industry. Do this for the most recent 10 years using information available in the Analysts’ Handbook or another source. Based on the results of the scatterplot, discuss whether the economic series was closely related to this industry’s sales.
3. Based on an analysis of the results in Problem 2, discuss the stage of your industry in its life cycle.
4. Evaluate your industry in terms of the five factors that determine an industry’s intensity of competition. Based on this analysis, what are your expectations about the industry’s profitability in the short run (1 or 2 years) and the long run (5 to 10 years)?

5. Using Standard and Poor’s Analysts’ Handbook or another source, plot the latest 10-year history of the operating profit margin for the S&P Industrials Index or another aggregate market series versus an industry of your choice. Is there a positive, negative, or zero correlation?

6. Using the Analysts’ Handbook or another source of industry data, calculate the means for the following variables of the S&P Industrials Index or another aggregate market series and the industry of your choice during the last 10 years:
   a. Price/earnings multiplier
   b. Retention rate
   c. Return on equity
   d. Equity turnover
   e. Net profit margin

   Briefly comment on how your industry and the S&P Industrials Index differ for each of the variables.

7. Prepare a table listing the variables that influence the earnings multiplier for your chosen industry and the market index series for the most recent 10 years.
   a. Do the average dividend-payout ratios for your industry and the market index differ? How should the dividend payout influence the difference between the multipliers?
   b. Based on the fundamental factors, would you expect the risk for this industry to differ from that for the market? In what direction, and why? Calculate the industry beta using monthly data for five years. Based on the fundamental factors and the computed systematic risk, how does this industry’s risk compare to the market? What effect will this difference in risk have on the industry multiplier relative to the market multiplier?
   c. Analyze and discuss the different components of growth (retention rate, total asset turnover, total assets/equity, and profit margin) for your chosen industry and a market index during the most recent 10 years. Based on this analysis, how would you expect the growth rate for your industry to compare with the growth rate for the market index? How would this difference in expected growth affect the multiplier?
A. Preparing an Industry Analysis: What Is an Industry?\(^6\)

Identifying a company’s industry can be difficult in today’s business world. Although airlines, railroads, and utilities may be easy to categorize, what about manufacturing companies with three different divisions, none of which is dominant? Perhaps the best way to test whether a company fits into an industry grouping is to compare the operating results for the company and an industry. For our purposes, an industry is a group of companies with similar demand, supply, and operating characteristics.

The following is a set of guidelines for preparing an industry appraisal, including the topics to consider and some specific items to include.

**Characteristics to Study**

1. Price history reveals valuable long-term relationships:
   a. Price/earnings ratios
   b. Common stock yields
   c. Price/book value ratios
   d. Price/cash flow ratios
   e. Price/sales ratios
2. Operating data show comparisons of:
   a. Return on total investment (ROI)
   b. Return on equity (ROE)
   c. Sales growth
   d. Trends in operating profit margin
   e. Evaluation of stage in industrial life cycle
   f. Book-value-per-share growth
   g. Earnings-per-share growth
   h. Profit margin trends (gross, operating, and net)
   i. Evaluation of exchange rate risk from foreign sales
3. Comparative results of alternative industries show:
   a. Effects of business cycles on each industry group
   b. Secular trends affecting results
   c. Industry growth compared to other industries
   d. Regulatory changes
   e. Importance of overseas operations

**Factors in Industry Analysis**

**Markets for Products**

1. Trends in the markets for the industry’s major products: historical and projected
2. Industry growth relative to GDP or other relevant economic series; possible changes from past trends
3. Shares of market for major products among domestic and global producers; changes in market shares in recent years; outlook for market share
4. Effect of imports on industry markets; share of market taken by imports; price and margin changes caused by imports; outlook for imports
5. Effect of exports on their markets; trends in export prices and units exported; outlook for exports
6. Expectations for the exchange rates in major non-U.S. countries; historical volatility of exchange rates; outlook for the level and volatility of exchange rates

Financial Performance
1. Capitalization ratios; ability to raise new capital; earnings retention rate; financial leverage
2. Ratio of fixed assets to capital invested; depreciation policies; capital turnover
3. Return on total capital; return on equity capital; components of ROE
4. Return on foreign investments; need for foreign capital

Operations
1. Degrees of integration; cost advantages of integration; major supply contracts
2. Operating rates as a percentage of capacity; backlogs; new-order trends
3. Trends of industry consolidation
4. Trends in industry competition
5. New-product development; research and development expenditures in dollars and as a percentage of sales
6. Diversification; comparability of product lines

Management
1. Management depth and ability to develop from within; organizational structure
2. Board of directors: internal versus external members; compensation package
3. Flexibility to deal with product demand changes; ability to identify and eliminate losing operations
4. Record and outlook regarding labor relations
5. Dividend policy and historical progression

B. Insights on Analyzing Industry ROAs

Insights on Industry ROAs Beyond the normal analysis of ROA as a component of ROE (ROA times total assets/equity equals ROE), an article by Selling and Stickney provides some interesting insights for industry analysis based upon an analysis of the two components of the ROA ratio (profit margin and total asset turnover) and what these two components signal regarding the industry strategy. Given the two components of the ROA, it is possible to graph each of these values, as shown in Exhibit 13A.1, and determine what each component contributed to the ROA at the point of intersection. As shown, it is possible to draw a constant ROA curve, which demonstrates that it is possible to achieve an 8 percent (or 4 percent) ROA with numerous combinations of profit margin and asset turnover. The particular combination of profit margin and asset turnover is generally dictated by the nature of the industry and the strategy employed by management. For example, many industries necessarily require large capital inputs for equipment (e.g., steel, auto, heavy machinery manufacturers). Therefore, the asset turnover is necessarily low, which means the profit margin must be higher. The firms in such an industry are typically in the upper left segment of the graph (Segment a), and improvements of ROA in these industries are derived by increasing profit margins because it is

difficult to increase asset turnover. In contrast, industries that have commodity-type products (e.g., retail food, paper, industrial chemicals) generally have low profit margins and succeed based upon high asset turnover. These industries are generally in the lower right segment of the graph (Segment c), and they attempt to improve their ROA by increasing their asset turnover rather than the profit margin (i.e., they are constrained regarding the profit margin by price competition). Industries in the middle segment (b) are in a more balanced position and can attempt to improve the ROA by increasing either the profit margin or the asset turnover.

CHAPTER 14
Company Analysis and Stock Valuation

After you read this chapter, you should be able to answer the following questions:

- Why is it important to differentiate between company analysis and stock valuation?
- What is the difference between a true growth company and a growth stock?
- How do we apply the two valuation approaches and the several valuation techniques to Walgreens?
- What techniques are useful when estimating the inputs to alternative valuation models?
- What techniques are useful when estimating company sales?
- How do we estimate the profit margins and earnings per share for a company?
- What factors are considered when estimating the earnings multiplier for a firm?
- What two specific competitive strategies can a firm use to cope with the competitive environment in its industry?
- In addition to the earnings multiplier, what insights can be gained from other relative valuation ratios?
- How do we apply the several present value of cash flow models to the valuation of a company?
- What value-added measures are available to evaluate the performance of a firm?
- How do we compute economic value added (EVA) and market value added (MVA)?
- How do these value-added measures relate to changes in the market value of firms?
- What is the relationship between positive EVA and a true growth company?
- Why is it inappropriate to use the standard dividend discount model (DDM) to value a true growth company?
- What is the difference between no growth, simple growth, and dynamic growth?
- What is the growth duration model, and what information does it provide?
- Once you compute a stock's growth duration, how do you make an investment decision?
- How can we use the growth duration model to estimate the P/E for a growth company?
- How can site visits and interviews provide unique insights (discovery) not generally available?
- What factors should lead you to sell a stock?
- What additional factors should be considered when analyzing a company on a global basis?

At this point, you have made two decisions about your investment in equity markets. First, after analyzing the economy and stock markets for several countries, you have decided what percent of your portfolio should be invested in common stocks and your allocation to alternative countries (i.e., overweight, market weight, or underweight). Second, after analyzing various industries, you have identified those that appear to offer above-average risk-adjusted performance over your investment horizon. The final questions in the fundamental analysis procedure are: (1) Which are the best companies within these desirable industries? and (2) What is the intrinsic value of the firm's stock? Specifically, is the intrinsic value of the stock above its market value, or is the expected rate of return on the stock equal to or greater than its required rate of return?

We begin with a discussion of the difference between company analysis and stock valuation. Company analysis should occur in the context of the prevailing economic

At this point, you have made two decisions about your investment in equity markets. First, after analyzing the economy and stock markets for several countries, you have decided what percent of your portfolio should be invested in common stocks and your allocation to alternative countries (i.e., overweight, market weight, or underweight). Specifically, is the intrinsic value of the stock above its market value, or is the expected rate of return on the stock equal to or greater than its required rate of return?

We begin with a discussion of the difference between company analysis and stock valuation. Company analysis should occur in the context of the prevailing economic
prices relatively quickly and accurately to reflect new information, available information is not always perfect or complete. Therefore, imperfect or incomplete information may cause a given stock to be undervalued or overvalued at a point in time. If the stock is undervalued, its price should eventually increase to reflect its true fundamental (intrinsic) value when the correct information becomes available. During this period of price adjustment, the stock’s realized return will exceed the required return for a stock with its risk, and during this period of adjustment, it will be a growth stock. Growth stocks are not necessarily limited to growth companies. A future growth stock can be the stock of any type of company; the stock need only be undervalued by the market.

The fact is, if investors recognize a growth company and discount its future earnings stream properly, the current market price of the growth company’s stock will reflect its future earnings stream. Those who acquire the stock of a growth company at this correct market price will receive a rate of return consistent with the risk of the stock, even when the superior earnings growth is attained. In many instances, overeager investors tend to overestimate the expected growth rate of earnings and cash flows for the growth company and, therefore, inflate the price of a growth company’s stock. Investors who pay the inflated stock price (compared to its true intrinsic value) will earn a rate of return below the risk-adjusted required rate of return, despite the fact that the growth company experiences above-average growth of sales and earnings. Studies by Solt and Statman (1989), Shefrin and Statman (1995), and Clayman (1987) have examined the stock price performance for samples of growth companies and found that their stocks performed poorly—that is, the stocks of growth companies have generally not been growth stocks.

14.1.2 Defensive Companies and Stocks

Defensive companies are those whose future earnings are likely to withstand an economic downturn. One would expect them to have relatively low business risk and not excessive financial risk. Typical examples are fast food chains or grocery stores—firms that supply basic consumer necessities.

There are two closely related concepts of a defensive stock. First, a defensive stock’s rate of return is not expected to decline during an overall market decline, or decline less than the overall market. Second, our CAPM discussion indicated that an asset’s relevant risk is its covariance with the market portfolio of risky assets—that is, an asset’s systematic risk. A stock with low or negative systematic risk (a small positive or negative beta) may be considered a defensive stock according to this theory because its returns are unlikely to be harmed significantly in a bear market.

14.1.3 Cyclical Companies and Stocks

A cyclical company’s sales and earnings will be heavily influenced by aggregate business activity. Examples would be firms in the steel, auto, or heavy machinery industries. Such companies will outperform other firms during economic expansions and seriously underperform during economic contractions. This volatile earnings pattern is typically a function of the firm’s business risk (both sales volatility and operating leverage) and can be compounded by financial risk.

A cyclical stock will experience changes in its rates of return greater than changes in overall market rates of return. In terms of the CAPM, these would be stocks that have high betas. The stock of a cyclical company, however, is not necessarily cyclical. A cyclical stock is the

prices relatively quickly and accurately to reflect new information, available information is not always perfect or complete. Therefore, imperfect or incomplete information may cause a given stock to be undervalued or overvalued at a point in time.

If the stock is undervalued, its price should eventually increase to reflect its true fundamental (intrinsic) value when the correct information becomes available. During this period of price adjustment, the stock’s realized return will exceed the required return for a stock with its risk, and during this period of adjustment, it will be a growth stock. A cyclical company’s sales and earnings will be heavily influenced by aggregate business activity. Examples would be firms in the steel, auto, or heavy machinery industries. Such companies will outperform other firms during economic expansions and seriously underperform during economic contractions. This volatile earnings pattern is typically a function of the firm’s business risk (both sales volatility and operating leverage) and can be compounded by financial risk.

A cyclical stock will experience changes in its rates of return greater than changes in overall market rates of return. In terms of the CAPM, these would be stocks that have high betas. The stock of a cyclical company, however, is not necessarily cyclical. A cyclical stock is the...

familiar with the cash flow and risk attributes of the firms they are studying. Given a period of economic-industry growth, the most attractive firms in the industry will typically have high levels of operating leverage wherein a modest percentage increase in revenue results in a much larger percentage rise in earnings and cash flow. The point is, firms in an industry will have varying sensitivities to economic variables, such as economic growth, interest rates, input costs, and exchange rates. Because each firm is different, an investor must determine the best candidates for purchase under expected economic conditions.

14.2.2 Structural Influences

In addition to economic variables, other factors, such as social trends, technology, and political and regulatory influences, can have a major effect on some firms in an industry. Some firms in the industry are able to take advantage of demographic changes or shifts in consumer tastes and lifestyles, or they can invest in technology to lower costs and better serve their customers. Such firms grow and succeed despite unfavorable industry or economic conditions. For example, Walmart became the nation’s leading retailer because of several smart management decisions. The geographic location of many of its stores allowed it to benefit from regional population growth and lower labor costs. Its competitive strategy, which emphasized everyday low prices, was appealing to consumers concerned about the price and value of purchases. Finally, its technologically advanced inventory and ordering systems and its outstanding distribution system gave Walmart a clear competitive (cost) advantage.

During the initial stage of an industry’s life cycle, the original firms in the industry can refine their technologies and move down the learning curve. Subsequent followers may benefit from these initial actions and can learn from the leaders’ mistakes and take the market lead (e.g., Walmart vs. Sears). Investors need to be aware of such leadership changes so that they can evaluate companies and their stocks accordingly.

Political and regulatory events can create opportunities in an industry even during weak economic periods. Deregulation in trucking, airlines, and the financial services industries in the 1980s led to the creation of new companies with innovative strategies. As a result, sharp price declines following bad industry news may be a good buying opportunity for astute investors. Some stocks in an industry may deserve lower prices following some political or regulatory events; but, if the market also punishes the stock prices of good companies with smaller exposures to the bad news, then an alert analyst will identify buying opportunities of underpriced stocks within an industry.

The bottom line is that, although the economy plays a major role in determining overall market trends and industry groups display sensitivity to economic variables, other structural changes may counterbalance the economic effects, or company management may be able to minimize the impact of economic or industry events on a company. Analysts who are familiar with industry trends and company strategies can include this economic-industry information into their valuation models and issue well-reasoned buy-and-sell recommendations irrespective of the economic forecast.

14.3 COMPANY ANALYSIS

This section groups various analysis components for discussion. The first subsection continues the Porter discussion of an industry’s competitive environment. The basic SWOT analysis is intended to articulate a firm’s strengths, weaknesses, opportunities, and threats. These two analyses should provide an understanding of a firm’s overall strategic approach. Given this background, we demonstrate the two valuation approaches: (1) the present value of cash flows, and (2) relative valuation ratio techniques. Subsequently, we discuss the unique features of true growth companies and demonstrate several models that can be used to value growth stocks.

14.3.2 Focusing a Strategy

Whichever strategy it selects, a firm must determine where it will focus this strategy. Specifically, a firm must select segments in the industry and tailor its strategy to serve these specific groups. For example, a low-cost strategy would typically exploit cost advantages for certain segments of the industry, such as being the low-cost producer for the expensive segment of the market. Similarly, a differentiation focus would target the special needs of buyers in specific segments. For example, in the athletic shoe market, companies have attempted to develop shoes for unique sport segments, such as tennis, basketball, aerobics, or walkers and hikers, rather than offering only shoes for runners. Athletic shoe firms thought that participants in these alternative activities needed shoes with characteristics different from those desired by joggers. Equally important, they believed that these athletes would be willing to pay a premium for these special shoes. Again, you must ascertain if special possibilities exist, if they are being served by another firm, and if they can be priced to generate abnormal returns to the firm. Exhibit 14.1 details some of Porter’s ideas for the skills, resources, and company or- ganizational requirements needed to successfully develop a cost leadership or a differentiation strategy.

Next, determine which strategy the firm is pursuing and its success. Also, can the strategy be sustained? Further, you should evaluate a firm’s competitive strategy over time, because strategies need to change as an industry evolves; different strategies work during different phases of an industry’s life cycle. For example, differentiation strategies may work for firms in an industry during the early growth stages. Subsequently, when the industry is in the mature stage, firms may try to lower their costs and become a cost leader.

process developing a company’s “story.” This evaluation enables the analyst to determine the outlook and risks facing the firm. In summary, understanding the industry’s competitive forces and the firm’s strategy for dealing with this competitive environment is the key to understanding how a company makes money and deriving an accurate and unique estimate of the firm’s long-run cash flows and its risks.

Another framework for examining and understanding a firm’s competitive position and its strategy is a company SWOT analysis.

14.3.3 SWOT Analysis

As before, SWOT analysis involves an examination of a firm’s strengths, weaknesses, opportunities, and threats. It should help you evaluate a firm’s strategies to exploit its competitive advantages or defend against its weaknesses. Strengths and weaknesses involve identifying the firm’s internal abilities or lack thereof. Opportunities and threats include external situations, such as competitive forces, discovery and development of new technologies, government regulations, and domestic and international economic trends.

The strengths of a company give the firm a comparative advantage in the marketplace. Perceived strengths can include good customer service, high-quality products, strong brand image, customer loyalty, innovative R&D, market leadership, or strong financial resources. To remain strengths, they must continue to be developed, maintained, and defended through prudent capital investment policies.

Weaknesses result when competitors have potentially exploitable advantages over the firm. Once weaknesses are identified, the firm can select strategies to mitigate or correct the weaknesses. For example, a firm that is only a domestic producer in a global market can make investments that will allow it to export or produce its product overseas. Another example would be a firm with poor financial resources that would form joint ventures with financially stronger firms.

Opportunities, or environmental factors that favor the firm, can include a growing market for the firm’s products (domestic and international), shrinking competition, favorable exchange rate shifts, identification of new markets or products, and new marketing or distribution channels (e.g., the Web).

Threats are environmental factors that can hinder the firm in achieving its goals. Examples include a slowing domestic economy (or sluggish overseas economies for exporters), additional government regulation, an increase in industry competition, threats of entry, buyers or suppliers seeking to increase their bargaining power, and new technology that can make the industry’s product obsolete. By recognizing and understanding opportunities and threats, an investor can make informed decisions about how the firm can exploit opportunities and mitigate threats.

14.3.4 Some Lessons from Lynch

Peter Lynch (1989, 1993), the former portfolio manager of Fidelity Investments’ highly successful Magellan Fund, looks for the following favorable attributes when he analyzes firms:

1. The firm’s product is not faddish; it is one that consumers will continue to purchase over time.
2. The company has a sustainable comparative competitive advantage over its rivals.
3. The firm’s industry or product has market stability. Therefore, it has little need to innovate or create product improvements or fear that it may lose a technological advantage. Market stability means less potential for entry.
4. The firm can benefit from cost reductions (e.g., a computer manufacturer that uses technology provided by suppliers to deliver a faster and less-expensive product).
5. The firm buys back its shares or management purchases shares, which indicates that its insiders are putting their money into the firm.
14.3.5 Tenets of Warren Buffett
The following tenets are from Robert Hagstrom (2001). The parenthetical comments are based on discussions in the book and Berkshire Hathaway annual report letters.

Business Tenets
- Is the business simple and understandable?
  (This makes it easier to estimate future cash flows with a high degree of confidence.)
- Does the business have a consistent operating history?
  (Again, cash flow estimates can be made with more confidence.)
- Does the business have favorable long-term prospects?
  (Does the business have a franchise product or service that is needed or desired, has no close substitute, and is not regulated? This implies that the firm has pricing flexibility.)

Management Tenets
- Is management rational?
  (Is the allocation of capital to projects that provide returns above the cost of capital? If not, does management pay capital to stockholders through dividends or the repurchase of stock?)
- Is management candid with its shareholders?
  (Does management tell owners everything you would want to know?)
- Does management resist the institutional imperative?
  (Does management not attempt to imitate the behavior of other managers?)

Financial Tenets
- Focus on return on equity, not earnings per share.
  (Look for strong ROE with little or no debt.)
- Calculate owner earnings.
  (Owner earnings are basically equal to free cash flow after capital expenditures.)
- Look for a company with relatively high sustainable profit margins for its industry.
- Make sure the company has created at least one dollar of market value for every dollar retained.

Market Tenets
- What is the intrinsic value of the business?
  (Value is equal to future free cash flows discounted at a government bond rate. Using this low discount rate is considered appropriate because Warren Buffett is very confident of his cash flow estimates due to his deep understanding of the business based on extensive analysis. This confidence implies low risk.)
- Can the business be purchased at a significant discount to its fundamental intrinsic value?

The point is to make use of research on the competitive forces in an industry, a firm’s responses to those forces, SWOT analysis, Lynch’s suggestions, and Buffett’s tenets.

14.4 Estimating Intrinsic Value
Now that the analysis of the economy, structural forces, the industry, the company, and its competitors is completed, it is time to estimate the intrinsic value of the firm’s common stock. If the intrinsic value estimate exceeds the stock’s current market price, the stock should be purchased. In contrast, if the current market price exceeds our intrinsic value estimate, we should avoid the stock or sell it if we own it.

As in Chapter 11, we will consider two general approaches to valuation and the following techniques.
### Present Value of Cash Flows (PVCF)

1. Present value of dividends (DDM)
2. Present value of free cash flow to equity (FCFE)
3. Present value of free operating cash flow to the firm (FCFF)

### Relative Valuation Techniques

1. Price/earnings ratio (P/E)
2. Price/cash flow ratio (P/CF)
3. Price/book value ratio (P/BV)
4. Price/sales ratio (P/S)

This section contains a brief presentation for each of these techniques as applied to Walgreens, the largest retail drugstore (RDS) chain in the United States. It operates 7,562 drugstores in 50 states, the District of Columbia, Guam, and Puerto Rico. Its pharmacy operation consistently generates over 65 percent of sales.

Although we limit our demonstration to Walgreens (whose ticker symbol is WAG), a complete analysis would cover all the firms in the retail drugstore industry to determine which stocks should perform the best. The objective is to estimate the expected return and risk for all the individual firms in the industry over your investment horizon. Initially, we consider the present value of cash flow (PVCF) models. Exhibit 14.2 contains historical data during the recent 20 years for Walgreens required for the PVCF models.

### 14.4.1 Present Value of Dividends

As noted in Chapter 11, because determining the present value of all future dividends is difficult, analysts typically apply simplifying assumptions when employing the dividend discount models (DDMs). The typical assumption is that the stock’s dividends will grow at a constant rate over time. Although unrealistic for fast-growing or cyclical firms, this assumption may be appropriate for many mature firms. More complex DDMs exist for more complicated growth forecasts, including two-stage growth models (a period of fast growth followed by a period of constant growth) and three-stage growth models (a period of fast growth followed by a period of diminishing growth rates followed by a period of constant growth).

Recall that the constant-growth DDM implies that when dividends grow at a constant rate, a stock’s price should equal next year’s dividend ($D_t$) divided by investors’ required rate of return on the stock ($k$) minus the dividend growth rate ($g$):

\[
\text{Intrinsic Value} = \frac{D_t}{k - g}
\]

Assuming constant dividend growth, next year’s dividend ($D_t$) should equal the current dividend, $D_0$, increased by the constant dividend growth rate: $D_t = D_0(1 + g)$. Because the current dividend is known, to estimate intrinsic value we need only estimate the dividend growth rate and investors’ required rate of return.

**Growth Rate Estimates** If the stock has had fairly constant dividend growth over the past 5 to 10 years, one estimate of the constant-growth rate is to use the actual growth of dividends over this period. The average compound rate of growth is found by computing:

\[
\text{Average Dividend Growth Rate} = \sqrt[10]{\frac{D_t}{D_0}} - 1
\]

In the case of Walgreens, if we use the recent 10 years, the dividend ($D_{0}$) was $0.14\text{ a share in 2001}$ and the 2010 dividend ($D_{10}$) was $0.55\text{ a share}$. The average dividend growth rate was:

$$r = \sqrt[10]{\frac{D_{10}}{D_{0}}} - 1 = \sqrt[10]{\frac{0.55}{0.14}} - 1 = 0.1466 = 14.66\%$$

or 14.66 percent. Clearly, blindly plugging historical growth rates into our formulas ignores our analysis of economic, structural, industry, and company influences. Our analysis may have indicated that growth is expected to increase or decrease due to such factors as changes in government programs, demographic shifts, or changes in product mix. The historical growth rate may need to be raised or lowered to incorporate our findings.

In Chapter 10, we learned other ways to estimate future growth. The sustainable-growth rate:

$$g = RR \times ROE$$

assumes the firm will maintain a constant debt-equity ratio as it finances asset growth. ROE is the product of the net profit margin, total asset turnover, and financial leverage multiplier. Thus, a firm’s future growth rate and its components of ROE can be compared to those of its competitors, its industry, and the market. Deciding on the time period to use is not easy. Using a very recent period (the last three years) would be biased down due to the very weak results in 2009 and 2010. Therefore, consistent with our mathematical estimate above, we will use the recent 10 years contained in Tables 10.6 and 10.8, as follows:

$$g = RR \times ROE = 0.83 \times 16.48 = 13.68\% = 13.68\%$$

The dividend growth rate will be influenced by the age of the industry life cycle, structural changes, industry competition, and economic trends. Economic-industry-firm analysis provides valuable information regarding future trends in dividend growth. Information derived about management’s plans to expand the firm, diversify into new areas, or change dividend policy can provide useful information about the firm’s dividend policy. Averaging the historical growth rate of dividends (14.66 percent) and the implied sustainable-growth estimate of 13.68 percent indicates a value of 14.17 percent. Because a firm’s ROE is the critical growth factor, we give this estimate more weight. In turn, since the firm’s ROE declined substantially during 2009–2010, we will use a conservative 13 percent for Walgreen Co.’s estimated g.

Required Rate of Return Estimate

We know an investor’s required rate of return has two basic components: the nominal risk-free interest rate and a risk premium. If the market is efficient, over time the return earned by investors should compensate them for the risk of the investment. Notably, we must estimate future risk premiums to determine the stock’s current intrinsic value. Estimates of the nominal risk-free interest rate are available from the initial analysis of the economy during the top-down approach. The risk premium of the firm must rely on other information including evaluation of the financial statements and capital market relationships. In Chapter 10, we examined ratios that measure business risk, financial risk, liquidity risk, exchange rate risk, and country risk. These measures can be compared against the firm’s major competitors, its industry, and the overall market. This fundamental comparison should indicate if the firm deserves a higher or lower risk premium than the overall market, other firms in the industry, or the firm’s historical risk premium. Accounting-based risk measures use historical data, whereas investment analysis requires an estimate of the future, including any information uncovered during the top-down process that would lead to higher or lower risk estimates.

10-year Growth Rate 14.66% 10.41% 16.17% 0.98% 10.59%

Source: Adapted from Walgreens’ financial statements.
In the case of Walgreens, if we use the recent 10 years, the dividend \((D_3)\) was $0.14 a share in 2001 and the 2010 dividend \((D_{10})\) was $0.55 a share. The average dividend growth rate was:

\[
\frac{\text{\$0.55}}{\text{\$0.14}} - 1 = \sqrt[10]{3.93} - 1 = 0.1466
\]

or 14.66 percent. Clearly, blindly plugging historical growth rates into our formulas ignores our analysis of economic, structural, industry, and company influences. Our analysis may have indicated that growth is expected to increase or decrease due to such factors as changes in government programs, demographic shifts, or changes in product mix. The historical growth rate may need to be raised or lowered to incorporate our findings.

In Chapter 10, we learned other ways to estimate future growth. The sustainable-growth rate:

\[
g = RR \times ROE
\]

assumes the firm will maintain a constant debt-equity ratio as it finances asset growth. ROE is the product of the net profit margin, total asset turnover, and financial leverage multiplier. Thus, a firm’s future growth rate and its components of ROE can be compared to those of its competitors, its industry, and the market. Deciding on the time period to use is not easy. Using a very recent period (the last three years) would be biased down due to the very weak results in 2009 and 2010. Therefore, consistent with our mathematical estimate above, we will use the recent 10 years contained in Tables 10.6 and 10.8, as follows:

\[
g = RR \times ROE = 0.83 \times 16.48 = 0.1368 = 13.68\%
\]

The dividend growth rate will be influenced by the age of the industry life cycle, structural changes, industry competition, and economic trends. Economic-industry-firm analysis provides valuable information regarding future trends in dividend growth. Information derived about management’s plans to expand the firm, diversify into new areas, or change dividend policy can provide useful information about the firm’s dividend policy. Averaging the historical growth rate of dividends (14.66 percent) and the implied sustainable-growth estimate of 13.68 percent indicates a value of 14.17 percent. Because a firm’s ROE is the critical growth factor, we give this estimate more weight. In turn, since the firm’s ROE declined substantially during 2009-2010, we will use a conservative 13 percent for Walgreen Co.’s estimated \(g\).

**Required Rate of Return Estimate** We know an investor’s required rate of return has two basic components: the nominal risk-free interest rate and a risk premium. If the market is efficient, over time the return earned by investors should compensate them for the risk of the investment.

Notably, we must estimate future risk premiums to determine the stock’s current intrinsic value. Estimates of the nominal risk-free interest rate are available from the initial analysis of the economy during the top-down approach. The risk premium of the firm must rely on other information including evaluation of the financial statements and capital market relationships.

In Chapter 10, we examined ratios that measure business risk, financial risk, liquidity risk, exchange rate risk, and country risk. These measures can be compared against the firm’s major competitors, its industry, and the overall market. This fundamental comparison should indicate if the firm deserves a higher or lower risk premium than the overall market, other firms in the industry, or the firm’s historical risk premium. Accounting-based risk measures use historical data, whereas investment analysis requires an estimate of the future, including any information uncovered during the top-down process that would lead to higher or lower risk estimates.

---

This sustainable-growth rate value from Chapter 10 uses year-end values for \(ROE\).
For a market-based risk estimate, the firm’s characteristic line is estimated by regressing market returns on the stock’s returns. The slope of this regression line is the stock’s measure of systematic risk. Estimates of the economy’s risk-free rate, the future long-run market return, and an estimate of the stock’s beta help estimate next year’s required rate of return:

\[
E(R_{stock}) = E(R_{F}) + \beta_{stock} \left[ E(R_{market}) - E(R_{F}) \right]
\]

We begin with an estimate of beta using historical market information. Because beta is affected by changes in a firm’s business and financial risks, as well as other influences, an investor should increase or lower the historical beta estimate based on his or her analysis of the firm’s future risk characteristics.

To demonstrate the estimate of the required rate of return equation for Walgreens, we make several assumptions regarding components of the security market line (SML). First, the prevailing nominal risk-free rate \((R_{FR})\) is estimated at about 3.5 percent—the current yield to maturity for the intermediate-term (10-year) government bond. The expected equity market rate of return \((R_{M})\) depends on the expected market risk premium on stocks. As noted earlier, this is a very controversial topic wherein the estimates range from a high of about 8 percent to a low of about 3 percent. The authors reject both of these extreme values and will use a 4.0 percent mid-range risk premium (0.040), as discussed in Chapter 12. The final estimate is the firm’s systematic risk value (beta), based upon the following regression model (the characteristic line):

\[
R_{WAG} = \alpha + \beta_{WAG} R_{M}
\]

where:

- \(R_{WAG}\) = monthly rate of return for Walgreens
- \(\alpha\) = constant term
- \(\beta_{WAG}\) = beta coefficient for Walgreens
  equal to \(\frac{Cov_{W,M}}{\sigma_{M}^{2}}\)
- \(R_{M}\) = monthly rates of return for a market proxy—typically the S&P 500 Index

When this regression was run using monthly rates of return during the five-year period 2006–2010 (60 observations), the beta coefficient was estimated at 0.95.

Reflecting the discussion in Chapter 12, we used the \(R_{FR}\) of 0.035 and the market risk premium of 0.040. This, combined with the Walgreen Co.’s beta of 0.95, indicates the following expected rate of return for Walgreens:

\[
E(R) = R_{FR} + \beta_{WAG} (R_{M} - R_{FR})
\]

\[
= 0.035 + 0.95 (0.04)
\]

\[
= 0.035 + 0.038
\]

\[
= 0.073 = 7.3\%
\]

Given that the 10-year Treasury yield is currently at an abnormally low value and we assumed a market risk premium at the low end of the historical range, we will round the CAPM estimate up to 8 percent for our intrinsic valuations.

### 14.4.2 Present Value of Dividends Model (DDM)

At this point, the analyst would face a problem: The intent was to use the basic DDM, which assumed a constant-growth rate for an infinite period. You will recall that the model also required that \(k > g\) (the required rate of return is larger than the expected growth rate), which is not true in this case because \(k = 8\) percent and \(g = 13\) percent (as computed earlier). Therefore, the analyst must employ a two- or three-stage growth model. Because of the fairly large
difference between the current growth rate of 13 percent and the long-run constant-growth rate of 6 percent, it seems reasonable to use a three-stage growth model, which includes a gradual transition period. We assume that the growth periods are as follows:

\[ g_1 = 3 \text{ years (growing at 13 percent a year)} \]
\[ g_2 = 6 \text{ years (during this period it is assumed that the growth rate declines 1 percent per year for 6 years)} \]
\[ g_3 = \text{constant perpetual growth of 6 percent} \]

Therefore, beginning with 2011 when dividends were expected to be \$0.62(0.55 \times 1.13), the future dividend payments will be as follows (the growth rates are in parentheses):

\[
\begin{array}{c|c|c|c|c|c|c|c}
\text{HIGH-GROWTH PERIOD} & \text{DECLINING-GROWTH PERIOD} \\
\hline
\text{Year} & \text{Gr. Rate} & \text{Div.} & 8\% \text{ PV Factor} & \text{PV} & \text{Year} & \text{Gr. Rate} & \text{Div.} & 8\% \text{ PV Factor} & \text{PV} \\
\hline
2012 & (13\%) & 0.70 & 0.9259 & 0.65 & 2015 & (12\%) & 1.00 & 0.7350 & 0.74 \\
2013 & (13\%) & 0.79 & 0.8573 & 0.68 & 2016 & (11\%) & 1.11 & 0.6806 & 0.76 \\
2014 & (13\%) & 0.89 & 0.7938 & 0.71 & 2017 & (10\%) & 1.22 & 0.6302 & 0.77 \\
& & & & & 2018 & (9\%) & 1.33 & 0.5835 & 0.78 \\
& & & & & 2019 & (8\%) & 1.44 & 0.5402 & 0.78 \\
& & & & & 2020 & (7\%) & 1.54 & 0.5002 & 0.77 \\
\hline
\text{Sum} & 2.04 & & & & \text{Sum} & 4.60 & & &
\end{array}
\]

**Constant-Growth Period:***

\[
P_{2020} = \frac{1.54(1.06)}{0.08 - 0.06} = \frac{1.63}{0.02} = \$81.50 \times 0.5002 = \$40.77
\]

The total value of the stock is the sum of the three present-value streams discounted at 8 percent:

1. Present value of high-growth period dividends $2.04
2. Present value of declining-growth period dividends 4.60
3. Present value of constant-growth period dividends 40.77

Total present value of dividends $47.41

The estimated value based on the DDM ($47.41) is above the market price in mid-2011 of about $43.00. This estimated value of $47.41 and expected earnings in 2011 of about $2.38 (to be discussed later) implies that at this valuation the stock would have a forward P/E ratio of 19.9x compared to the market P/E ratio estimated in Chapter 12 of 20 times. In a subsequent section on relative valuation techniques, we compare Walgreen Co.’s P/E ratio to that of its industry and the market.

### 14.4.3 Present Value of Free Cash Flow to Equity

As noted in Chapter 11, this technique resembles a present value of earnings concept except that it considers the capital expenditures required to maintain and grow the firm and the change in working capital required for a growing firm (that is, an increase in accounts receivable and inventory). The specific definition of free cash flow to equity (FCFE) is:

\[
\text{Net Income} + \text{Depreciation Expense} - \text{Capital Expenditures} - \Delta \text{ in Working Capital} - \text{Principal Debt Repayments} + \text{New Debt Issues}
\]

This technique attempts to determine the free cash flow that is available to the stockholders after payments to all other capital suppliers and after providing for the continued growth of the firm. As noted in Chapter 11, given the current FCFE values, the alternative forms of the model are similar to those available for the DDM, which in turn depends on the firm’s growth
The total value of the stock is the sum of the three present value streams discounted at 8 percent:

\[
\text{Value} = \frac{\text{FCFE}_1}{k - g_{\text{FCFE}}}
\]

where:

- \( \text{FCFE} \) = the expected free cash flow to equity in Period 1
- \( k \) = the required rate of return on equity for the firm
- \( g_{\text{FCFE}} \) = the expected constant-growth rate of free cash flow to equity for the firm

We already know from the prior dividend model and Exhibit 14.2 that the firm’s net income has grown at a rate (about 10 percent) that exceeds the required rate of return on equity of 8 percent. In the case of FCFE, it is necessary to consider the effect of capital expenditures relative to depreciation and changes in working capital as well as debt repayments and new debt issues. The historical data in Exhibit 14.2 show negative FCFE values in 1998–2002 due to very heavy capital expenditures and significant working capital requirements during these years. The firm subsequently reduced the growth rate of stores due to the prevailing shortage of pharmacists. While Walgreens continued adding stores, the slower rate of growth and a reduction in the growth of inventory allowed the firm to increase its positive cash flows. In fact, the firm’s FCFE exploded during 2007–2010 to almost $3 billion in 2007 and $5 billion in 2010. This level of FCFE is not sustainable and would obviously imply an unreasonable value for the stock. Therefore, to derive a FCFE value that is “typical” for the long run and can be used to demonstrate the model we will employ estimates for the components of FCFE during 2011 as follows:

| Net Income | 2,300 |
| Depreciation | 1,100 |
| Capital Expenditures | −1,000 |
| Δ Working Capital | −1,200 |
| Principal Repayment | 0 |
| New Debt Issued | 150 |
| Total FCFE | $1,350 |

Using this as our 2011 estimate, we will assume a conservative set of growth rates going forward for a three-stage growth valuation model, as follows:

- \( g_1 = 9 \) percent for the three years after 2011
- \( g_2 = \) a steady declining growth rate to a constant 6 percent in 2017 and beyond
- \( k = 8 \) percent cost of equity

The specific estimates of annual FCFE beginning with the estimated value of 2011 of $1,350 are as follows:

\]

\[
\text{PV @ 8%} = 107,050 \times 0.6806 = $72,858
\]
where:

\[ FCFF_1 = \text{the free cash flow for the firm in Period 1} \]

\[ OFCF_1 = \text{the firm’s operating free cash flow in Period 1} \]

\[ WACC = \text{the firm’s weighted average cost of capital} \]

\[ g_{FCFF} = \text{the constant infinite growth rate of free cash flow for the firm} \]

\[ g_{OFCF} = \text{the constant infinite growth rate of operating free cash flow} \]

As noted in Exhibit 14.2, the compound annual growth rate for operating free cash flow (free cash flow to the firm) during the 24-year period was not meaningful because it was negative between 1998 and 2003, and similar to FCFE it became very large during the period 2008–2010 due to a large decline in working capital and reduced capital expenditure. Under more normal conditions, it is estimated that it would be about $1,200 million during 2011. An alternative measure of long-run growth is the growth implied by the equation:

\[ g = \frac{\text{RR}}{\text{ROIC}} \]

where:

\[ \text{RR} = \text{the average retention rate} \]

\[ \text{ROIC} = \frac{\text{EBIT} \times (1 - \text{Tax Rate})}{\text{Total Capital}} \]

For Walgreens, the recent retention rate (i.e., the average over the last 5 years) has been about 80 percent and:

\[ \text{ROIC} = \frac{\text{EBIT} \times (1 - \text{Tax Rate})}{\text{Total Capital}} = \frac{3,458 \times 0.63}{(18,536 + 18,123)} = 2,179/18,330 = 0.1189 = 11.89\% \]

Therefore,

\[ g = \frac{0.80 \times 0.1189}{0.02} = 0.095 = 9.5\% \]

Given the expensive initiatives planned by Walgreens and the intensive competition from CVS, we will round this down to a beginning growth estimate for \( OFCF/FCFF \) of 9 percent.

**Calculation of WACC**

We calculate the discount rate (i.e., the firm’s WACC) using the following formula:

\[ WACC = W_E k + W_D i \]

where:

\[ W_E = \text{the proportion of equity in total capital} \]

\[ k = \text{the after-tax cost of equity (from the SML)} \]

\[ W_D = \text{the proportion of debt in total capital} \]

\[ i = \text{the after-tax cost of debt} \]

Recall from corporate finance courses that there are differences of opinion regarding how one should estimate the debt and equity weights—that is, using proportions based upon relative book values or based on relative market value weights. Without getting into the reasons for each choice, it is important to recognize that the use of market value weights will almost always result in a higher WACC because it will imply a higher proportion of equity financing.

This is meant to be "invested capital," which is total equity plus only interest-bearing debt, which excludes accounts payable, accrued expenses, and deferred income taxes.

The proportions of debt and equity capital used in the WACC estimate will be computed using both book value weights that consider the value of capitalized lease payments as debt and market value weights.

For this estimate, we use the prevailing interest rate on corporate A-rated bonds (7 percent) and Walgreen Co.’s (ticker symbol WAG) recent tax rate of 36 percent.

The total value of the stock is the sum of the three present value streams discounted at 8 percent:

<table>

</tr>
<tr>
<td>Total Present Value of FCFEs</td>
<td>$78,747</td>
</tr>
</tbody>
</table>

Outstanding average shares in 2010 were 988 million. While it is difficult to estimate the average shares for 2011, a conservative value is the actual shares outstanding at the end of 2010, which is 938.6 million. Therefore, the per-share value based on the present value of FCFE is $84.93 ($79,747/0.939). In this case, the estimated value is substantially above the prevailing market price of about $43.00.

**Value Assuming Only Constant Growth**

Because of the very high valuation generated with the three-stage growth model, one might consider a very conservative form of the model by assuming only the constant-growth version, wherein it is assumed that the firm will only grow at base rate of 6 percent in the future. The results of this scenario are as follows:

Using the $1,350 as the value for 2011, the valuation would be:

\[
\text{Constant-Growth Period Value:} \quad \frac{1,350 \times (1.06)}{0.08 - 0.06} = \frac{1.431}{0.02} = 71,550 \\
\text{Per-Share Value:} \quad \frac{71,550}{0.939} = 76.20
\]

Again, even the most conservative version of the FCFE model indicates that the stock is undervalued at its current market price of $43.00.

### 14.4.4 Present Value of Operating Free Cash Flow

This is also referred to as free cash flow to the firm (FCFF) by Damodaran (2006) and the entity DCF model by Koller et al. (2010). The object is to determine a value for the total firm and subtract the value of the firm’s debt obligations to arrive at a value for the firm’s equity. Notably, in this valuation technique, we discount the firm’s operating free cash flow to the firm (FCFF) at the firm’s weighted average cost of capital (WACC) rather than its cost of equity.

*Operating free cash flow or free cash flow to the firm* is equal to:

\[
\text{EBIT} \times (1 - \text{Tax Rate}) + \text{Depreciation Expense} \\
- \text{Capital Expenditures} - \Delta \text{in Working Capital} \\
- \Delta \text{in Other Assets}
\]

This is the cash flow generated by a company’s operations and available to all who have provided capital to the firm—both equity and debt. As noted, because it is the cash flow available to all capital suppliers, it is discounted at the firm’s WACC.

Again, the alternative specifications of this operating FCF model are similar to the DDM—that is, the specification depends upon the firm’s growth prospects. Assuming an expectation of constant growth, you can use the reduced form model:

\[
\text{Firm Value} = \frac{FCFF_1}{WACC - g_{FCFF}} \quad \text{or} \quad \frac{OFCF_1}{WACC - g_{OFCF}}
\]
since most firms have a $P/BV$ ratio greater than one (for Walgreens, the $P/BV$ ratio is currently about 3.0). To demonstrate this, we compute a WACC using both weightings. The cost of debt and cost of equity will be the same for both sets.

**WACC Using Book Value Weights**

\[
\begin{align*}
  k_e &= 0.080 \text{ (based upon rounded prior SML calculation)} \\
  k_d &= 0.047 \text{ (current interest rate of 7.5% and recent tax rate of 37% for WAG)} \\
  \text{0.075} \times (1 - 0.37) &= 0.047 \\
  W_d &= 0.30 \text{ (including leases)} \\
  W_e &= 0.70
\end{align*}
\]

\[
WACC = (W_d \times k_d) + (W_e \times k_e) = \left(0.30 \times 0.047\right) + \left(0.70 \times 0.080\right) = 0.014 + 0.056 = 0.070 = 7.00\% 
\]

**WACC Using Market Value Weights**

\[
\begin{align*}
  k_e &= 0.080 \\
  W_e &= 0.90 \\
  k_d &= 0.047 \\
  W_d &= 0.10
\end{align*}
\]

\[
WACC = (W_d \times k_d) + (W_e \times k_e) = \left(0.10 \times 0.047\right) + \left(0.90 \times 0.080\right) = 0.0047 + 0.072 = 0.0767 = 7.67\% 
\]

Therefore, we have a range of 7.00 percent to 7.67 percent and an average of 7.34 percent. We will use a WACC of 7.5 percent in the demonstration.

Again, because the expected growth rate of operating free cash flow (9.0 percent) is greater than the firm’s WACC, we cannot use the reduced form model that assumes constant growth at this relatively high rate for an infinite period. Therefore, the following demonstration will employ the three-stage growth model with the following growth duration assumptions.

Given the firm’s WACC, we will use the following growth estimates for a three-stage growth model:

\[
g_1 = 9\% \text{ for three years} \\
g_2 = \text{a constantly declining rate to 6}\% \text{ over three years}
\]

The specific estimates for future OFCF (or FCFF) are as follows, beginning from the 2011 normalized value of $1,200 million.

Total 3,700

Constant-Growth Period Value = \[
1,796 \times (1 - 0.06) = 1,903\]

\[
(1 - 0.060) = 126,867 \\
PV @7.5\% = 126,867 \times 0.697 = 88,426
\]

As noted in Exhibit 14.2, the compound annual growth rate for operating free cash flow (free cash flow to the firm) during the 24-year period was not meaningful because it was negative between 1998 and 2003, and similar to FCFE it became very large during the period 2008–2010 due to a large decline in working capital and reduced capital expenditure. Under more normal conditions, it is estimated that it would be about $1,200 million during 2011. An alternative measure of long-run growth is the growth implied by the equation:

\[
g = (RR)(ROIC)
\]

where:

\[
RR = \text{the average retention rate} \\
ROIC = \frac{EBIT(1 - \text{Tax Rate})}{\text{Total Capital}}^4
\]

For Walgreens, the recent retention rate (i.e., the average over the last 5 years) has been about 80 percent and:

\[
ROIC = \frac{EBIT(1 - \text{Tax Rate})}{\text{Total Capital}} = \frac{3,458 \times (0.63)}{(18,536 + 18,123)/2} = \frac{2,179}{18,330} = 0.1189 = 11.89\%
\]

Therefore,

\[
g = (0.80)(0.1189) = 0.095 = 9.5\%
\]

Given the expensive initiatives planned by Walgreens and the intensive competition from CVS, we will round this down to a beginning growth estimate for OFCF/FCFF of 9 percent.

**Calculation of WACC** We calculate the discount rate (i.e., the firm’s WACC) using the following formula:

\[
WACC = W_ek + W_di
\]

where:

\[
W_E = \text{the proportion of equity in total capital} \\
k = \text{the after-tax cost of equity (from the SML)} \\
W_D = \text{the proportion of debt in total capital}^5 \\
i = \text{the after-tax cost of debt}^6
\]

Recall from corporate finance courses that there are differences of opinion regarding how one should estimate the debt and equity weights—that is, using proportions based upon relative book values or based on relative market value weights. Without getting into the reasons for each choice, it is important to recognize that the use of market value weights will almost always result in a higher WACC because it will imply a higher proportion of equity financing.

---

4This is meant to be “invested capital,” which is total equity plus only interest-bearing debt, which excludes accounts payable, accrued expenses, and deferred income taxes.

5The proportions of debt and equity capital used in the WACC estimate will be computed using both book value weights that consider the value of capitalized lease payments as debt and market value weights.

6For this estimate, we use the prevailing interest rate on corporate A-rated bonds (7 percent) and Walgreen Co.’s (ticker symbol WAG) recent tax rate of 36 percent.
since most firms have a P/BV ratio greater than one (for Walgreens, the P/BV ratio is currently about 3.0). To demonstrate this, we compute a WACC using both weightings. The cost of debt and cost of equity will be the same for both sets.

**WACC Using Book Value Weights**

\[ k_e = 0.080 \] (based upon rounded prior SML calculation)
\[ k_d = 0.047 \] (current interest rate of 7.5% and recent tax rate of 37% for WAG)
\[ W_d = 0.30 \] (including leases)
\[ W_e = 0.70 \]
\[ WACC = (W_d \times k_d) + (W_e \times k_e) \]
\[ = (0.30 \times 0.047) + (0.70 \times 0.080) \]
\[ = 0.014 + 0.056 = 0.070 = 7.00\% \]

**WACC Using Market Value Weights**

\[ k_e = 0.080 \]
\[ k_d = 0.047 \]
\[ W_d = 0.90 \]
\[ W_e = 0.10 \]
\[ WACC = (W_d \times k_d) + (W_e \times k_e) \]
\[ = (0.10 \times 0.047) + (0.90 \times 0.080) \]
\[ = 0.0047 + 0.072 = 0.0767 = 7.67\% \]

Therefore, we have a range of 7.00 percent to 7.67 percent and an average of 7.34 percent. We will use a WACC of 7.5 percent in the demonstration.

Again, because the expected growth rate of operating free cash flow (9.0 percent) is greater than the firm’s WACC, we cannot use the reduced form model that assumes constant growth at this relatively high rate for an infinite period. Therefore, the following demonstration will employ the three-stage growth model with the following growth duration assumptions:

- \( g_1 = 9 \) percent for three years
- \( g_2 = a \) constantly declining rate to 6 percent over three years

Recall that the value of equity is the total value of the firm (PV of OFCF) minus the current market value of debt, which is the present value of debt payments at the firm’s cost of debt (0.07%). The values are as follows:

</tbody>
</table>

Again, this estimated value compares to the recent market value of about $43.00. The $71.24 value implies a P/E of about 31 times estimated 2011 earnings of $2.30 per share.

To summarize, the valuations derived from the present value of cash flow techniques are as follows:

- Present value of dividends $47.41
- Present value of FCF $80.96
- Present value of OFCF ($ or the PV of FCFF) $71.24

All of these prices must be compared to the prevailing market price of $43.00 to determine the investment decision.

### 14.4.5 Relative Valuation Ratio Techniques

In this section, we present the data required to compute the several relative valuation ratios and demonstrate the use of these relative valuation ratio techniques for Walgreens compared to the Drugstore Retail (DR) industry and the S&P Industrials Index.

Exhibit 14.3 contains the basic data required to compute the relative valuation ratios, and Exhibit 14.4 contains the four sets of relative valuation ratios for Walgreens, its industry, and the aggregate market. This exhibit also contains a comparison of the company ratios to similar ratios for the company’s industry and the market. This comparison indicates the changes in the relative valuation ratios over time and helps determine if the current valuation ratio for the company (Walgreens) is reasonable based on the financial characteristics of the firm versus its industry and the market. To aid in the analysis, four graphs contain the time series of the relative valuation ratios for the company, its industry, and the market. Four additional graphs show the relationship between the relative valuation ratios: for the company compared to its industry and for the company compared to the stock market. We begin with the P/E ratio approach where we derive an intrinsic value for the stock based upon an estimate of future EPS and an earnings multiple (P/E) for the stock that reflects future expectations for WAG compared to its industry and the market.

Mean Price calculated as average of yearly high and low closing price.

**Source:** Walgreens financial reports and Standard & Poor’s Analysts’ Handbook.
An estimate of the earnings per share for the company is a function of the sales forecast and the estimated profit margin. The sales forecast includes an analysis of the relationship of company sales to various relevant economic series and to the DR industry series. These comparisons indicate how the company is performing relative to the economy and its competition.

### 14.5.1 Company Sales Forecast

Besides providing background on the company, these relationships can help us develop specific sales forecasts for Walgreens.

Exhibit 14.5 contains data on sales for Walgreens from its annual report, sales per share for the DR industry, and several personal consumption expenditure (PCE) series for the period 1993 to 2009.

To examine the relationship of Walgreen Co.’s sales to the economy, we considered several alternative series. The series that had the strongest relationship was personal consumption expenditure for medicine (PCE medical care).

The scatterplot of Walgreen Co.’s sales and the PCE medical care expenditures contained in Exhibit 14.6 indicates a strong linear relationship, including the fact that Walgreen Co.’s sales grew faster than PCE medical care (i.e., 13.51 percent versus 6.51 percent). As a result, Walgreen Co.’s sales have gone from about 1.3 percent of PCE medical care to 3.9 percent.

We also compared Walgreen Co.’s sales and sales per share for the DR industry. Unfortunately, it did not reflect as strong a relationship and is not used subsequently.

### 14.5 Estimating Company Earnings per Share

An estimate of the earnings per share for the company is a function of the sales forecast and the estimated profit margin. The sales forecast includes an analysis of the relationship of company sales to various relevant economic series and to the DR industry series. These comparisons indicate how the company is performing relative to the economy and its competition.

#### 14.5.1 Company Sales Forecast

Besides providing background on the company, these relationships can help us develop specific sales forecasts for Walgreens.

Exhibit 14.5 contains data on sales for Walgreens from its annual report, sales per share for the DR industry, and several personal consumption expenditure (PCE) series for the period 1993 to 2009.

To examine the relationship of Walgreen Co.’s sales to the economy, we considered several alternative series. The series that had the strongest relationship was personal consumption expenditure for medicine (PCE medical care).\(^6\) The scatterplot of Walgreen Co.’s sales and the PCE medical care expenditures contained in Exhibit 14.6 indicates a strong linear relationship, including the fact that Walgreen Co.’s sales grew faster than PCE medical care (i.e., 13.51 percent versus 6.51 percent). As a result, Walgreen Co.’s sales have gone from about 1.3 percent of PCE medical care to 3.9 percent.

We also compared Walgreen Co.’s sales and sales per share for the DR industry. Unfortunately, it did not reflect as strong a relationship and is not used subsequently.

\(^6\)The relationship between Walgreen Co.’s sales and total PCE or per capita PCE was significant but not as strong as PCE medical care.
Another internal estimate employs the number of stores and sales per store. Walgreens is expected to open 230 net new stores during 2011 resulting in 7,792 drugstores at the end of 2011. Assuming sales per store reverses the recent decline and increases from $8.92 million to $9.0 million indicates an estimate of $70.13 billion (7,792 × $9.0), a sales increase of only 4 percent over 2010. Therefore, the three sales estimates were:

</tr>
<tr>
<td>Sales per Square Foot</td>
<td>$71.85 billion</td>
</tr>
<tr>
<td>Sales per Store</td>
<td>$70.13 billion</td>
</tr>
</tbody>
</table>

Given the three estimates, the preference is for a midrange estimate of $72 billion, which implies a 6.8 percent increase over 2010 sales.

The figures in the last column of Exhibit 14.5 indicate that during this period, the proportion of PCE allocated to medical care went from almost 14.5 percent in 1993 to 16.2 percent in 2009. The increasing proportion of PCE spent on medical care is a function of the growing proportion of the population over 65 and the rising cost of medical care. Because Walgreen Co.’s sales are growing faster than medical expenditures, these increases should continue to be beneficial for Walgreens because about 65 percent of its sales are prescriptions. Notably, these increases in medical care expenditures continued during the economic recessions in 2001–2002 and 2008–2009.

As shown in Exhibit 14.7, the internal sales growth for Walgreens going back to 1977 resulted from an increase in the number of stores (from 626 in 1977 to 7,562 in 2010) and an annual increase in the sales per store of 4.5 percent because of the upgrading of stores. The net increase in stores each year includes numerous new, large stores and the closing of many smaller stores. As a result, the average size of stores has increased. More important, the firm has increased its sales per thousand square feet at about 4 percent a year. This is a critical statistic in the retailing industry. The fact that Walgreens has been able to experience consistent growth in this metric is significant evidence of strong management.

**Sample Estimate of Walgreen Co.’s Sales** The foregoing analysis indicates that you should use the Walgreens-PCE Medical Care graph. To estimate PCE medical care, you need to initially project total PCE and then estimate how much would be included in the medical care component. As noted in Chapter 13 (industry analysis), economists were forecasting an increase in PCE for 2011 of 6.3 percent to $11,173 billion. In addition, we estimated that the percentage of PCE spent on medical care would be about 16.5 percent. This implies an estimate of PCE Medical Care of $1,844 billion, a 5.0 percent increase from 2010. In turn, Exhibit 14.6, which shows the historical relationship between PCE Medical Care and Walgreen Co.’s sales, implies that this PCE Medical Care increase should generate an 8.3 percent increase in Walgreens’ sales for 2011 to about $73.02 billion ($67.42 × 1.083).

Because Walgreens provides data on square footage and the number of stores, it allows us to use the data in Exhibit 14.7 to compute alternative sales estimates to support the prior estimate. If we assume an increase in store area during 2011 of about 5 million square feet (which is less than in recent years), the firm’s total sales area would be about 88.7 million square feet. As noted, sales per square foot have likewise increased. If we assume a conservative increase to $810 of sales per thousand square feet, it implies a sales forecast of $71.85 billion for 2011, a 6.6 percent increase over 2010.
14.5.2 Estimating the Company Profit Margin

The next step in projecting earnings per share is to estimate the firm’s net profit margin, which should include three considerations: (1) identification and evaluation of the firm’s specific competitive strategy—that is, either low-cost or differentiation, (2) the firm’s internal performance, including general company trends and consideration of any problems that might affect its future performance, and (3) the firm’s relationship with its industry, which should indicate whether the company’s past performance is attributable to its industry or if it is unique to the firm. These examinations should help us understand the firm’s past performance but should also provide the background to make a meaningful estimate for the future. In this analysis, we only consider the company-economy relationship briefly because the significant economy-wide profit factors are reflected in the industry results.

14.6 Walgreens’ Competitive Strategies

The question is, has Walgreens pursued a low-cost strategy or has the firm attempted to differentiate itself from its competitors in some unique way? Based on its annual reports, Walgreens has pursued both strategies with different segments of its business. The firm’s size and buying power allow it to be a cost leader for some of its nonprescription products, such as liquor, ice cream, candy, and soft drinks. These items are advertised heavily to attract customer traffic and to build consumer loyalty. At the same time, Walgreens has attempted to build a very strong franchise in the medical prescription business based on differentiation in service. Computer technology in the prescription area makes it possible for the firm to distinguish itself by providing outstanding service to its prescription customers. Specifically, the firm refers to itself as the nation’s prescription druggist, based on the number of prescriptions it fills and a nationwide computer system that allows customers to have their prescriptions filled at any of the 7,562 Walgreen Co.’s drugstores in the country. This service leadership in the growing medical field is a major goal.

14.6.1 The Internal Performance

Profit margin figures for Walgreens and the DR industry are in Exhibit 14.8. The net profit margins for Walgreens increased from 2.67 percent to a peak of 3.80 percent in 2007, but declined to 3.16 percent in 2009 and 3.10 percent in 2010. The margins for the DR industry experienced an overall increase with a small decline in 2009 from a record value in 2008. To predict future values, you need to determine the reasons for the overall increase in the industry profit margin and, more important, what factors have contributed to Walgreen Co.’s strong longer-term performance but recent weakness.

Industry Factors

Industry profit margins were relatively flat in the late 1990s due to price discounting by aggressive regional drug chains. The discussion in Chapter 13 suggested this as one of the competitive structure conditions that affect long-run profitability. On a positive note, industry analysts have observed that price cutting has subsided, and they foresee relative price stability following a period of consolidation in which WAG and CVS acquired several of the smaller, less profitable chains. In addition, drugstores have tended toward a more profitable product mix featuring high-profit-margin items, such as cosmetics and private label products. This has had a positive influence on profit margins over the longer term but not during the recent significant recession.

Another internal estimate employs the number of stores and sales per store. Walgreens is expected to open 230 net new stores during 2011 resulting in 7,792 drugstores at the end of 2011. Assuming sales per store reverses the recent decline and increases from $8.92 million to $9.0 million indicates an estimate of $70.13 billion (7,792 × $9.0), a sales increase of only 4 percent over 2010.

Therefore, the three sales estimates were:

- PCE Medical Care: $73.02 billion
- Sales per Square Foot: $71.85 billion
- Sales per Store: $70.13 billion

Given the three estimates, the preference is for a midrange estimate of $72 billion, which implies a 6.8 percent increase over 2010 sales.

all of the decline in the operating profit margin that went from 5.70% in 2006 to 5.13% in 2010. Finally, the tax rate increased from about 36 percent to 38 percent in 2010.

Net Profit Margin Estimate

The overall industry outlook is encouraging because of stable prices, an increase in mechanization within the industry, and the inclusion of more high-profit-margin items. As noted, while Walgreens experienced a small decline in its net profit margin as shown in Exhibit 14.10, it is estimated that the firm will experience stability in its net profit margin in 2011 due to offsetting trends. On the positive side, the economy continues its recovery. On the downside, there is the added cost of several new programs intended to help WAG become a broad health care provider.

Computing Earnings per Share

This net profit margin estimate of 3.10 percent, combined with the prior sales estimate of $72 billion, indicates net income of $2,232 million. We will assume 939 million common shares outstanding (based upon the shares outstanding at the end of 2010), which indicates earnings per share of about $2.38 for 2011, which is an increase of about 12 percent over the earnings of $2.12 per share in 2010. This is considered a reasonable estimate because we used our midrange estimate of sales, assumed no recovery in the profit margin, and employed shares outstanding as of the end of fiscal 2010 (938.6 million), although the firm has been consistently repurchasing shares in recent years.

Our next step is to estimate an earnings multiplier for Walgreens.

14.6.2 Importance of Quarterly Estimates

Once we have derived an estimate of next year’s sales and net earnings, it is essential that we estimate results for each quarter for two important reasons. First, this is a way to confirm our annual estimate—that is, do the quarterly estimates required to arrive at the annual estimate seem reasonable? If not, we need to reevaluate the annual forecast. Second, unless we have quarterly forecasts that confirm our annual forecast, we will not be in a position to determine whether the subsequent actual quarterly results are a positive surprise, negative surprise, or no surprise.

Company Performance The Walgreen Co.’s profit margin has shown consistent improvement over the long run because of a change in corporate structure and sales mix. The outlook for its profit margins is of some concern because it has declined in both 2009 and 2010. The good news is that the firm has developed a strong position in the pharmacy business and has invested in service (including mail-order prescriptions) and inventory-control technology that should contribute to strong margins on this business. The firm also has emphasized high-profit-margin items, such as greeting cards, photofinishing, and cosmetics. We will discuss some concerns when we analyze the common-size income statement.

Specific estimates for Walgreen Co.’s future margins typically would begin with an analysis of the firm’s relationship with retail store margins using time-series plots, such as those in Exhibit 14.9. This time-series plot for the period 1993–2009 showed inconsistent results for Walgreens versus its industry. While Walgreens showed a slow but steady increase in its margin until 2009, the retail drugstore margin was very volatile with a sharp decline in 2000–2001, followed by a recovery in 2002–2003 and steady improvement since 2004. Unfortunately, it appears that we cannot depend on this company/industry relationship when attempting to estimate future profit margins.
