Next, you should analyze the firm’s common-size income statement for the period 2006–2010, contained in Exhibit 14.10. An analysis of the main items of interest—cost of goods sold and SG&A expense—provided mixed results. The cost of sales percentage was volatile over the period, but in 2010 the cost percent declined and provided a higher gross profit margin than in 2006. In contrast, the selling, general, and administration (SG&A) expense ratio experienced a gradual increase from 22.08 percent in 2006 to 23.02 percent in 2010 and accounted for virtually 10 Both the operating margin and the net before tax margin were analyzed; the results indicated that the net profit margins yielded the best relationships.
all of the decline in the operating profit margin that went from 5.70% in 2006 to 5.13% in 2010. Finally, the tax rate increased from about 36 percent to 38 percent in 2010.

**Net Profit Margin Estimate** The overall industry outlook is encouraging because of stable prices, an increase in mechanization within the industry, and the inclusion of more high-profit-margin items. As noted, while Walgreens experienced a small decline in its net profit margin as shown in Exhibit 14.10, it is estimated that the firm will experience stability in its net profit margin in 2011 due to offsetting trends. On the positive side, the economy continues its recovery. On the downside, there is the added cost of several new programs intended to help WAG become a broad health care provider.

**Computing Earnings per Share** This net profit margin estimate of 3.10 percent, combined with the prior sales estimate of $72 billion, indicates net income of $2,232 million. We will assume 939 million common shares outstanding (based upon the shares outstanding at the end of 2010), which indicates earnings per share of about $2.38 for 2011, which is an increase of about 12 percent over the earnings of $2.12 per share in 2010. This is considered a reasonable estimate because we used our midrange estimate of sales, assumed no recovery in the profit margin, and employed shares outstanding as of the end of fiscal 2010 (938.6 million), although the firm has been consistently repurchasing shares in recent years.

Our next step is to estimate an earnings multiplier for Walgreens.

### 14.6.2 Importance of Quarterly Estimates

Once we have derived an estimate of next year’s sales and net earnings, it is essential that we estimate results for each quarter for two important reasons. First, this is a way to confirm our annual estimate—that is, do the quarterly estimates required to arrive at the annual estimate seem reasonable? If not, we need to reevaluate the annual forecast. Second, unless we have quarterly forecasts that confirm our annual forecast, we will not be in a position to determine whether the subsequent actual quarterly results are a positive surprise, negative surprise, or no
If the actual quarterly results are a surprise relative to our quarterly estimate, we will want to understand the reason for the surprise—

for example, did we under- or overestimate sales growth and/or was it due to differences in the profit margin from our estimates? This understanding is needed for an estimated earnings revision that reflects the new information from the company. Typically, an analyst would revise each of his or her future quarterly estimates to arrive at a new annual estimate.

### Estimating Company Earnings Multipliers

As in our analysis of industry multipliers in Chapter 13, we use two approaches to estimate a company multiplier. First, we estimate the P/E ratio from the relationships between Walgreens, its industry, and the market. This is the macroanalysis. Second, we estimate a multiplier based on the three components of the multiplier: the dividend-payout ratio, the required rate of return, and the rate of growth. We then resolve the estimates derived from each approach and settle on a set of estimates.

#### 14.7.1 Macroanalysis of the Earnings Multiple

Exhibit 14.11 shows the forward earnings multiple for the company, the retail drugstore industry, and the aggregate market for the period 1993–2009. As shown in Exhibit 14.4, the Walgreen Co.’s multiplier has generally followed the industry multipliers with a company/industry ratio between 0.70 and 1.81, and an average of 1.05, although recent values have been closer to 1.10. The Walgreen Co.’s earnings multiplier has recently been higher than the market multiplier by an average of 10 percent. This pattern raises the question: Are the higher P/E ratios for Walgreens relative to both its industry and the market justified? The microanalyses should provide some insights regarding this question.

14.7 Estimating Company Earnings Multipliers

As in our analysis of industry multipliers in Chapter 13, we use two approaches to estimate a company multiplier. First, we estimate the P/E ratio from the relationships between Walgreens, its industry, and the market. This is the macroanalysis. Second, we estimate a multiplier based on the three components of the multiplier: the dividend-payout ratio, the required rate of return, and the rate of growth. We then resolve the estimates derived from each approach and settle on a set of estimates.

14.7.1 Macroanalysis of the Earnings Multiple

Exhibit 14.11 shows the forward earnings multiple for the company, the retail drugstore industry, and the aggregate market for the period 1993–2009. As shown in Exhibit 14.4, the Walgreen Co.’s multiplier has generally followed the industry multipliers with a company/industry ratio between 0.70 and 1.81, and an average of 1.05, although recent values have been closer to 1.10. The Walgreen Co.’s earnings multiplier has recently been higher than the market multiplier by an average of 10 percent.

This pattern raises the question: Are the higher P/E ratios for Walgreens relative to both its industry and the market justified? The microanalyses should provide some insights regarding this question.

14.7.2 Microanalysis of the Earnings Multiplier

Again, the relevant question is, why has the earnings multiplier for Walgreens been higher than for the market and industry? As before, we are looking for estimates of D/E, k, and g to find an earnings multiplier. We will use the historical data in Exhibit 14.12 to determine patterns for the data and to develop future projections.\(^\text{11}\)

**Comparing Dividend-Payout Ratios** The dividend-payout ratio for Walgreens typically has been lower than the aggregate market but similar to its industry in recent years. This payout by itself would imply a lower P/E ratio for Walgreens relating to the market, but a P/E similar to its industry.

**Estimating the Required Rate of Return** To find Walgreen Co.’s required rate of return \((k)\), we recall the analysis of the firm’s fundamental risk characteristics \((BR, FR, LR, ERR, \text{ and CR})\) and also our estimate based on Walgreen Co.’s systematic risk \((i.e., \text{its beta})\).

Walgreens has had relatively low business risk due to its stable sales growth compared to its industry and the economy. As noted in Chapter 10, for a growth company like Walgreens it is necessary to adjust for both the growth and the size factor by measuring variability around the growth trend and relating this volatility to the mean, as in Exhibit 14.13. As shown in the appendix in Chapter 10, after adjusting for size and trend, the results indicated that Walgreen Co.’s sales and EBIT experienced *very stable growth*, which indicates low business risk.

Several financial risk variables for Walgreens, its industry, and the aggregate market are shown in Exhibit 14.14. Notably, except for Walgreens, these interest coverages do not consider fairly large leases of stores. Without considering these financial leases, these financial risk ratios indicate that Walgreens has substantially lower financial risk than the aggregate stock market. In contrast, as shown in Chapter 10, when the leases are considered as they should be, the firm’s financial risk is probably comparable to its industry where most firms lease their stores, but its financial risk is clearly higher than the market.

The firm’s market liquidity risk is low compared to its industry and the average firm in the market. Indicators of market liquidity are (1) the number of stockholders, (2) the number and market value of shares outstanding, (3) the number of shares traded, and (4) institutional interest in the stock. As of January 1, 2011, Walgreens had 30,000 holders of common stock—a relatively large number. At mid-2011, there were almost 1 billion common shares outstanding with a market value of over $40 billion. Clearly, Walgreens would qualify as an investment for institutions that require firms with large market value. Walgreen Co.’s stock has an annual trading turnover of about 80 percent, which is a little below average. Financial institutions own about 460 million shares of Walgreens, which is about 50 percent of the outstanding shares. Therefore, Walgreen Co.’s large number of stockholders, very large market capitalization, fairly active trading of its stock, and strong institutional interest indicate that Walgreens has very little liquidity risk.

The exchange rate risk for companies depends on what proportion of sales and earnings are generated outside the United States and the volatility of the exchange rates in the specific countries. Walgreens has very little exchange rate risk or country risk because the firm has virtually no non-U.S. sales.

In summary, Walgreens has below-average business risk, above-average financial risk when we consider leases, low market liquidity risk, and virtually no exchange rate and country risk. This implies that the overall fundamental risk for Walgreens should be lower than the market.

\(^{11}\)Although some prior tables included data through 2010 using estimates for specific ratios, it is not possible to do this for industry and market variables in Exhibit 14.12 as of mid-2011.
Analysts should also consider market-determined risk (beta) based on the CAPM. As noted in connection with the cash flow models, the stock’s beta derived from five years of monthly data relative to the S&P Industrials for the period 2006–2010 was 0.95. These results are consistent with those derived from an analysis of the fundamental factors—both indicate that Walgreen Co.’s risk is below the aggregate market. This means that the required rate of return ($k$) of 8 percent for Walgreen Co.’s stock estimated earlier using the CAPM is reasonable. By itself, this lower $k$ would suggest an earnings multiplier above the market multiplier. Walgreens’ risk is comparable to its industry based on both fundamental and market risk.

Estimating the Expected Growth Rate

Recall that the expected growth rate ($g$) is determined by the firm’s retention rate and its expected return on equity ($ROE$). We have already noted Walgreen Co.’s dividend payout is similar to its industry and clearly lower than the aggregate market, which implies a higher retention rate than the market. As discussed, a firm’s $ROE$ can be estimated in terms of the three ratios: (1) net profit margin ($NPM$), (2) total asset turnover ($TAT$), and (3) the financial leverage multiplier. We also know that $NPM \times TAT = Return on Assets (ROA)$. It is important to compare the ROA of alternative firms as a measure of operating performance—that is, profitability and asset efficiency. As shown in Exhibit 14.12, Walgreens has experienced a decline in TAT from 3.27 to 2.52. Prior to 2007, this had been offset by an increase in NPM, but the NPM experienced a decline in 2009 and a further decline in 2010. As a result, ROA declined from about 10.50 percent to about 8 percent in 2009. While its ROA is still above the industry and market, the difference has narrowed.

Finally, the firm’s ROE equals the ROA times the financial leverage multiplier (total assets/equity). Notably, since 1993, Walgreens has reduced its leverage multiplier from 1.84 to 1.75, while the industry and market have experienced similar declines. As a result, Walgreens has a higher ROE than its industry, but it is about equal to the market. Finally, WAG has financial risk that is equal to the industry and lower than the market using the ratios in Exhibit 14.12.

Chapter 14: Company Analysis and Stock Valuation

Analysts should also consider market-determined risk (beta) based on the CAPM. As noted in connection with the cash flow models, the stock’s beta derived from five years of monthly data relative to the S&P Industrials for the period 2006–2010 was 0.95.

These results are consistent with those derived from an analysis of the fundamental factors—both indicate that Walgreen Co.’s risk is below the aggregate market. This means that the required rate of return (k) of 8 percent for Walgreen Co.’s stock estimated earlier using the CAPM is reasonable. By itself, this lower k would suggest an earnings multiplier above the market multiplier. Walgreens’ risk is comparable to its industry based on both fundamental and market risk.

**Estimating the Expected Growth Rate** Recall that the expected growth rate (g) is determined by the firm’s retention rate and its expected return on equity (ROE). We have already noted Walgreen Co.’s dividend payout is similar to its industry and clearly lower than the aggregate market, which implies a higher retention rate than the market.

As discussed, a firm’s ROE can be estimated in terms of the three ratios: (1) net profit margin (NPM), (2) total asset turnover (TAT), and (3) the financial leverage multiplier. We also know that $NPM \times TAT = \text{Return on Assets (ROA)}$. It is important to compare the ROA of alternative firms as a measure of operating performance—that is, profitability and asset efficiency. As shown in Exhibit 14.12, Walgreens has experienced a decline in TAT from 3.27 to 2.52. Prior to 2007, this had been offset by an increase in NPM, but the NPM experienced a decline in 2009 and a further decline in 2010. As a result, ROA declined from about 10.50 percent to about 8 percent in 2009. While its ROA is still above the industry and market, the difference has narrowed.

Finally, the firm’s ROE equals the ROA times the financial leverage multiplier (total assets/equity). Notably, since 1993, Walgreens has reduced its leverage multiplier from 1.84 to 1.75, while the industry and market have experienced similar declines.

As a result, Walgreens has a higher ROE than its industry, but it is about equal to the market. Finally, WAG has financial risk that is equal to the industry and lower than the market using the ratios in Exhibit 14.12.
Using the results for the last five years (2005–2009), the ROEs would be approximately as follows:

<table>

The foregoing highlights the difference among the three units based on recent history. An analyst would need to estimate future components and derive an expected ROE that reflects the firm’s expected future performance.

The demonstration can be extended by combining the average annual ROEs derived in the table above and the average of recent retention rates from Exhibit 14.15 to derive potential growth rates, assuming that you felt these recent results would continue in the future.

Taken alone, these potential growth rates for Walgreens would indicate that it should have a multiple above its industry and clearly above the market.

Computing the Earnings Multiplier

Comparing our estimates of D/E, k, and g to comparable values for the industry and the market, we find that the Walgreen Co.’s earnings multiplier based on the microanalysis should be greater than the multiplier for its industry and clearly larger than for the market. Specifically, the dividend-payout ratio points toward a lower multiplier for Walgreens, whereas both the risk analysis and the higher expected growth rate would indicate a multiplier for Walgreens somewhat above that of its industry and definitely larger than the market.

The macroanalysis indicated that the Walgreen Co.’s multiplier typically has been above its industry and the market, and the microanalysis supported this relationship. Assuming a market multiple of about 18 and a retail drugstore multiplier of about 20 times, the multiplier of Walgreens should be between 18 and 22 (18–20–22 times) with a tendency toward the upper end of the range. Alternatively, if we inserted some earlier estimated values for D/E, k, and g into the P/E ratio formula, we would not be able to derive an estimated multiplier for Walgreens because g is greater than k.

As noted in Chapter 11, because Walgreens is a true growth company, we cannot use the standard DDM formula to estimate a specific multiple. We would need to estimate an intrinsic value based on the direction of change and the macroanalysis estimates of 18–20–22 times.

Estimates of Intrinsic Value for Walgreens

Earlier, we estimated 2011 earnings for Walgreens of about $2.38 per share. Assuming multipliers of 18–20–22 implies the following estimated intrinsic values:

- 18 × $2.38 = $42.84
- 20 × $2.38 = $47.60
- 22 × $2.38 = $52.68

14.7.3 Making the Investment Decision

In our prior discussions of valuation, we set forth the following investment decision rule: Compute the estimated intrinsic value for an investment using your required rate of return as the discount rate. If this intrinsic value is equal to or greater than the current market price of...
Using the results for the last five years (2005–2009), the ROEs would be approximately as follows:

<table>

</tbody>
</table>

The foregoing highlights the difference among the three units based on recent history. An analyst would need to estimate future components and derive an expected ROE that reflects the firm’s expected future performance.

The demonstration can be extended by combining the average annual ROEs derived in the table above and the average of recent retention rates from Exhibit 14.15 to derive potential growth rates, assuming that you felt these recent results would continue in the future.

Computing the Earnings Multiplier Comparing our estimates of D/E, k, and g to comparable values for the industry and the market, we find that the Walgreen Co.’s earnings multiplier based on the microanalysis should be greater than the multiplier for its industry and clearly larger than for the market. Specifically, the dividend-payout ratio points toward a lower multiplier for Walgreens, whereas both the risk analysis and the higher expected growth rate would indicate a multiplier for Walgreens somewhat above that of its industry and definitely larger than the market.

The macroanalysis indicated that the Walgreen Co.’s multiplier typically has been above its industry and the market, and the microanalysis supported this relationship. Assuming a market multiple of about 18 and a retail drugstore multiplier of about 20 times, the multiplier of Walgreens should be between 18 and 22 (18–20–22 times) with a tendency toward the upper end of the range. Alternatively, if we inserted some earlier estimated values for D/E, k, and g into the D/E ratio formula, we would not be able to derive an estimated multiplier for Walgreens because g is greater than k. As noted in Chapter 11, because Walgreens is a true growth company, we cannot use the standard DDM formula to estimate a specific multiple. We would need to estimate an intrinsic value based on the direction of change and the macroanalysis estimates of 18–20–22 times.

Estimates of Intrinsic Value for Walgreens Earlier, we estimated 2011 earnings for Walgreens of about $2.38 per share. Assuming multipliers of 18–20–22 implies the following estimated intrinsic values:

18 × $2.38 = $42.84
20 × $2.38 = $47.60
22 × $2.38 = $52.36

14.7.3 Making the Investment Decision

In our prior discussions of valuation, we set forth the following investment decision rule: Compute the estimated intrinsic value for an investment using your required rate of return as the discount rate. If this intrinsic value is equal to or greater than the current market price of
the investment, buy it. If the estimated intrinsic value is less than the market price, do not buy it, and if you own it, sell it.

Therefore, the required comparisons are the estimated values derived using the present value of cash flow models and the values estimated using the earnings multiple model to the current market price of Walgreens of about $43.00 a share. The following is a summary of these estimated values. Recall that we could not calculate constant-growth models because Walgreens has consistently experienced growth rates above its required rates of return (it is a true growth company).

### Present Value of Cash Flow Models

<table>
<thead>
<tr>
<th>Model Type</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Three-stage DDM</td>
<td>$47.41</td>
</tr>
<tr>
<td>Three-stage FCFE</td>
<td>$80.96</td>
</tr>
<tr>
<td>Three-stage FCFF (OFCF)</td>
<td>$71.24</td>
</tr>
</tbody>
</table>

### Earnings Multiple Models

<table>
<thead>
<tr>
<th>Earnings Multiple</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>18 times estimated earnings</td>
<td>$42.84</td>
</tr>
<tr>
<td>20 times estimated earnings</td>
<td>$47.60</td>
</tr>
<tr>
<td>22 times estimated earnings</td>
<td>$52.36</td>
</tr>
</tbody>
</table>

Because all of the computed values are about equal to or larger than the current market price of $43.00, you would recommend a purchase of the stock. Stated in terms of our earlier discussion, Walgreens is apparently a true growth company (although not as strong as in the past), and based on several valuations the firm's stock is expected to be a growth stock, assuming that it is acquired at its current price.

### Additional Measures of Relative Value

Beyond the well-known price/earnings ratio, analysts also calculate three additional measures of relative value—the price/book value ratio, the price/cash flow ratio, and the price/sales ratio, which were discussed in Chapter 11.

#### Price/Book Value (P/BV) Ratio

The price-to-book-value ratio (P/BV) has gained prominence because of the studies by Fama and French (1992); Rosenberg, Reid, and Lanstein (1985); and Fairfield (1994). Book value is a reasonable measure of value for firms that have consistent accounting practice (e.g., firms in the same industry) and can apply to firms with negative earnings or cash flows. You should not attempt to use this ratio to compare firms with different levels of hard assets—for example, a heavy industrial firm and a service firm.

The annual P/BV ratios for Walgreens, its industry, and the market are in Exhibit 14.16. In this instance, the major variable that should cause a difference in the P/BV ratio is the firm's return on investment (ROI) relative to its cost of capital (its WACC). Assuming that most firms in an industry have comparable WACCs, the major differential should be the firm's ROI because the larger the ROI-WACC difference, the greater the justified P/BV ratio.

As shown in Exhibit 14.16, the P/BV ratios for the industry and market have increased from about 2.5–3.5 to a peak of 5–6 and ended at about 2.0. In contrast, WAG started at about 2.8, peaked at 6.2, and ended at 2.1. A plot of relative valuation ratios in Exhibit 14.17 indicates that Walgreens has consistently sold at a higher P/BV ratio than its industry and the market. A higher P/BV ratio for WAG is clearly justified relative to both the market and its industry due to its consistently higher ROE. The recent reduction in the differences between P/BV ratios is also justified because of WAG's declining ROE. Still, a relative ratio of 0.99 to the market for 2008 as shown in Exhibit 14.17 appears to be too low.

Because all of the computed values are about equal to or larger than the current market price of $43.00, you would recommend a purchase of the stock. Stated in terms of our earlier discussion, Walgreens is apparently a true growth company (although not as strong as in the past), and based on several valuations the firm’s stock is expected to be a growth stock, assuming that it is acquired at its current price.

## 14.8 Additional Measures of Relative Value

Beyond the well-known price/earnings ratio, analysts also calculate three additional measures of relative value—the price/book value ratio, the price/cash flow ratio, and the price/sales ratio, which were discussed in Chapter 11.

### 14.8.1 Price/Book Value (P/BV) Ratio

The price-to-book-value ratio (P/BV) has gained prominence because of the studies by Fama and French (1992); Rosenberg, Reid, and Lanstein (1985); and Fairfield (1994). Book value is a reasonable measure of value for firms that have consistent accounting practice (e.g., firms in the same industry) and can apply to firms with negative earnings or cash flows. You should not attempt to use this ratio to compare firms with different levels of hard assets—for example, a heavy industrial firm and a service firm.

The annual P/BV ratios for Walgreens, its industry, and the market are in Exhibit 14.16. In this instance, the major variable that should cause a difference in the P/BV ratio is the firm’s return on investment (ROI) relative to its cost of capital (its WACC). Assuming that most firms in an industry have comparable WACCs, the major differential should be the firm’s ROI because of the larger the ROI-WACC difference, the greater the justified P/BV ratio.

As shown in Exhibit 14.16, the P/BV ratios for the industry and market have increased from about 2.5–3.5 to a peak of 5–6 and ended at about 2.0. In contrast, WAG started at about 2.8, peaked at 6.2, and ended at 2.1. A plot of relative valuation ratios in Exhibit 14.17 indicates that Walgreens has consistently sold at a higher P/BV ratio than its industry and the market. A higher P/BV ratio for WAG is clearly justified relative to both the market and its industry due to its consistently higher ROE. The recent reduction in the differences between P/BV ratios is also justified because of WAG’s declining ROE. Stil, a relative ratio of 0.99 to the market for 2008 as shown in Exhibit 14.17 appears to be too low.
As noted in Chapter 10, the price/cash flow ratio has grown in prominence and use because many observers contend that a firm’s cash flow is less subject to manipulation than its earnings per share and because cash flows are widely used in the present value of cash flow models discussed earlier. An important question is: Which of the several cash flow specifications should an analyst employ? In this analysis, we use the EBITDA cash flow measure equal to net income plus interest, depreciation, and taxes because this cash flow measure can be derived for both the retail drugstore industry and the market. Although it is certainly legitimate to have a preference for other cash flow measures as discussed in Chapter 10, a demonstration using this measure should provide a valid comparison for learning purposes.

The time-series graph of the P/CF ratio in Exhibit 14.18 shows that the industry and market ratios were highly correlated and ranged from about 10 in 1993 to a high of about 25 and 30 in 1999–2000 and ended in 2008 at 10 times for the industry and 6 times for the market. In contrast, the volatile Walgreens ratio ranged from about 10 at the beginning to a high of almost 45 in 2000 and ended at about 7 times in 2008. The P/CF ratio is similar to the P/E ratio because it is driven by the growth rate and volatility of cash flow, which means that Walgreens should have a higher ratio. Specifically, as shown in Exhibit 14.3, WAG’s growth rate of cash flow is much higher than both the industry and the market (almost 21 percent for Walgreens versus about 10 percent for the industry and only 3 percent for the market). Further, its growth rate is quite stable compared to the industry and market. Therefore, since WAG’s cash flow growth rate is higher and risk is lower, its P/CF ratios should definitely be larger—the question is whether it should be 73 and 81 percent higher, as shown by the average relative ratios in Exhibit 14.4. Notably, the Co./Ind. and Co./Mkt. ratios (in Exhibit 14.19) in 2008 indicate relative undervaluation of Walgreens stock based on values of 0.77 and 1.20.

Exhibit 14.16 Time-Series Plot of Mean Price/Book Value Ratios for Walgreens, Retail Drugstores, and Industrials: 1993–2009

14.8.3 Prices/Sales (P/S) Ratio

The price-to-sales ratio (P/S) has had a long but generally neglected existence followed by a recent reawakening. Phillip Fisher (1958), in his classic book, suggested this ratio as a valuable tool when considering investments, including growth stocks. Subsequently, his son Kenneth Fisher (1984) used the P/S ratio as a major stock selection variable in his book. P/S was also suggested by Leibowitz (1997) and was likewise espoused by O’Shaughnessy (1997), when he compared several stock selection techniques. Leibowitz makes the point that sales growth drives the growth of all subsequent earnings and cash flows. Further, those concerned with accounting manipulation point out that sales is one of the purest numbers available. Notably, this ratio is equal to the P/E ratio times the net profit margin (earnings/sales), which implies that the P/S ratio is heavily influenced by the profit margin of the entity being analyzed in addition to sales growth and sales volatility (risk).

As shown in Exhibit 14.4 and Exhibit 14.20, the P/S ratio for Walgreens has experienced a range from 0.43 to a peak of 1.29 and finished at 0.48, compared to its industry that ranged from 0.39 to 1.05 and also ended at 0.48. Finally, the market P/S series ranged from 0.76 to 2.09 and ended at 0.99. Notably, the market P/S ratio was always higher than both Walgreens and its industry. The plot of relative ratios in Exhibit 14.21 shows that the company-to-industry ratio increased to a peak of 1.56 in 2002 and has generally declined since then. Alternatively, the company-to-market ratio reached a peak of 0.80 in 2002 and likewise generally declined after that. Recall that three variables should impact the P/S ratio: sales growth rate, volatility of sales growth, and the profit margin. An analysis of the three variables justifies a higher P/S ratio for WAG relative to its industry but not relative to the market. Specifically, as shown in Exhibit 14.3, the 10-year growth rate of sales for WAG was clearly higher at 13.61 percent compared to 9.21 percent and 3.66 percent for the industry and market. In addition, the volatility of sales growth for WAG was close to zero compared to the industry that experienced a slowdown in 2001 and 2002, while the market experienced a sales decline in 2001–2002.

![Time-Series Plot of Price/Cash Flow Ratios for Walgreens, Retail Drugstores, and Industrials: 1993–2009](image-url)
14.8.3 Prices/Sales (P/S) Ratio

The price-to-sales ratio (P/S) has had a long but generally neglected existence followed by a recent reawakening. Phillip Fisher (1958), in his classic book, suggested this ratio as a valuable tool when considering investments, including growth stocks. Subsequently, his son Kenneth Fisher (1984) used the P/S ratio as a major stock selection variable in his book. P/S was also suggested by Leibowitz (1997) and was likewise espoused by O’Shaughnessy (1997), when he compared several stock selection techniques. Leibowitz makes the point that sales growth drives the growth of all subsequent earnings and cash flows. Further, those concerned with accounting manipulation point out that sales is one of the purest numbers available. Notably, this ratio is equal to the P/E ratio times the net profit margin (earnings/sales), which implies that the P/S ratio is heavily influenced by the profit margin of the entity being analyzed in addition to sales growth and sales volatility (risk).

As shown in Exhibit 14.4 and Exhibit 14.20, the P/S ratio for Walgreens has experienced a range from 0.43 to a peak of 1.29 and finished at 0.48, compared to its industry that ranged from 0.39 to 1.05 and also ended at 0.48. Finally, the market P/S series ranged from 0.76 to 2.09 and ended at 0.99. Notably, the market P/S ratio was always higher than both Walgreens and its industry. The plot of relative ratios in Exhibit 14.21 shows that the company-to-industry ratio increased to a peak of 1.56 in 2002 and has generally declined since then.

Alternatively, the company-to-market ratio reached a peak of 0.80 in 2002 and likewise generally declined after that. Recall that three variables should impact the P/S ratio: sales growth rate, volatility of sales growth, and the profit margin. An analysis of the three variables justifies a higher P/S ratio for WAG relative to its industry but not relative to the market. Specifically, as shown in Exhibit 14.3, the 10-year growth rate of sales for WAG was clearly higher at 13.61 percent compared to 9.21 percent and 3.66 percent for the industry and market. In addition, the volatility of sales growth for WAG was close to zero compared to the industry that experienced a slowdown in 2001 and 2002, while the market experienced a sales decline in 2001–2002.
and again in 2009. Finally, the PM comparison in Exhibit 14.8 shows that the average PM over the last 10 years for WAG was above the industry (3.61 percent versus 3.05 percent), but below the market (3.61 percent versus 6.17 percent). Therefore, because of the superior WAG/Industry performance in sales growth, sales volatility, and profit margin, the Walgreens P/S ratio clearly should be higher than its industry—probably in the range of 1.20 compared to 1.00 in 2008. In contrast, the large difference in the Co./Mkt. profit margin in favor of the market (3.61 percent versus 6.17 percent) dominates the sales growth and stability and calls for a consistently higher P/S ratio for the market relative to WAG—but should the market ratio be twice as large?

### 14.8.4 Summary of Relative Valuation Ratios

The first observation related to these four ratios is that all of them experienced a cyclical change over the 17 years—they generally started at a low point in 1993, increased dramatically to a peak prior to the 2000–2001 crash, then typically declined toward the original values by 2008. The performance of the ratios for Walgreens relative to its industry and the market varied between the specific ratios.

Regarding the P/E ratio based on risk and earnings growth, WAG should clearly have a higher P/E than its industry and also a little higher than the market. If you apply a higher than market P/E to future earnings, WAG is currently undervalued. An analysis of relative ROEs indicated that Walgreens should have a higher P/BV ratio than both the industry and the market—the recent company/market ratio of less than 1.00 again implies WAG is undervalued relative to the market. The P/CF ratio for WAG should be higher than both the industry and the market due to a higher rate of growth and more stable growth. While the long-run relative P/CF ratios appear high, the more recent ratio of 0.77 for the company/industry is clearly too low and the 1.20 for the company/market appears appropriate. Finally, the P/S ratio that is a function of stable sales growth and the profit margin should be much higher for WAG than its industry and a little higher for the market than the company. A relative P/S ratio of 1.00 for the industry clearly indicates undervaluation for WAG, while a relative ratio of 0.48 for the company/market is in the right direction but seems too low, which also points toward undervaluation for WAG.

In conclusion, virtually all the ratios for Walgreens were in the expected direction relative to its industry and the market—the only questions were the extent of difference. Both the P/E and the P/BV ratios pointed toward an undervaluation of WAG, while the relative P/CF ratios for WAG were mixed—the Co./Ind. results implied undervaluation, while the Co./Mkt. ratio was reasonable. Finally, both of the relative P/S ratios indicated that WAG was undervalued.

The following section considers some techniques used to analyze and derive values for growth companies.

### 14.9 Analysis of Growth Companies

Investment literature contains numerous accounts of the rapid growth of such companies as Walmart, Intel, Microsoft, Apple, Pfizer, and Google, along with stories about investors who became wealthy because of the timely acquisition of these stocks. The very high rates of return on these stocks indicate that the early and proper valuation of true growth companies can be extremely rewarding. At the same time, for every successful Apple or Google, numerous firms did not survive. In addition, there are many instances where the stock price of a true growth company overcompensated for the firm’s expected growth, and subsequent returns on the company’s stock were below expectations. As noted in Solt and Statman (1989) and our earlier discussion, the common stock of a growth company is not always a growth stock.

You are familiar with the DDM assumptions—that is, that dividends are expected to grow at a constant rate for an infinite time period. As explained in Chapter 11, although these assumptions are reasonable when evaluating the aggregate market and some large mature companies, they are too simplistic for growth companies.
and again in 2009. Finally, the PM comparison in Exhibit 14.8 shows that the average PM over the last 10 years for WAG was above the industry (3.61 percent versus 3.05 percent), but below the market (3.61 percent versus 6.17 percent). Therefore, because of the superior WAG/Industry performance in sales growth, sales volatility, and profit margin, the Walgreens P/S ratio clearly should be higher than its industry—probably in the range of 1.20 compared to 1.00 in 2008. In contrast, the large difference in the Co./Mkt. profit margin in favor of the market (3.61 percent versus 6.17 percent) dominates the sales growth and stability and calls for a consistently higher P/S ratio for the market relative to WAG—but should the market ratio be twice as large?

**14.8.4 Summary of Relative Valuation Ratios**

The first observation related to these four ratios is that all of them experienced a cyclical change over the 17 years—they generally started at a low point in 1993, increased dramatically to a peak prior to the 2000–2001 crash, then typically declined toward the original values by 2008. The performance of the ratios for Walgreens relative to its industry and the market varied between the specific ratios.

Regarding the P/E ratio based on risk and earnings growth, WAG should clearly have a higher P/E than its industry and also a little higher than the market. If you apply a higher than market P/E to future earnings, WAG is currently undervalued. An analysis of relative ROEs indicated that Walgreens should have a higher P/BV ratio than both the industry and the market—the recent company/market ratio of less than 1.00 again implies WAG is undervalued relative to the market. The P/CF ratio for WAG should be higher than both the industry and the market due to a higher rate of growth and more stable growth. While the long-run relative P/CF ratios appear high, the more recent ratio of 0.77 for the company/industry is clearly too low and the 1.20 for the company/market appears appropriate. Finally, the P/S ratio that is a function of stable sales growth and the profit margin should be much higher for WAG than its industry and a little higher for the market than the company. A relative P/S ratio of 1.00 for the industry clearly indicates undervaluation for WAG, while a relative ratio of 0.48 for the company market is in the right direction but seems too low, which also points toward undervaluation for WAG.

In conclusion, virtually all the ratios for Walgreens were in the expected direction relative to its industry and the market—the only questions were the extent of difference. Both the P/E and the P/BV ratios pointed toward an undervaluation of WAG, while the relative P/CF ratios for WAG were mixed—the Co./Ind. results implied undervalue, while the Co./Mkt. ratio was reasonable. Finally, both of the relative P/S ratios indicated that WAG was undervalued.

The following section considers some techniques used to analyze and derive values for growth companies.

**14.9 Analysis of Growth Companies**

Investment literature contains numerous accounts of the rapid growth of such companies as Walmart, Intel, Microsoft, Apple, Pfizer, and Google, along with stories about investors who became wealthy because of the timely acquisition of these stocks. The very high rates of return on these stocks indicate that the early and proper valuation of true growth companies can be extremely rewarding. At the same time, for every successful Apple or Google, numerous firms did not survive. In addition, there are many instances where the stock price of a true growth company overcompensated for the firm’s expected growth, and subsequent returns on the company’s stock were below expectations. As noted in Solt and Statman (1989) and our earlier discussion, the common stock of a growth company is not always a growth stock.

You are familiar with the DDM assumptions—that is, that dividends are expected to grow at a constant rate for an infinite time period. As explained in Chapter 11, although these assumptions are reasonable when evaluating the aggregate market and some large mature
industries, they can be very tenuous when analyzing individual securities. These assumptions are extremely questionable for a true growth company.

14.9.1 Growth Company Defined
Recall that a growth company has the opportunities and ability to invest capital in projects that generate rates of return greater than the firm’s cost of capital. Such a condition is considered to be temporary. The point is, in a competitive economy, if the rates of return for a given industry or company exceed the rates of return expected based on the risk involved, other companies will enter the industry, increase the supply, and eventually drive prices down until the rates of return earned on capital invested are consistent with the risk involved.

14.9.2 Actual Returns above Required Returns
The notion of a firm consistently earning rates of return above its required rate of return needs elaboration. Firms are engaged in business ventures that offer opportunities for investment of corporate capital, and these investments entail some risk. Investors determine their required return for owning a firm based on the risk of its investments compared to the risk of other firms. This required rate of return on all of the firm’s capital is referred to as the firm’s weighted average cost of capital (WACC). In a state of equilibrium, the rates of return earned on risky investments by the firm should equal the rates of return required by investors. Rates of return above those required for the risk involved are referred to as pure profits or excess profits.

Excess profits are possible only in a noncompetitive environment. Assume that a medical equipment firm is able to earn 20 percent on its capital, while investors require only 15 percent from the firm because of its risk. The extra 5 percent is defined as pure profit, and numerous companies would enter the medical equipment field to enjoy these excess profits. These competitors would increase the supply of equipment and reduce the price that producers could charge for the equipment until the marginal returns equaled the required return due to risk.

Because many firms have derived excess profits for a number of years, these excess returns are probably not due to a temporary disequilibrium but rather because of some noncompetitive factors that exist, such as patents or copyrights that provide monopoly rights to a process or a manuscript for a specified period. During this period of protection from competition, the firm can derive above-normal returns. Also, a firm could possess strategies, discussed by Porter, that provide added profits (e.g., a unique marketing technique or other organizational characteristics). Finally, there may be significant barriers to entry, such as capital requirements.

In a purely competitive economy, true growth companies would not exist because competition would not allow continuing excess return investments. The fact is, our economy is not perfectly competitive (although this typically is the best model to use) because there are a number of frictions that restrict competition. Therefore, it is possible for temporary true growth companies to exist in our economy. The significant question is: How long can these growth companies earn these excess profits?

14.9.3 Growth Companies and Growth Stocks
Recall that a growth stock is expected to experience above-average risk-adjusted rates of return during some future period. This means that any undervalued stock can be a growth stock, regardless of the type of company. Alternatively, the stock of a growth company that is substantially overvalued could be a speculative stock because the probability of below-normal returns on the stock would be very high even if the company fulfilled expectations.

In this section, we discuss models that are meant to help you evaluate the unique earnings stream of a growth company. As a result, you should derive a better estimate of the firm’s value and be able to judge whether the stock of a growth company is (1) a growth stock, (2) a properly valued stock, or (3) a speculative overvalued stock.
14.9.4 Alternative Growth Models

In this section, we consider the full range of growth models, from no growth and negative growth to dynamic true growth. Knowledge of the full range will help you understand the life cycle of true growth companies. We assume the company is an all-equity firm to simplify the computations.

14.9.5 No-Growth Firm

The no-growth firm is a mythical company that is established with a specified portfolio of investments that generate a constant stream of earnings \( E \) equal to the rate of return on assets \( r \) times the value of assets. Earnings are calculated after allowing for depreciation expense used to maintain the assets at their original value. Therefore:

\[
E = r \times \text{Assets}
\]

An important assumption for a no-growth firm is that all earnings of the firm are paid out in dividends; if \( b \) is the rate of retention, \( b = 0 \). Hence:

\[
E = r \times \text{Assets} = \text{Dividends}
\]

Under these assumptions, the value of the firm is the discounted value of the perpetual stream of earnings \( E \). The discount rate (the investor’s required rate of return) is specified as \( k \). In this case, it is assumed that \( r = k \). The firm’s rate of return on assets equals its required rate of return. Therefore, the value of the firm is:

\[
V = \frac{E}{k} = \frac{(1 - b)E}{k}
\]

In the no-growth case, the earnings stream never changes because the asset base never changes, and the rate of return \( r \) on the assets never changes. Therefore, the value of the firm never changes, and investors continue to receive \( k \) on their investment.

\[
k = E/V
\]

14.9.6 Long-Run Growth Models

Long-run models differ from the no-growth models because they assume some of the earnings are reinvested. In all cases, it is postulated that the market value \( V \) of an all-equity firm is the capitalized value of three component forms of returns discounted at the rate \( k \).

- \( E \) = the level of (constant) net earnings expected from existing assets, without further net investments.
- \( G \) = the growth component that equals the present value of capital gains expected from reinvested funds. The return on reinvested funds is equal to \( r \), which equals \( mk \) (\( m \) is the relative rate of return operator). If \( m \) is equal to 1, then \( r = k \). If \( m \) is greater than 1, the projects that generate these returns are considered true growth investments \( (r > k) \). If \( m \) is less than 1, the investments are generating returns \( (r) \) below the cost of capital \( (r < k) \).
- \( R \) = the reinvestment of net earnings \( E \) is equal to \( bE \), where \( b \) is a percent of retention which is between zero (no reinvestment) and unity (total reinvestment; no dividends).

**Simple-Growth Model** This model assumes the firm has growth investment opportunities that provide rates of return equal to \( r \), where \( r \) is greater than \( k \) (\( m \) is above 1). Further, it is assumed that the firm can invest \( R \) dollars a year at these rates and that \( R = bE \); \( R \) is a constant dollar amount because \( E \) is the constant earnings at the beginning of the period.

---

12The discussion in this section draws heavily from Salomon (1963) and Miller and Modigliani (1961).
This discussion indicates that simply because a firm retains earnings and reinvests them, it is not necessarily beneficial to the stockholder unless the reinvestment rate is above the required rate ($r > k$). Otherwise, the investor in a tax-free world would be as well off with all earnings paid out in dividends. Either way, your return is $k$.

### Negative-Growth Model

The negative-growth model applies to a firm that retains earnings ($b > 0$) and reinvests these funds in projects that generate rates of return below the firm’s cost of capital ($r < k$ or $m < 1$). The impact of this on the value of the firm can be seen from equation 14.15, which indicates that with $m < 1$, the net present value of the growth investments would be negative. Therefore, the value of the firm in equation 14.16 would be less than the value of a no-growth firm or an expansion firm. This also can be seen by examining the effect of $m < 1$ in equation 14.19. The firm is withholding funds from the investor and investing them in projects that generate returns less than those available from comparable risk investments. Such poor performance may be difficult to uncover because the firm’s asset base will grow since the firm is retaining earnings and acquiring assets. Notably, the earnings of the firm will also increase if it earns any positive rate of return on the new assets. The important point is, the earnings will not grow by as much as they should, so the value of the firm will decline over time when investors discount the below required cash flows from this reinvestment stream at the firm’s cost of capital.

### What Determines the Capital Gain Component?

These equations highlight the factors that influence the capital gain component. Beginning with Equation 14.14, all the equations suggest that the gross present value of growth investments is equal to $bEm/k$. Therefore, the net present value of growth investments is equal to:

$$14.14 \quad \frac{bEmk}{k^2} = \frac{bEm}{k} \quad \text{(Gross Present Value of Growth Investments)}$$

To derive these flows, the firm must invest $bE$ dollars each year. The present value of these annual investments is equal to $bE/k$. Therefore, the net present value of growth investments is equal to:

$$14.15 \quad \frac{bEm}{k} - \frac{bE}{k} \quad \text{(Net Present Value of Growth Investments)}$$

The important variable is the value of $m$, which indicates the relationship of $r$ to $k$. Combining this growth component with the capitalized value of the constant earnings stream indicates that the value of the firm is:

$$14.16 \quad V = \frac{E}{k} + \left[ \frac{bEm}{k} - \frac{bE}{k} \right]$$

This equation indicates that the value of the firm is equal to the capitalized value of the constant earnings stream plus a growth component equal to the net present value of reinvestment in growth projects. By combining the first and third terms in Equation 14.16, it becomes:

$$14.17 \quad V = \frac{E(1 - b)}{k} + \frac{bEm}{k}$$

Because $E(1 - b)$ is the dividend ($D$), this model becomes:

$$14.18 \quad V = \frac{D}{k} + \frac{bEm}{k} \quad \text{(Present Value of Constant Dividend plus the Gross Present Value of Growth Investments)}$$

It can be stated as earnings only by rearranging equation 14.16:

$$14.19 \quad V = \frac{E}{k} + \frac{bEm(m - 1)}{k} \quad \text{(Present Value of Constant Earnings plus the Present Value of Excess Earnings from Growth Investments)}$$

**Expansion Model** The expansion model assumes a firm retains earnings to reinvest but receives a rate of return on its investments that is equal to its cost of capital ($m = 1, \text{ so } r = k$). The effect of such a change can be seen in Equation 14.15, where the net present value of growth investments would be zero. Therefore, Equation 14.16 would become:

$$14.20 \quad V = \frac{E}{k}$$

Equation 14.17 would become:

$$14.21 \quad V = \frac{E(1 - b)}{k} + \frac{bE}{k} = \frac{E}{k}$$

Equation 14.18 is still valid, but the present value of the growth investment component would be smaller because $m$ would be equal to 1. Finally, the last term in equation 14.19 would disappear.
Applying this model to a true growth company means that earnings and dividends are growing at a constant rate and the firm is investing larger and larger dollar amounts in projects that generate returns greater than $k$. Moreover, the DDM model implicitly assumes that the firm can continue to do this for an infinite time period. If the growth rate ($g$) is greater than $k$, the model blows up and indicates that the firm should have an infinite value. Durand (1957) considered this possibility and concluded that, although many firms had current growth rates above the normal required rates of return, very few of their stocks were selling for infinite values. He explained this by contending that investors expected the reinvestment rate to decline or they felt that the growing set of investment opportunities would not be available for an infinite time period. Exhibit 14.22 contains a summary of the alternative company characteristics.

14.9.7 The Real World

Because these models are simplified to allow us to develop a range of alternatives, several of them are extremely unrealistic. In the real world, companies generally would combine these models. Unfortunately, most firms have made some investments where $r < k$, and many firms invest in projects that generate returns about equal to their cost of capital. Finally, most firms invest in some projects that provide rates of return above the firm’s cost of capital ($r > k$). The crucial questions are (1) how much is invested in these true growth projects? and (2) how long do these true growth opportunities last?

Given this understanding of growth companies and what creates their value, the rest of the chapter considers various models that help you understand how to identify a true growth company and estimate specific values for these growth companies. We begin with models that are intended to identify growth companies in terms of providing excess economic value, which some contend is due to franchise value. Subsequently, we consider several models that are intended to provide a valuation of these companies by concentrating on how long the superior growth can continue and, alternatively, the extent and length of the superior growth. This final model has some similarities to the three-stage cash flow models.

14.10 Measures of Value Added

In addition to the DDM, which feeds into the $P/E$ ratio valuation technique and the supplementary $P/BV$, $P/CF$, and $P/S$ ratios, there is also interest in a set of performance measures.

Exhibit 14.22

This section benefited from Peterson and Peterson (1996).
Applying this model to a true growth company means that earnings and dividends are growing at a constant rate and the firm is investing larger and larger dollar amounts in projects that generate returns greater than k. Moreover, the DDM model implicitly assumes that the firm can continue to do this for an infinite time period. If the growth rate (g) is greater than k, the model blows up and indicates that the firm should have an infinite value. Durand (1957) considered this possibility and concluded that, although many firms had current growth rates above the normal required rates of return, very few of their stocks were selling for infinite values. He explained this by contending that investors expected the reinvestment rate to decline or they felt that the growing set of investment opportunities would not be available for an infinite time period. Exhibit 14.22 contains a summary of the alternative company characteristics.

14.9.7 The Real World

Because these models are simplified to allow us to develop a range of alternatives, several of them are extremely unrealistic. In the real world, companies generally would combine these models. Unfortunately, most firms have made some investments where r < k, and many firms invest in projects that generate returns about equal to their cost of capital. Finally, most firms invest in some projects that provide rates of return above the firm’s cost of capital (r > k). The crucial questions are (1) how much is invested in these true growth projects? and (2) how long do these true growth opportunities last?

Given this understanding of growth companies and what creates their value, the rest of the chapter considers various models that help you understand how to identify a true growth company and estimate specific values for these growth companies. We begin with models that are intended to identify growth companies in terms of providing excess economic value, which some contend is due to franchise value. Subsequently, we consider several models that are intended to provide a valuation of these companies by concentrating on how long the superior growth can continue and, alternatively, the extent and length of the superior growth. This final model has some similarities to the three-stage cash flow models.

14.10 Measures of Value Added

In addition to the DDM, which feeds into the P/E ratio valuation technique and the supplementary P/BV, P/CF, and P/S ratios, there is also interest in a set of performance measures.
referred to as “value-added” measures. Notably, these value-added measures of performance are directly related to the capital budgeting techniques used in corporation finance. Specifically, they consider economic profit, which is analogous to the net present value (NPV) technique used in corporate capital budgeting. These value-added measures examine management performance based on the ability of managers to add value to the firm. They are also considered by some security analysts as possible indicators of future equity returns, based on the logic that superior management performance should be reflected in a company’s stock returns. In the subsequent discussion, we concentrate on three measures of value added: economic value added (EVA) and market value added (MVA), pioneered by Stern and Stewart, and discussed in Stewart (1991), and the franchise factor developed by Leibowitz and Kogelman (1994).

14.10.1 Economic Value Added (EVA)

As noted, EVA is closely related to the net present value (NPV) technique, wherein you evaluate the expected performance of an investment by discounting its future cash flows at the firm’s weighted average cost of capital (WACC) and compare this sum of discounted future cash flows to the cost of the project. If the discounted cash flows are greater than its cost, the project is expected to generate a positive NPV, which implies that it will add to the value of the firm and, therefore, should be undertaken. EVA extends this concept to evaluate the annual performance of management by comparing the firm’s net operating profit less adjusted taxes (NOPLAT) to the firm’s total cost of capital in dollar terms, including the cost of equity. In this analysis, if the firm’s NOPLAT during a specific year exceeds its dollar cost of capital, it has a positive EVA for the year and has added value for its stockholders. In contrast, if the EVA is negative, the firm has not earned enough during the year to cover its total cost of capital and the value of the firm has declined. Specifically, NOPLAT indicates what the firm has earned for all capital suppliers, and the dollar cost of capital is what all the capital suppliers required—including the firm’s equity holders. The following summarizes the major calculations.\(^\text{14}\)

\[
EVA = \frac{(A) \text{ Adjusted Operating Profits before Taxes}}{(B) \text{ Cash Operating Taxes}} - \frac{(C) \text{ Net Operating Profits Less Adjusted Taxes (NOPLAT)}}{(D) \text{ the Dollar Cost of Capital}}
\]

\[= \text{Economic Value Added (EVA)}\]

In turn, these items are calculated as follows:

<table>
<thead>
<tr>
<th>Operating Profit (after Depreciation and Amortization)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Add:</td>
</tr>
<tr>
<td>Implied Interest on Operating Leases</td>
</tr>
<tr>
<td>An Increase in the LIFO Reserve</td>
</tr>
<tr>
<td>Goodwill Amortization</td>
</tr>
<tr>
<td>Equals:</td>
</tr>
<tr>
<td>(A) Adjusted Operating Profits before Taxes</td>
</tr>
</tbody>
</table>

\(^{14}\)EVA is a registered trademark of Stern, Stewart, & Co.

\(^{15}\)For a detailed discussion, see Stewart (1991), or Peterson and Peterson (1996). For summary discussions, see Jones (1995).
### Income Tax Expense

Add:  
- Decrease in Deferred Taxes
- Tax Benefit from Interest Expenses
- Tax Benefit from Interest on Leases
- Taxes on Nonoperating Income

Equals:  
- (B) Cash Operating Taxes

\[(A) - (B) = (C) \text{ Net Operating Profits Less Adjusted Taxes (NOPLAT)}\]

### Capital

\[
\text{Capital} = \begin{align*}
\text{Net Working Capital (current assets less non-interest-bearing liabilities)} \\
\text{Add: LIFO Reserve} \\
\text{Add: Net Plant, Property, and Equipment} \\
\text{Add: Other Assets} \\
\text{Add: Goodwill} \\
\text{Add: Accumulated Goodwill Amortized} \\
\text{Add: Present Value of Operating Leases} \\
\text{Equals: Capital}
\end{align*}
\]

### Weighted Average Cost of Capital (WACC)

\[
\text{WACC} = \\
(\text{Book Value of Debt/Total Book Value}) \times (\text{Market Cost of Debt}) \\
(1 - \text{Tax Rate}) \\
(\text{Book Value of Equity/Total Book Value}) \times (\text{Cost of Equity}) \\
(\text{Cost of equity is based on the CAPM using the prevailing 10-year Treasury bond as the RFR, a calculated beta, and a market risk premium between 3 and 6 percent.})
\]

\[(D) \text{ Dollar Cost of Capital} = \text{Capital} \times \text{WACC}\]

\[(E) \text{ Economic Value Added (EVA)} = \]

\[(C) \text{ Net Operating Profits Less Adjusted Taxes (NOPLAT)} \]

Minus (D) Dollar Cost of Capital

### EVA Return on Capital

The preceding calculations provide a positive or negative dollar value, which indicates whether the firm earned an excess above its cost of capital during the year analyzed. There are two problems with this annual dollar value for EVA. First, how does one judge over time if the firm is prospering relative to its past performance? Although you would want the absolute EVA to grow over time, the question is whether the rate of growth of EVA is adequate for the additional capital provided. Second, how does one compare alternative firms of different sizes? Both of these concerns can be met by calculating an EVA return on capital equal to:

\[
\text{EVA Return on Capital} = \frac{\text{EVA}}{\text{Capital}}
\]

You would want this EVA rate of return on capital for a firm to remain constant over time, or, ideally, to grow. Using this ratio, you can compare firms of different sizes and determine which firm has the largest economic profit per dollar of capital.

---

16Recall that during the discussion earlier in this chapter when we calculated the WACC for Walgreens’ we made the point that using book value weights typically resulted in a lower WACC than using market value weights—for WAG, the difference was 6.90 percent using book values versus 7.65 percent for market weights. A lower WACC means a higher EVA.
An Alternative Measure of EVA
An alternative but equal way to measure and think about EVA is to compare directly the firm’s return on capital employed to the firm’s average cost of capital (i.e., its WACC). As noted previously, it is this difference in the actual rate of return earned compared to the firm’s required rate of return that identifies a company as a true growth company. Another way to measure EVA is to multiply this EVA spread (return on capital minus WACC) by the amount of capital employed. The appeal of this EVA spread approach is that it concentrates on the factors that create a growth company. Also, it helps the management and analysts recognize that true growth can be created by either (1) increasing the firm’s return on capital or (2) reducing its cost of capital.

14.10.2 Market Value Added (MVA)
In contrast to EVA, which generally is an evaluation of internal performance, MVA is a measure of external performance—how the market has evaluated the firm’s performance in terms of the market value of debt and market value of equity compared to the capital invested in the firm.

\[
\text{Market Value Added (MVA) = (Market Value of Firm) – Capital} \\
\quad \text{– Market Value of Debt} \\
\quad \text{– Market Value of Equity}
\]

Again, to properly analyze this performance, it is necessary to look for positive changes over time—that is, the percent change each year. Subsequently, you need to compare these annual changes in MVA with those for the aggregate stock and bond markets, because these market values can be impacted by interest rate changes and general economic conditions.

14.10.3 Relationships between EVA and MVA
Although EVA is used primarily for evaluating management performance, it also is being used by external analysts to evaluate management with the belief that superior internal performance should be reflected in a company’s stock performance. Several studies have attempted to determine the relationship between the two variables (EVA and MVA), and the results have not been encouraging. Although the stock of firms with positive EVAs has tended to outperform the stocks of negative EVA firms, the differences are typically insignificant and the relationship does not occur every year. This poor relationship may be due to the timing of the analysis (how fast EVA is reflected in stocks) or because the market values (MVAs) are affected by factors other than EVA—for example, MVA can be impacted by market interest rates and by changes in future expectations for a firm not considered by EVA. The point is, EVA does an outstanding job of evaluating management’s past performance in terms of adding value. While one would certainly hope that superior past performance will continue, there is nothing certain about this relationship.

14.10.4 The Franchise Factor
The franchise factor concept is similar to EVA since it recognizes that, to add value to a firm, it is necessary to invest in projects that provide excess NPV—that is, the firm must generate rates of return above its WACC. This technique is directly related to the valuation approach we have been using since the franchise value approach breaks a firm’s observed P/E ratio down into two components: (1) the P/E that is based on the company’s ongoing business (its base P/E), and (2) a franchise P/E that the market assigns to the expected value of new and profitable business opportunities. This can be visualized as:

\[
\text{Franchise P/E = Observed P/E – Base P/E}
\]
The base $P/E$ is the reciprocal of the market discount rate $k$ (it is $1/k$). For example, if the stock’s market discount rate is 8 percent, the base $P/E$ would be about 12.5 times.

What determines the franchise $P/E$? Not surprising, it is a function of the relative rate of return on new business opportunities compared to the firm’s cost of equity (the franchise factor) and the size of the superior return opportunities (the growth factor).

14.24 Incremental Franchise $P/E = \text{Franchise Factor} \times \text{Growth Factor} = \frac{R - k}{r_k} \times G$

where:

- $R$ = the expected return on the new opportunities
- $k$ = the current cost of equity
- $r$ = the current ROE on investment
- $G$ = the present value of the new growth projects relative to the current value of the firm

The critical factors determining the franchise $P/E$ are the difference between $R$ and $k$ and the size of these growth opportunities relative to the firm’s current size (i.e., $G$).

14.10.5 Growth Duration Model

The purpose of the growth duration model is to help you evaluate the high $P/E$ ratio for the stock of a growth company by relating its $P/E$ ratio to the firm’s rate of growth and duration of growth. As discussed previously, a stock’s $P/E$ ratio is a function of (1) the firm’s expected rate of growth of earnings per share, (2) the stock’s required rate of return, and (3) the firm’s dividend-payout ratio. Assuming equal risk and no significant difference in the payout ratio for different firms, the principal variable affecting differences in the earnings multiple for two firms is the difference in expected growth. As noted earlier, the growth estimate must consider both the rate of growth and how long this growth rate can be sustained—that is, the duration of the expected growth rate. Recall that, no company can grow indefinitely at a rate substantially above normal. For example, Apple cannot continue to grow at 20 percent a year for an extended period, or it will eventually become the entire economy. In fact, Apple or any similar growth firm will eventually run out of excess profit investment projects. Recall that continued growth at a constant rate requires that larger amounts of money be invested in high-return projects because the constant-growth model requires that you invest a constant percentage of current earnings. Eventually, competition will encroach on these high-return investments and the firm’s growth rate will decline to a rate consistent with the rate for the overall economy. Therefore, a reasonable and accurate estimate of the implied duration of a firm’s high-growth period becomes significant.

**Computation of Growth Duration** The growth duration concept was suggested by Holt (1962), who showed that if you assume equal risk between a given security and a market security, such as the S&P Industrials (i.e., a beta close to 1.0), you can concentrate on the differential expected growth rates for the market and for the growth firm as a factor causing the alternative $P/E$ ratios. Given these assumptions, you can compute the market’s *implied growth duration* for the growth firm.

If $E'(0)$ is the firm’s current earnings, then $E'(t)$ is earnings in Period $t$ according to the expression:

14.25 $E(t) = E(0)(1 + G)^t$

17For further detail and examples of the application, see Leibowitz and Kogelman (1994).
where \( G \) is the expected annual percentage growth rate for earnings. To adjust for dividend payments, it was assumed that all dividend payments are used to purchase further shares of the stock. This means the number of shares \( (N) \) will grow at the dividend yield rate \( (D) \). Therefore:

\[
14.26 \quad N(t) = N(0)(1 + D)^t
\]

To derive the total earnings for a firm, \( E(t) \), the growth rate in per-share earnings and the growth rate in shares are combined as follows:

\[
14.27 \quad E(t) = E'(t)N(t) = E'(0)[(1 + G)(1 + D)]^t
\]

Because \( G \) and \( D \) are small, this expression can be approximated by:

\[
14.28 \quad E(t) = E'(0)(1 + G + D)^t
\]

Assuming the growth stock \( (g) \) and the nongrowth stock \( (a) \) have similar risk and dividend payout, the market should value the two stocks in direct proportion to their earnings in year \( T \) (i.e., they will have the same \( P/E \) ratio), where \( T \) is the time when the growth company will begin to grow at the same rate as the market (i.e., the nongrowth stock). Put another way, \( T \) is the number of years the growth stock is expected to grow at the high rate. In other words, current prices should be in direct proportion to the expected future earnings ratio that will prevail in year \( T \). This relationship can be stated:

\[
14.29 \quad \left( \frac{P_g(0)}{P_a(0)} \right) = \left( \frac{E_g(0)(1 + G_g + D_g)^T}{E_a(0)(1 + G_a + D_a)^T} \right)
\]

or

\[
14.30 \quad \left( \frac{P_g(0)/E_g(0)}{P_a(0)/E_a(0)} \right) = \left( \frac{1 + G_g + D_g}{1 + G_a + D_a} \right)^T
\]

Equation 14.30 implies that the \( P/E \) ratios of the two stocks are in direct proportion to the ratio of composite growth rates raised to the \( T \)th power. You can solve for \( T \) by taking the log of both sides as follows:

\[
14.31 \quad \ln \left( \frac{P_g(0)/E_g(0)}{P_a(0)/E_a(0)} \right) = T \ln \left( \frac{1 + G_g + D_g}{1 + G_a + D_a} \right)
\]

The growth duration model answers the question: How long must the earnings of the growth stock grow at this expected high rate, relative to the nongrowth stock, to justify its prevailing above-average \( P/E \) ratio? You must then determine whether this implied growth duration estimate is reasonable in terms of the company’s potential.

Consider the following example. The stock of Walgreens is selling for \$43 \) a share with expected per-share earnings of \$2.38 \) (its future earnings multiple is about 18 times). The expected \( \text{EPS} \) growth rate for Walgreens is estimated to be about 10 percent a year, and its dividend yield has been 1 percent and is expected to remain at this level. In contrast,
Further, you believe that Walgreens can continue to grow at this above-normal rate for about 5 years. Using Equation 14.31, this becomes:

\[
\ln \left( \frac{X}{1.08} \right) = 5 \ln \left( \frac{1 + 0.10 + 0.01}{1 + 0.06 + 0.02} \right)
\]

\[
\ln(1.125) = T \ln(1.1118)
\]

\[
\ln(1.125) = T \ln(1.028)
\]

\[
T = \frac{\ln(1.125)}{\ln(1.028)} \times (\text{log base } 10)
\]

\[
= 0.0511482
\]

\[
= 0.01199311
\]

\[
= 4.26 \text{ years}
\]

To determine what the P/E ratio for Walgreens should be given these assumptions, you must derive the antilog of 0.059965, which is approximately 1.148. Therefore, assuming the market multiple is 16, the earnings multiple for Walgreens should be about 1.148 times the market P/E ratio, or about 18.4 times.

Alternatively, if you estimate that Walgreens can maintain a lower growth rate of 9 percent for a longer period (e.g., 10 years), you would derive the antilog for 0.07961 (10 × 0.007961). The answer is 1.203, which implies a P/E ratio of about 19.22 times for Walgreen Co.’s stock.

Notably, both of these estimates are above the current forward P/E for Walgreens of 18 times.

Factors to Consider

When using the growth duration technique, remember the following factors: First, the technique assumes equal risk, which may be acceptable when comparing two large, well-established firms in the same industry (e.g., Merck and Pfizer) to each other. It is also reasonable for a large conglomerate, like General Electric, with a beta close to 1.0. In the case of Walgreens, which has a beta of about 0.95, the result is conservative, meaning that the duration would be slightly lower for WAG than the estimated years. It is probably not a valid assumption when comparing a small growth company with a beta of 1.50 to the aggregate market. In this case, the growth duration generated would be an underestimate of what is required.

Second, which growth estimate should be used? We prefer to use the expected rate of growth based on the factors that affect g (i.e., the retention rate and the components of ROE). Third, the growth duration technique assumes that stocks with higher P/E ratios have the higher growth rates. However, there are cases in which the stock with the higher P/E ratio does not have a higher expected growth rate or the stock with a higher expected growth rate has a lower P/E ratio. Either of the cases generates a useless negative-growth duration value. Inconsistency between the expected growth and the P/E ratio could be attributed to one of four factors:

1. A major difference in the risk involved (the low P/E, high-growth company is much riskier).
2. Inaccurate growth rate estimates. You may want to reexamine your growth rate estimate for the firm with the higher P/E ratio; that is, could it be higher or should the growth estimate for the low P/E stock be lower?
3. The stock with a low P/E ratio relative to its expected growth rate is undervalued. (Before you accept this possibility, consider the first two factors.)
4. The stock with a high P/E and a low expected growth rate is overvalued. (Before this is accepted, consider both its risk and your estimated growth rate.)

The growth duration concept is valid, given the assumptions made, and can help you evaluate growth investments. It is not universally valid, though, because its answers are only as good as the data inputs (expected growth rates) and the applicability of the assumptions. The answer must be evaluated based on the analyst’s knowledge.

The technique probably is most useful for helping spot overvalued growth companies with very high multiples. In such a case, the technique will highlight that the company must continue to grow at some very high rate for an extended period of time to justify its high P/E ratio (e.g., duration of 15 to 20 years). Also, it can help you decide between two growth companies.

### Intraindustry Analysis

Besides comparing a company to a market series, you can directly compare two firms. For an intercompany analysis, you should compare firms in the same industry because the equal risk assumptions of this model are probably more reasonable.

Consider the following example from the computer software industry:

<table>
<thead>
<tr>
<th>Company A</th>
<th>Company B</th>
</tr>
</thead>
<tbody>
<tr>
<td>P/E ratios 31.00</td>
<td>25.00</td>
</tr>
<tr>
<td>Expected annual growth rate 0.1700</td>
<td>0.1200</td>
</tr>
<tr>
<td>Dividend yield 0.0100</td>
<td>0.0150</td>
</tr>
<tr>
<td>Growth rate plus dividend yield 0.1800</td>
<td>0.1350</td>
</tr>
</tbody>
</table>

| Estimate of T* | 5.53 years |

*Readers should check to see that they get the same answer.

These results imply that the market expects Company A to grow at an annual rate of 18 percent for about 5.5 years, after which it will grow at Company B's rate of 13.5 percent. If you believe the implied duration for growth at 18 percent is too long, you will prefer Company B; if you believe the estimated duration is reasonable or low, you will recommend Company A.

**An Alternative Use of T** Instead of solving for T and then deciding whether the figure derived is reasonable, you can use this formulation to compute a reasonable P/E ratio for a security relative to the aggregate market (or another stock) if the implicit assumptions are reasonable for the stock involved. Again, using Walgreens as an example, you estimate its expected composite growth to be 11 percent a year compared to the expected total market growth of 8 percent.
Further, you believe that Walgreens can continue to grow at this above-normal rate for about 5 years. Using Equation 14.31, this becomes:

\[
\ln(X) = 5 \times \ln \frac{1.11}{1.08} = 5 \times \ln(1.028) = 5 \times 0.011993 = 0.059965
\]

To determine what the P/E ratio for Walgreens should be given these assumptions, you must derive the antilog of 0.059965, which is approximately 1.148. Therefore, assuming the market multiple is 16, the earnings multiple for Walgreens should be about 1.148 times the market P/E ratio, or about 18.4 times.

Alternatively, if you estimate that Walgreens can maintain a lower growth rate of 9 percent for a longer period (e.g., 10 years), you would derive the antilog for 0.07961 (10 \times 0.007961). The answer is 1.203, which implies a P/E ratio of about 19.22 times for Walgreen Co.’s stock. Notably, both of these estimates are above the current forward P/E for Walgreens of 18 times.

**Factors to Consider** When using the growth duration technique, remember the following factors: First, the technique assumes equal risk, which may be acceptable when comparing two large, well-established firms in the same industry (e.g., Merck and Pfizer) to each other. It is also reasonable for a large conglomerate, like General Electric, with a beta close to 1.0. In the case of Walgreens, which has a beta of about 0.95, the result is conservative, meaning that the duration would be slightly lower for WAG than the estimated years. It is probably not a valid assumption when comparing a small growth company with a beta of 1.50 to the aggregate market. In this case, the growth duration generated would be an underestimate of what is required.

Second, which growth estimate should be used? We prefer to use the expected rate of growth based on the factors that affect g (i.e., the retention rate and the components of ROE).

Third, the growth duration technique assumes that stocks with higher P/E ratios have the higher growth rates. However, there are cases in which the stock with the higher P/E ratio does not have a higher expected growth rate or the stock with a higher expected growth rate has a lower P/E ratio. Either of the cases generates a useless negative-growth duration value. Inconsistency between the expected growth and the P/E ratio could be attributed to one of four factors:

1. A major difference in the risk involved (the low P/E high-growth company is much riskier).
2. Inaccurate growth rate estimates. You may want to reexamine your growth rate estimate for the firm with the higher P/E ratio; that is, could it be higher or should the growth estimate for the low P/E stock be lower?
3. The stock with a low P/E ratio relative to its expected growth rate is undervalued. (Before you accept this possibility, consider the first two factors.)
4. The stock with a high P/E and a low expected growth rate is overvalued. (Before this is accepted, consider both its risk and your estimated growth rate.)

The growth duration concept is valid, given the assumptions made, and can help you evaluate growth investments. It is not universally valid, though, because its answers are only as good as the data inputs (expected growth rates) and the applicability of the assumptions. The answer must be evaluated based on the analyst’s knowledge.

The technique probably is most useful for helping spot overvalued growth companies with very high multiples. In such a case, the technique will highlight that the company must continue to grow at some very high rate for an extended period of time to justify its high P/E ratio (e.g., duration of 15 to 20 years). Also, it can help you decide between two growth companies...
in the same industry by comparing each to the market, the industry, or directly to each other. Such a comparison has provided interesting insights wherein the new firms in an industry were growing faster than the large competitor, but their P/E ratios were substantially higher and implied that these new firms had to maintain this large growth rate superiority for over 10 years to justify the much higher P/E ratio.

14.11 Site Visits and the Art of the Interview

Brokerage house analysts and portfolio managers have access to persons that the typical small investor does not. Analysts frequently have contact with corporate personnel by telephone (conference calls), at formal presentations, or during plant site visits. Though insider trading laws restrict the analyst’s ability to obtain material nonpublic information, these visits facilitate dialog between the corporation and the investor community. The analyst can gather information about the firm’s plans and strategies, which helps the analyst understand the firm’s prospects as an investment.

Interviewing is an art. The analyst wants information about the firm, and top management wants to put the firm in the best light possible. Thus, the analyst must be prepared to focus the interview on management’s plans, strategies, and concerns. Analysts try to gauge the sensitivity of the firm’s revenues, costs, and earnings to different scenarios by asking “what if” questions.

Analysts have frequent telephone contact with the firm’s investor relations (IR) department regarding company pronouncements. The chief financial officer and chief executive officer of the firm also meet with security analysts and discuss the firm’s planning process and major issues confronting the industry.

The analyst should work to talk with people other than top managers. Talking with middle managers or factory workers during a plant tour, visiting stores of a retail firm, and talking with customers provide insights beyond those of management. The firm’s major customers can provide information regarding product quality and customer satisfaction. The firm’s suppliers can furnish information about rising or falling supply orders and the timeliness of payments. Finally, an outstanding source of information is the firm’s competitors, who will be happy to point out the firm’s weaknesses or possible problems. Alternatively, they may be willing to admit which firm is its toughest competitor (If you could eliminate one competitor, who would it be?).

The idea was always that analysts were able to create a mosaic regarding future expectations for the firm from numerous sources (including the company) and transmit this information to the market by sending research reports to brokerage clients and portfolio managers of pensions and mutual funds. This traditional way of doing research was changed by the SEC in 2000 when they issued the Fair Disclosure (FD) guidelines that required all disclosure of “material information” to be made public to all interested parties at the same time. The intent was to level the playing field by ensuring that professional analysts did not have a competitive advantage over nonprofessional investors. The result of this law is that many firms will not agree to interviews with analysts and will only provide information during large public presentations over the Internet.

The long-run impact of this FD requirement is not clear in terms of how firms will relate to the professional analyst community. One benefit is that analysts will spend more time with information sources beyond the firm, such as trade shows, customers, suppliers, and competitors, to build the mosaic.

14.12 When to Sell

Our analysis has focused on determining if a stock should be purchased. In fact, when we make a purchase, a subsequent question gains prominence: When should the stock be sold? Many times, holding on to a stock too long leads to a return below expectations or less than what was available earlier. When a stock’s price declines immediately following an analyst’s
valuation and recommendation, is this a further buying opportunity, or does the decline indicate new information or that the analysts missed some information or misinterpreted the impact of some event that would significantly decrease the valuation?

The answer to the question of when to sell a stock is contained in the research that convinced the analyst to purchase the stock in the first place. The analyst should have identified the key assumptions and variables driving the expectations for the stock. Analysis of the stock doesn’t end when intrinsic value is computed and the research report is written. Once the key value drivers are identified, the analyst must continually monitor and update his or her knowledge base about the firm. Notably, if the key value drivers experience weakness or there is a major change in management, it is time to reevaluate, and possibly sell, the stock. A good question to ask an analyst who is recommending a stock is: What events would cause you to change your recommendation?

The stock should also be closely evaluated when the current price approaches its intrinsic value estimate. When the stock becomes fairly priced (the undervaluation has been corrected), it may be time to sell it and reinvest the funds in other underpriced stocks. In short, if the “story” for buying the stock still appears to be true, continue to hold it if it has not become fully priced (i.e., market price equal to intrinsic value). If the “story” changes, it may be time to sell the stock. If you know why you bought the stock and constantly update your valuation to objectively reflect new information, you’ll be able to recognize when to sell it.

### 14.13 Influences on Analysts

Stock analysts and portfolio managers are, for the most part, highly trained individuals who possess expertise in financial analysis and background in their industry. A computer hardware analyst knows as much about industry trends and new product offerings as any industry insider. A pharmaceutical analyst is able to independently determine the market potential of drugs undergoing testing and the FDA approval process. So why don’t more brokerage house customers and portfolio managers who receive expert advice from highly trained analysts achieve investment success? The following subsections discuss several factors that make it difficult to “beat the market.”

#### 14.13.1 Efficient Markets

As noted in Chapter 6, the efficient market is difficult to outsmart, especially if you are considering actively traded and frequently analyzed companies. Information about the economy, a firm’s industry, and the firm itself is constantly being reviewed by numerous bright analysts, investors, and portfolio managers. Investors look for situations where stocks may not be fairly valued. Notably, because there are numerous bright, hardworking analysts, it is difficult to successfully, frequently, and consistently find undervalued shares. Put another way, in most instances the value estimated for a stock will be very close to its market price, which indicates that it is properly valued. The best place for an analyst to seek attractive stocks is not among well-known companies and actively traded stocks, because they are analyzed by dozens of Wall Street analysts. Stocks with smaller market capitalizations, those not covered by many analysts, or those whose shares are mainly held by individual investors may be the best places to search for inefficiencies. Smaller capitalization stocks sometimes are too small for time-constrained analysts or too small for purchase by institutional investors. The price of stocks not researched by many analysts (“neglected stocks”) may not reflect all relevant information.\(^\text{19}\)

\(^{18}\)According to SEC regulations, mutual funds cannot own more than 10 percent of a firm’s shares. For some large funds, this constraint will make the resulting investment too small to have any significant impact on fund returns, so analysts do not bother to consider such stocks for purchase.

\(^{19}\)Information on the number of analysts covering a stock is available from research firms, such as IBES and Zacks.
14.14.2 Differential Accounting Conventions

Even when the financial data for an industry and a firm are timely and reliable, it is necessary to recognize that the accounting rules and practices differ dramatically around the world. Not only are the financial statements very different in general presentation, but the accounting practices differ related to sales and expense recognition. The fact is, identical transactions in different countries can generate significant differences in income and cash flow. As a result, stocks in different countries will have very different P/E and P/CF ratios, not because investors differ in valuation but because the accounting numbers used are not the same. Because of these accounting problems, many investors advocate using the price-to-sales ratio in valuations across countries since sales revenue is the least contaminated accounting figure. The good news is the movement toward using global accounting standards. For an overview of this transition, see SEC Staff Paper (2011) and SEC Release (2010).

14.14.3 Currency Differences (Exchange Rate Risk)

A significant factor that must be considered by global investors is currency risk caused by changes in exchange rates among countries. While these rate changes can work for or against you, the point is that it creates a major uncertainty that must be considered when analyzing a company and valuing its stock.

14.14.4 Political (Country) Risk

In the United States, we have been blessed with a stable political and economic environment. Unfortunately, this stability was undermined by the political gridlock related to the debt ceiling debate during the summer of 2011 that eventually led to the downgrade of our Treasury bond rating in August 2011. Even with this "political problem" that we envision will be temporary, most observers recognize that most other countries have greater political/country risk than the U.S., and in some cases (e.g., Russia, Indonesia, Thailand, and Iran), it can be substantial. Therefore, you must acknowledge this different risk factor and estimate its effect on the cost of equity for firms in other countries.

14.14.5 Transaction Costs and Liquidity

Higher transaction costs result from less-liquid markets—where it takes longer to trade and there is more price volatility connected to a trade—or from a trade that costs more (e.g., higher commissions). Again, these costs vary dramatically among countries. The good news is the creation and consolidation of markets, as discussed in Chapter 4.

14.14.6 Valuation Differences

These individual country differences combine to cause a clear differential in the stock valuation for an international stock. Specifically, the earnings or cash flow numbers will differ and the required rate of return (the discount rate) for a non-U.S. stock will differ substantially because there are additional risks noted, such as exchange rate risk, political risk, and higher liquidity costs.

14.14.7 Summary

In summary, the good news when investing globally is that the valuation process is the same around the world, and the investment decision in terms of the ultimate comparison of intrinsic value and price is similar. The negative news is that the valuation of international securities requires attention to several additional factors that must be considered when valuing an international stock. Therefore, everything you have learned about analysis and valuation is relevant, but it must be applied differently (i.e., the inputs differ), depending on the country.

Chapter 14: Company Analysis and Stock Valuation

14.13.2 Paralysis of Analysis

Analysts spend most of their time in a relentless search for one more contact or one more piece of information that will ensure the correct stock recommendation. Analysts need to develop a systematic approach for gathering, monitoring, and reviewing relevant information about economic trends, industry competitive forces, and company strategy. Analysts must evaluate the information as a whole to discern patterns that indicate the intrinsic value of the stock rather than searching for one more piece of information.

Because markets are generally efficient, the consensus view about the firm is already reflected in its stock price. As noted previously, there are two requirements to earn above-average returns: (1) the analyst must have expectations that differ from the consensus, and (2) the analyst must be correct. Thus, the analyst should concentrate on (1) identifying what is wrong with the market consensus (i.e., why do you differ from the consensus?), or (2) what surprises may upset the market consensus—that is, work at estimating earning surprises.

14.13.3 Analyst Conflicts of Interest

A potential conflict can arise if communication occurs between a firm’s investment banking and equity research division. If the investment bankers assist a firm in a stock or bond offering, it will be difficult for an analyst to issue a negative evaluation of the company. Advisory fees have been lost because of a negative stock recommendation. Despite attempts to ensure the independence of stock analysts, firm politics may get in the way.

The analyst is in frequent contact with the top officers of the company he or she analyzes. Although there are guidelines about receiving gifts and favors, it is sometimes difficult to separate personal friendship and impersonal corporate relationships. Corporate officials may try to convince the analyst that his or her pessimistic report is in error or suggest that it glosses over recent positive developments. To mitigate these problems, an analyst should call the company’s investor relations department immediately after changing a recommendation to explain his or her perspective. The analyst needs to maintain independence and be objective in his or her analysis. Unfortunately, there have been instances where firms have ostracized analysts who have issued “negative” reports on firms (i.e., not returning calls, not being available for visits, or not calling on them during conference calls).

14.14 Global Company and Stock Analysis

As indicated on numerous occasions, a major goal of this text is to demonstrate investment techniques that can be applied globally to markets, industries, and companies around the world. This chapter has been heavily concerned with presenting and demonstrating these techniques to U.S. firms. While space constraints do not allow a full demonstration to international firms, it is important to point out some of the major factors and constraints that analysts and portfolio managers need to acknowledge and adjust for when investing globally.

14.14.1 Availability of Data

In the United States, we suffer from information (data) overload, which is a blessing and a curse since we have more information than anywhere else in the world (which is good), but as a result there is a lot of information to digest and analyze. When you start analyzing international markets, industries, and stocks and cannot get the necessary data for valuation, you come to appreciate what is available in the United States. Beyond the limited amount of information, there is also the problem of timeliness (how long before you get the data?) and the reliability (can you believe and depend upon the data published in some countries and by some global industries?).
14.14.2 Differential Accounting Conventions
Even when the financial data for an industry and a firm are timely and reliable, it is necessary to recognize that the accounting rules and practices differ dramatically around the world. Not only are the financial statements very different in general presentation, but the accounting practices differ related to sales and expense recognition. The fact is, identical transactions in different countries can generate significant differences in income and cash flow. As a result, stocks in different countries will have very different P/E and P/CF ratios, not because investors differ in valuation but because the accounting numbers used are not the same. Because of these accounting problems, many investors advocate using the price-to-sales ratio in valuations across countries since sales revenue is the least contaminated accounting figure. The good news is the movement toward using global accounting standards. For an overview of this transition, see SEC Staff Paper (2011) and SEC Release (2010).

14.14.3 Currency Differences (Exchange Rate Risk)
A significant factor that must be considered by global investors is currency risk caused by changes in exchange rates among countries. While these rate changes can work for or against you, the point is that it creates a major uncertainty that must be considered when analyzing a company and valuing its stock.

14.14.4 Political (Country) Risk
In the United States, we have been blessed with a stable political and economic environment. Unfortunately, this stability was undermined by the political gridlock related to the debt ceiling debate during the summer of 2011 that eventually led to the downgrade of our Treasury bond rating in August 2011. Even with this “political problem” that we envision will be temporary, most observers recognize that most other countries have greater political/country risk than the U.S., and in some cases (e.g., Russia, Indonesia, Thailand, and Iran), it can be substantial. Therefore, you must acknowledge this different risk factor and estimate its effect on the cost of equity for firms in other countries.

14.14.5 Transaction Costs and Liquidity
Higher transaction costs result from less-liquid markets—where it takes longer to trade and there is more price volatility connected to a trade—or from a trade that costs more (e.g., higher commissions). Again, these costs vary dramatically among countries. The good news is the creation and consolidation of markets, as discussed in Chapter 4.

14.14.6 Valuation Differences
These individual country differences combine to cause a clear differential in the stock valuation for an international stock. Specifically, the earnings or cash flow numbers will differ and the required rate of return (the discount rate) for a non-U.S. stock will differ substantially because there are additional risks noted, such as exchange rate risk, political risk, and higher liquidity costs.

14.14.7 Summary
In summary, the good news when investing globally is that the valuation process is the same around the world, and the investment decision in terms of the ultimate comparison of intrinsic value and price is similar. The negative news is that the valuation of international securities requires attention to several additional factors that must be considered when valuing an international stock. Therefore, everything you have learned about analysis and valuation is relevant, but it must be applied differently (i.e., the inputs differ), depending on the country.
SUMMARY

- This chapter demonstrates how to complete the fundamental analysis process by analyzing a company and deciding whether you should buy its stock. This requires a separate analysis of a company followed by the valuation of its stock. A wonderful company can have an overpriced stock, or a mediocre firm can have an underpriced stock.
- The chapter is mainly concerned with discussing and demonstrating alternative valuation techniques. The initial section contained a discussion of the strategic alternatives available to firms in response to different competitive pressures in their industries. The alternative corporate strategies include low-cost leadership or differentiation, which if properly implemented, should help the company attain above-average rates of return. In addition, we discussed applying SWOT analysis to a firm. This strategic analysis of the firm’s goals, objectives, and strategy should put you in a position to properly estimate the intrinsic value of the stock.
- When estimating a stock’s intrinsic value, we considered two approaches—the present value of cash flow and the analysis of relative valuation ratios. We reviewed how to estimate the major inputs to the techniques and demonstrated these techniques on Walgreens.
- We derived several estimated values for Walgreens using the two approaches and compared the relative valuation ratios for the company to comparable ratios for both the retail drugstore industry and the aggregate market.
- The investment decision compares a stock’s intrinsic value to its prevailing market price. If the stock’s intrinsic value exceeds the market price, we would buy the stock. If the intrinsic value is less than the market price, we would not buy the stock and would sell it if we owned it.
- Because of the difficulty in estimating the intrinsic value of growth firms, we considered alternative specifications for growth companies and several techniques that provide insights on valuing these firms. These techniques include economic value added, the franchise factor models, and a growth duration model. These models help the analyst concentrate attention on the relevant factors that determine true growth. The critical question is, is the stock of the growth company going to be a growth stock?
- We concluded with a discussion of several unique considerations when analyzing and valuing global industries and firms.

SUGGESTED READINGS

QUESTIONS

1. Give an example of a growth company, and discuss why you identify it as such. Based on its $P/E$, do you think it is a growth stock? Explain.
2. Give an example of a cyclical stock, and discuss why you have designated it as such. Is it issued by a cyclical company?
3. A biotechnology firm is growing at a compound rate of more than 21 percent a year. (Its $ROE$ is over 30 percent, and it retains about 70 percent of its earnings.) The stock
of this company is priced at about 65 times next year’s earnings. Discuss whether you consider this a growth company and/or a growth stock.

4. Select a company outside the retail drugstore industry and indicate what economic series you would use for a sales projection. Discuss why this is a relevant series.

5. Select a company outside the retail drugstore industry and indicate what industry series you would use in an industry analysis. (Use one of the industry groups designated by Standard & Poor’s.) Discuss why this industry series is appropriate. Were there other possible alternatives?

6. Select a company outside the retail drugstore industry and, based on reading its annual report and other public information, discuss what you perceive to be its competitive strategy (i.e., low-cost producer or differentiation).

7. Discuss a company that is known to be a low-cost producer in its industry and consider why it is a cost leader. Do the same for a firm known for differentiating.

8. Under what conditions would you use a two- or three-stage cash flow model rather than the constant-growth model?

9. What is the rationale for using the price/book value ratio as a measure of relative value?

10. What would you look for to justify a price/book value ratio of 3.0? What would you expect to be the characteristics of a firm with a P/BV ratio of 0.6?

11. Why has the price/cash flow ratio become a popular measure of relative value during the recent past? What factors would help explain a difference in this ratio for two firms?

12. Assume that you uncover two stocks with substantially different price/sales ratios (e.g., 0.5 versus 2.5). Discuss the factors that might explain the difference.

13. Specify the major components for the calculation of economic value added. Describe what a positive EVA signifies.

14. Discuss why you would want to use EVA return on capital rather than absolute EVA to compare two companies or to evaluate a firm’s performance over time.

15. Differentiate between EVA and MVA, and discuss the relatively weak relationship between these two measures of performance. Is this relationship surprising to you? Explain.

16. Discuss the two factors that determine the franchise value of a firm. Assuming a firm has a base cost of equity of 11 percent and does not have a franchise value, what will be its P/E?

17. You are told that a company retains 80 percent of its earnings and its earnings are growing at a rate of about 8 percent a year versus an average growth rate of 6 percent for all firms. Discuss whether you would consider this a growth company.

18. Discuss the reasoning behind the contention that in a completely competitive economy, there would never be a true growth company.

19. Why is it not feasible to use the dividend discount model in the valuation of true growth companies?

20. Discuss the major assumptions of the growth duration model. Why could these assumptions present a problem?

21. You are told that a growth company has a P/E ratio of 13 times and a growth rate of 15 percent compared to the aggregate market, which has a growth rate of 8 percent and a P/E ratio of 16 times. What does this comparison imply regarding the growth company? What else do you need to know to properly compare the growth company to the aggregate market?

22. Given the alternative companies described in the chapter (negative growth, simple growth, dynamic growth), indicate what your label would be for Walgreens. Justify your label.

23. Indicate and justify a growth label for General Motors.
24. Using book value to measure profitability and to value a company’s stock has limitations. Discuss five such limitations from an accounting perspective. Be specific.

25. On your visit to Alessandra Chemical Corp. (ACC), you learned that the board of directors has periodically debated the company’s dividend-payout policy.
   a. Briefly discuss two arguments for and two arguments against a high dividend payout policy.
      A director of ACC said that the use of dividend discount models by investors is “proof that ‘the higher the dividend, the higher the stock price.’”
   b. Using a constant-growth dividend discount model as a basis of reference, evaluate the director’s statement.
   c. Explain how an increase in dividend payout would affect each of the following (holding all other factors constant):
      (1) Internal (implied, normalized, or sustainable) growth rate
      (2) Growth in book value

26. Sophie Corporation (SC) is planning to acquire a slower-growth competitor, which will materially increase SC’s sales volume. The company to be acquired has pretax margins that are approximately the same as those of SC. SC plans to issue $300 million in long-term debt to finance the entire cost of the acquisition.
   a. Discuss how SC’s potential acquisition might decrease its valuation based on a constant-growth dividend discount model. Be sure to comment on each of the three factors in such a model.
   b. Discuss two reasons why SC’s potential acquisition might increase the P/E multiple investors are willing to pay for SC.

27. A generalized model for the value of any asset is the present value of the expected cash flows:

\[ \text{Value} = \sum_{t=1}^{N} \frac{CF_t}{(1 + k)^t} \]

where:

- \( N \) = life of the asset
- \( CF_t \) = cash flow in Period \( t \)
- \( k \) = appropriate discount rate

Both stock and bond valuation models use a discounted cash flow approach, which includes the estimation of three factors \((N, CF_t, k)\).

Explain why each of these three factors is generally more difficult to estimate for common stocks than for traditional corporate bonds.

**PROBLEMS**

1. Select two stocks in an industry of your choice, and perform a common-size income statement analysis over a two-year period.
   a. Discuss which firm is more cost effective.
   b. Discuss the relative year-to-year changes in gross profit margin, operating profit margin, and net profit margin for each company.

2. Select a company outside the retail drugstore industry, and examine its operating profit margin relative to the operating margin for its industry during the most recent 10-year period. Discuss the annual results in terms of levels and percentage changes.

3. Given Cara’s beta of 1.75 and a risk-free rate of 7 percent, what is the expected rate of return for Cara assuming:
   a. a 15 percent market return?
   b. a 10 percent market return?
4. Select three companies from any industry except retail drugstores.
   a. Compute their forward P/E ratios using last year’s average price [(high plus low)/2] and estimated earnings.
   b. Compute their growth rate of earnings over the last five years.
   c. Look up the most recent beta reported in Value Line.
   d. Discuss the relationships among P/E, growth, and risk.

5. What is the implied growth duration of Kayleigh Industries, given the following:

<table>
<thead>
<tr>
<th>Present Value of $1</th>
<th>6%</th>
<th>8%</th>
<th>10%</th>
<th>12%</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>0.943</td>
<td>0.926</td>
<td>0.909</td>
<td>0.893</td>
</tr>
<tr>
<td>2</td>
<td>0.890</td>
<td>0.857</td>
<td>0.826</td>
<td>0.797</td>
</tr>
<tr>
<td>3</td>
<td>0.840</td>
<td>0.794</td>
<td>0.751</td>
<td>0.712</td>
</tr>
<tr>
<td>4</td>
<td>0.792</td>
<td>0.735</td>
<td>0.683</td>
<td>0.636</td>
</tr>
<tr>
<td>5</td>
<td>0.747</td>
<td>0.681</td>
<td>0.621</td>
<td>0.567</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>S&amp;P Industrials</th>
<th>Kayleigh Industries</th>
</tr>
</thead>
<tbody>
<tr>
<td>P/E ratios</td>
<td>16.00</td>
</tr>
<tr>
<td>Expected growth</td>
<td>0.06</td>
</tr>
<tr>
<td>Dividend yield</td>
<td>0.04</td>
</tr>
</tbody>
</table>

6. Lauren Entertainment, Inc., has an 18 percent annual growth rate compared to the market rate of 8 percent. If the market multiple is 18, determine P/E ratios for Lauren Entertainment, Inc., assuming its beta is 1.0 and you feel it can maintain its superior growth rate for:
   a. the next 10 years.
   b. the next 5 years.

7. You are given the following information about two computer software firms and the S&P Industrials:

<table>
<thead>
<tr>
<th>Company</th>
<th>Company B</th>
<th>S&amp;P Industrials</th>
</tr>
</thead>
<tbody>
<tr>
<td>P/E ratio</td>
<td>30.00</td>
<td>27.00</td>
</tr>
<tr>
<td>Expected annual growth rate</td>
<td>0.18</td>
<td>0.15</td>
</tr>
<tr>
<td>Dividend yield</td>
<td>0.00</td>
<td>0.01</td>
</tr>
</tbody>
</table>

   a. Compute the growth duration of each company stock relative to the S&P Industrials.
   b. Compute the growth duration of Company A relative to Company B.
   c. Given these growth durations, what determines your investment decision?

8. The value of an asset is the present value of the expected returns from the asset during the holding period. An investment will provide a stream of returns during this period, and it is necessary to discount this stream of returns at an appropriate rate to determine the asset’s present value. A dividend valuation model such as the following is frequently used:

   \[ P_t = \frac{D_t}{(k_t - g_t)} \]

   where:
   \[ P_t \] = the current price of Common Stock \( i \)
   \[ D_t \] = the expected dividend in Period \( t \)
   \[ k_t \] = the required rate of return on Stock \( i \)
   \[ g_t \] = the expected constant-growth rate of dividends for Stock \( i \)

   a. Identify the three factors that must be estimated for any valuation model, and explain why these estimates are more difficult to derive for common stocks than for bonds.
   b. Explain the principal problem involved in using a dividend valuation model to value:
      (1) companies whose operations are closely correlated with economic cycles.
      (2) companies that are of very large and mature.
      (3) companies that are quite small and are growing rapidly.

   Assume that all companies pay dividends.
9. Your client is considering the purchase of $100,000 in common stock, which pays no dividends and will appreciate in market value by 10 percent per year. At the same time, the client is considering an opportunity to invest $100,000 in a lease obligation that will provide the annual year-end cash flows listed in Exhibit 14.23 below. Assume that each investment will be sold at the end of three years and that you are given no additional information.

Calculate the present value of each of the two investments assuming a 10 percent discount rate, and state which one will provide the higher return over the three-year period. Use the data in Exhibit 14.23, and show your calculations.

10. The constant-growth dividend discount model can be used both for the valuation of companies and for the estimation of the long-term total return of a stock.

Assume: $20 = Price of a Stock Today
8% = Expected Growth Rate of Dividends
$0.60 = Annual Dividend One Year Forward

a. Using only the preceding data, compute the expected long-term total return on the stock using the constant-growth dividend discount model.
b. Briefly discuss three disadvantages of the constant-growth dividend discount model in its application to investment analysis.
c. Identify three alternative methods to the dividend discount model for the valuation of companies.

11. An analyst expects a risk-free return of 4.5 percent, a market return of 14.5 percent, and the returns for Stocks A and B that are shown in Exhibit 14.24.

a. Show on a graph:

(1) where Stocks A and B would plot on the security market line (SML) if they were fairly valued using the capital asset pricing model (CAPM).

(2) where Stocks A and B actually plot on the same graph according to the returns estimated by the analyst and shown in Exhibit 14.24.

b. State whether Stocks A and B are undervalued or overvalued if the analyst uses the SML for strategic investment decisions.

12. Lauren Turk is reviewing Francesca Toy’s financial statements in order to estimate its sustainable growth rate. Using the information presented in Exhibit 14.25:

a. (1) identify and calculate the three components of the DuPont formula.

(2) calculate the ROE for 2011, using the three components of the DuPont formula.

(3) calculate the sustainable-growth rate for 2011.

b. Turk has calculated actual and sustainable growth for each of the past four years and finds in each year that its calculated sustainable-growth rate substantially exceeds its actual growth rate. Cite two courses of action (other than ignoring the problem) that Turk should encourage Francesca Toy to take, assuming the calculated sustainable-growth rate continues to exceed the actual growth rate.

| Exhibit 14.25 Francesca Toy, Inc.: Actual 2010 and Estimated 2011 Financial Statements for Fiscal Year Ending December 31 ($ Millions, except Per-Share Data) |
|-------------------------------------------------|-------|-------|
| **Income Statement**                            | 2010  | 2011  |
| Revenue                                         | $4,750| $5,140|
| Cost of goods sold                              | $2,400| $2,540|
| Selling, general, and administrative            | 1,400 | 1,550 |
| Depreciation                                    | 180   | 210   |
| Goodwill amortization                           | 10    | 10    |
| Operating income                                | $ 760 | $ 830 |
| Interest expense                                | 20    | 25    |
| Income before taxes                             | $ 740 | $ 805 |
| Income taxes                                    | 265   | 295   |
| Net income                                      | $ 475 | $ 510 |
| Earnings per share                              | $ 1.79| $ 1.96|
| Average shares outstanding (millions)           | 265   | 260   |
| **Balance Sheet**                               |       |       |
| Cash                                           | $ 400 | $ 400 |
| Accounts receivable                             | $ 680 | $ 700 |
| Inventories                                     | $ 570 | $ 600 |
| Net property, plant, and equipment              | $ 800 | $ 870 |
| Intangibles                                     | $ 500 | $ 530 |
| Total assets                                    | $2,950| $3,100|
| Current liabilities                             | $ 550 | $ 600 |
| Long-term debt                                  | $ 300 | $ 300 |
| Total liabilities                               | $ 850 | $ 900 |
| Stockholders’ equity                            | $2,100| $2,200|
| Total liabilities and equity                    | $2,950| $3,100|
| Book value per share                            | $ 7.92 | $ 8.46|
| Annual dividend per share                       | $ 0.55 | $ 0.60|
13. Cara Partners has a client who has inquired about the valuation method best suited for comparison of companies in an industry that has the following characteristics:

- Principal competitors within the industry are located in the United States, France, Japan, and Brazil.
- The industry is currently operating at a cyclical low, with many firms reporting losses.
- The industry is subjected to rapid technological change.

Jones recommends that the client consider the following valuation ratios:

1. Price to earnings
2. Price to book value
3. Price to sales

a. Determine which one of the three valuation ratios is most appropriate for comparing companies in this industry. Support your answer with two reasons that make that ratio superior to either of the other two ratios.

The client also has expressed interest in economic value added (EVA) as a measure of company performance. Clarence Jones asks his assistant to prepare a presentation about EVA for the client. The assistant’s presentation includes the following statements:

1. EVA is a measure of a firm’s excess shareholder value generated over a long period of time.
2. In calculating EVA, the cost of capital is the weighted average of the after-tax yield on long-term bonds with similar risk and the cost of equity as calculated by the capital asset pricing model.
3. EVA provides a consistent measure of performance across firms.

b. Determine whether each of the statements is correct or incorrect and, if incorrect, explain why.

Explanations cannot repeat the statement in negative form but must indicate what is needed to make the statement correct.

**Note: Answer Question 13b using the following template.**

<table>
<thead>
<tr>
<th>Statement</th>
<th>Determine Whether Correct or Incorrect (circle one)</th>
<th>If Incorrect, Explain Why</th>

**THOMSON REUTERS**

Use the Thomson One—Business School Edition Online Database to answer the following questions.

1. Identify two firms in an industry: one that seems to follow a “cost leadership” strategy and one that tries to be a “differentiator.” How do their common-size financial statements differ? Examine their trends in ROE using DuPont analysis. Comment on the differences and/or similarities you find.

2. Update the analysis of Walgreens in this chapter by computing the following:
   a. average compound dividend growth rate from 1993 until the most recent year
   b. sustainable-growth rate
   c. expected returns, based on Thomson One—Business School Edition’s beta estimate and estimates you obtain of the current risk-free rate (the 10-year Treasury bond yield) and a market risk premium of 3 percent, 5 percent, and 7 percent
   d. the present value of dividends, using the growth assumptions in the chapter; compare your estimated value to the current market price of WAG and indicate if you would buy the stock.

3. Estimate Walgreen Co.’s free cash flow to equity and its operating free cash flow for the most recent year.

4. Using peer analysis, compare Walgreen Co.’s relative valuation ratios with those of its peers (click on the “peers” tab, then click on “overviews” and “valuation comparison”).

5. Compute the current growth duration for WAG using the growth rate determined in Question 2b and assuming a dividend yield of 1 percent. For the market, assume a P/E of 18 times, growth of 6 percent, and a dividend yield of 2 percent.
CHAPTER 15

Technical Analysis*

After you read this chapter, you should be able to answer the following questions:

1. How does technical analysis differ from fundamental analysis?
2. What are the underlying assumptions of technical analysis?
3. What assumptions differ between technical analysis and the efficient market hypothesis?
4. What are the major advantages of technical analysis?
5. What are the major challenges to technical analysis?
6. What is the logic for the major contrary-opinion rules used by technicians?
7. What rules are used by technicians who want to "follow the smart money"?
8. What is the breadth of market measures, and what are they intended to indicate?
9. What are the three price movements postulated in the Dow Theory, and how are they used?
10. Why is trading volume important, and how do technicians use it?
11. What are support and resistance levels, and how are they used?
12. How do technicians use moving-average lines to detect changes in trends?
13. What is the rationale behind a relative-strength line?
14. How are bar charts different from point-and-figure charts?
15. What are some uses of technical analysis in foreign security markets?
16. How is technical analysis used when analyzing bonds?

The market reacted yesterday to the report of a large increase in the short interest on the NYSE. Although the market declined today, it was not considered bearish because of the light volume. The market declined today after three days of increases due to profit taking by investors. These and similar statements appear daily in the financial news. All of them have as their rationale one of numerous technical trading rules.

Technical analysts, technicians or market analysts develop technical trading rules from observations of past price movements of the stock market and individual stocks. The philosophy behind technical analysis is in sharp contrast to the efficient market hypothesis that we studied, which contends that past performance has no influence on future performance or market values. It also differs from what we learned about fundamental analysis, which involves making investment decisions based on the examination of the economy, an industry, and company variables that lead to an estimate of intrinsic value for an investment, which is then compared to its prevailing market price. In contrast to the efficient market hypothesis or fundamental analysis, technical analysis, according to the Market Technicians Association, is a method of evaluating securities by analyzing statistics*

*The following individuals from B of A Merrill Lynch Global Research have provided helpful comments and material for this chapter over several editions: Richard T. McCabe, Walter G. Murphy, and Mary Ann Bartels.
CHAPTER 15
Technical Analysis*

After you read this chapter, you should be able to answer the following questions:

- How does technical analysis differ from fundamental analysis?
- What are the underlying assumptions of technical analysis?
- What assumptions differ between technical analysis and the efficient market hypothesis?
- What are the major advantages of technical analysis?
- What are the major challenges to technical analysis?
- What is the logic for the major contrary-opinion rules used by technicians?
- What rules are used by technicians who want to “follow the smart money”?
- What is the breadth of market measures, and what are they intended to indicate?
- What are the three price movements postulated in the Dow Theory, and how are they used?
- Why is trading volume important, and how do technicians use it?
- What are support and resistance levels, and how are they used?
- How do technicians use moving-average lines to detect changes in trends?
- What is the rationale behind a relative-strength line?
- How are bar charts different from point-and-figure charts?
- What are some uses of technical analysis in foreign security markets?
- How is technical analysis used when analyzing bonds?

The market reacted yesterday to the report of a large increase in the short interest on the NYSE.
Although the market declined today, it was not considered bearish because of the light volume.
The market declined today after three days of increases due to profit taking by investors.

These and similar statements appear daily in the financial news. All of them have as their rationale one of numerous technical trading rules. Technical analysts, technicians or market analysts develop technical trading rules from observations of past price movements of the stock market and individual stocks. The philosophy behind technical analysis is in sharp contrast to the efficient market hypothesis that we studied, which contends that past performance has no influence on future performance or market values. It also differs from what we learned about fundamental analysis, which involves making investment decisions based on the examination of the economy, an industry, and company variables that lead to an estimate of intrinsic value for an investment, which is then compared to its prevailing market price. In contrast to the efficient market hypothesis or fundamental analysis, technical analysis, according to the Market Technicians Association, is a method of evaluating securities by analyzing statistics

*The following individuals from B of A Merrill Lynch Global Research have provided helpful comments and material for this chapter over several editions: Richard T. McCabe, Walter G. Murphy, and Mary Ann Bartels.
generated by market activity. Whereas fundamental analysts use economic data that are usually separate from the stock or bond market, technical analysts use data \textit{from the market itself}, such as prices and the volume of trading, because they contend that \textit{the market is its own best predictor}. Therefore, technical analysis is an alternative method of making the investment decision and answering the questions What securities should an investor buy or sell? When should these investments be made?

Technical analysts see no need to study the multitude of economic, industry, and company variables to arrive at an estimate of future value because they believe that past price and volume movements or some other market series will signal future price movements. Technicians also believe that a change in the price trend may predict a forthcoming change in some fundamental variables such as earnings and risk before the change is perceived by most fundamental analysts. Are technicians correct? Many investors using these techniques claim to have experienced superior rates of return on many investments. In addition, many newsletter writers base their recommendations on technical analysis. Finally, even the major investment firms that employ many fundamental analysts also employ technical (market) analysts to provide investment advice. Numerous investment professionals and individual investors believe in and use technical trading rules to make their investment decisions. Therefore, whether a fan of fundamental analysis or an advocate of the efficient market hypothesis, investors should still have an understanding of the basic philosophy and reasoning behind technical approaches. Thus, we begin this chapter with an examination of the basic philosophy underlying technical analysis. Subsequently, we consider the advantages and potential problems with the technical approach. Finally, we present alternative technical trading rules applicable to both the U.S. and foreign securities markets.

\section*{15.1 Underlying Assumptions of Technical Analysis}

Technical analysts base trading decisions on examinations of prior price and volume data to determine past market trends from which they predict future behavior for the market as a whole and for individual securities. Several assumptions summarized in Levy (1966) lead to this view of price movements. Certain aspects of these assumptions are controversial, leading fundamental analysts and advocates of efficient markets to question their validity. We have italicized those aspects in our list.

\begin{enumerate}
  \item The market value of any good or service is determined solely by the interaction of supply and demand.
  \item Supply and demand are governed by numerous rational and irrational factors. Included in these factors are those economic variables relied on by the fundamental analyst as well as opinions, moods, and guesses. The market weighs all these factors continually and automatically.
  \item Disregarding minor fluctuations, the \textit{prices for individual securities and the overall value of the market tend to move in trends, which persist for appreciable lengths of time}.
  \item Prevailing trends change in reaction to shifts in supply and demand relationships. These shifts, no matter why they occur, \textit{can be detected sooner or later in the action of the market itself}.
\end{enumerate}

The first two assumptions are almost universally accepted by technicians and nontechnicians alike. Almost anyone who has had a basic course in economics would agree that, at any point in time, the price of a security (or any good or service) is determined by the interaction of supply and demand. In addition, most observers would acknowledge that supply and demand are governed by many variables. The only difference in opinion might concern the influence of the irrational factors. Certainly, everyone would agree that the market continually weighs all these factors.
the past performance of a firm or industry. As we know from Chapters 13 and 14, the fundamental analyst evaluates such statements to help project future return and risk characteristics for industries and individual securities. The technician contends that there are several major problems with accounting statements:

1. They lack a great deal of information needed by security analysts, such as information related to sales, earnings, and capital utilized by product line and customers.

2. According to GAAP (Generally Accepted Accounting Principles), corporations may choose among several procedures for reporting expenses, assets, or liabilities. Notably, these alternative procedures can produce vastly different values for expenses, income, return on assets, and return on equity, depending on whether the firm is conservative or aggressive. As a result, an investor can have trouble comparing the statements of two firms within the same industry, much less firms across industries.

3. Many psychological factors and other nonquantifiable variables do not appear in financial statements. Examples include employee training and loyalty, customer goodwill, and general investor attitude toward an industry. Investor attitudes could be important when investors become concerned about the risk from restrictions or taxes on products such as tobacco or alcohol or when firms do business in countries that have significant political risk.

Therefore, because technicians are suspicious of financial statements, they consider it advantageous not to depend on them. As we will show, most of the data used by technicians, such as security prices, volume of trading, and other trading information, are derived from the stock market itself.

Also, a fundamental analyst must process new information correctly and quickly to derive a new intrinsic value for the stock or bond before other investors. Technicians, on the other hand, only need to quickly recognize a movement to a new equilibrium value for whatever reason—that is, they do not need to know about a specific event and determine the effect of the event on the value of the firm and its stock.

Finally, assume a fundamental analyst determines that a given security is under- or overvalued a long time before other investors. He or she still must determine when to make the purchase or sale. Ideally, the highest rate of return would come from making the transaction just before the change in market value occurs. For example, assume that based on your analysis in February, you expect a firm to report substantially higher earnings in June. Although you could buy the stock in February, you would be better off waiting until about May to buy the stock so that your funds would not be tied up for an extra three months, but you may be reticent to wait that long. Because most technicians do not invest until the move to the new equilibrium is underway, they contend that they are more likely than a fundamental analyst to experience ideal timing.

### 15.3 Challenges to Technical Analysis

Those who doubt the value of technical analysis for investment decisions question the usefulness of this technique in two areas. First, they challenge some of its basic assumptions. Second, they challenge some specific technical trading rules and their long-run usefulness. In this section, we consider these challenges.

#### 15.3.1 Challenges to the Assumptions of Technical Analysis

The major challenge to technical analysis is based on the results of empirical tests of the efficient market hypothesis (EMH). As discussed in Chapter 6, for technical trading rules to generate superior risk-adjusted returns after taking account of transaction costs, the market would have to be slow to adjust prices to the arrival of new information; that is, it would have to be a period of time. This pattern of information access occurs because of different sources of information or because certain investors receive the information or perceive fundamental changes earlier than others. As various groups—ranging from insiders to well-informed professionals to the average investor—receive the information and buy or sell a security accordingly, its price moves gradually toward the new equilibrium. Therefore, technicians do not expect the price adjustment to be as abrupt as fundamental analysts and efficient market supporters do; rather, they expect a gradual price adjustment to reflect the gradual dissemination of information.

Exhibit 15.1 shows this process wherein new information causes a decrease in the equilibrium price for a security but the price adjustment is not rapid. It occurs as a trend that persists until the stock reaches its new equilibrium. Technical analysts look for the beginning of a movement from one equilibrium value to a new equilibrium value but do not attempt to predict the new equilibrium value. They attempt to create techniques that will identify the start of a change so that they can get on the bandwagon early and benefit from the move to the new equilibrium price by buying if the trend is up or selling if the trend is down. Obviously, if there is a rapid adjustment of prices to the new information (as expected by those who espouse an efficient market), the ride on the bandwagon would be so short that investors could not benefit.

### 15.2 Advantages of Technical Analysis

Although technicians understand the logic of fundamental analysis, they see several benefits in their approach. Most technical analysts admit that a fundamental analyst with good information, good analytical ability, and a keen sense of information’s impact on the market should achieve above-average returns. However, this statement requires qualification. According to technical analysts, it is important to recognize that the fundamental analysts can experience superior returns only if they obtain new information before other investors and process it correctly and quickly. Technical analysts do not believe the majority of investors can consistently get new information before other investors and consistently process it correctly and quickly. Further, technicians attempt to take the emotion out of investing by applying rules that usually apply to almost every investment.

In addition, technical analysts claim that a major advantage of their method is that it is not heavily dependent on financial accounting statements—the major source of information about
the past performance of a firm or industry. As we know from Chapters 13 and 14, the fundamental analyst evaluates such statements to help project future return and risk characteristics for industries and individual securities. The technician contends that there are several major problems with accounting statements:

1. They lack a great deal of information needed by security analysts, such as information related to sales, earnings, and capital utilized by product line and customers.

2. According to GAAP (Generally Accepted Accounting Principles), corporations may choose among several procedures for reporting expenses, assets, or liabilities. Notably, these alternative procedures can produce vastly different values for expenses, income, return on assets, and return on equity, depending on whether the firm is conservative or aggressive. As a result, an investor can have trouble comparing the statements of two firms within the same industry, much less firms across industries.

3. Many psychological factors and other nonquantifiable variables do not appear in financial statements. Examples include employee training and loyalty, customer goodwill, and general investor attitude toward an industry. Investor attitudes could be important when investors become concerned about the risk from restrictions or taxes on products such as tobacco or alcohol or when firms do business in countries that have significant political risk.

Therefore, because technicians are suspicious of financial statements, they consider it advantageous not to depend on them. As we will show, most of the data used by technicians, such as security prices, volume of trading, and other trading information, are derived from the stock market itself.

Also, a fundamental analyst must process new information correctly and quickly to derive a new intrinsic value for the stock or bond before other investors. Technicians, on the other hand, only need to quickly recognize a movement to a new equilibrium value for whatever reason—that is, they do not need to know about a specific event and determine the effect of the event on the value of the firm and its stock.

Finally, assume a fundamental analyst determines that a given security is under- or overvalued a long time before other investors. He or she still must determine when to make the purchase or sale. Ideally, the highest rate of return would come from making the transaction just before the change in market value occurs. For example, assume that based on your analysis in February, you expect a firm to report substantially higher earnings in June. Although you could buy the stock in February, you would be better off waiting until about May to buy the stock so that your funds would not be tied up for an extra three months, but you may be reticent to wait that long. Because most technicians do not invest until the move to the new equilibrium is underway, they contend that they are more likely than a fundamental analyst to experience ideal timing.

### 15.3 Challenges to Technical Analysis

Those who doubt the value of technical analysis for investment decisions question the usefulness of this technique in two areas. First, they challenge some of its basic assumptions. Second, they challenge some specific technical trading rules and their long-run usefulness. In this section, we consider these challenges.

#### 15.3.1 Challenges to the Assumptions of Technical Analysis

The major challenge to technical analysis is based on the results of empirical tests of the efficient market hypothesis (EMH). As discussed in Chapter 6, for technical trading rules to generate superior risk-adjusted returns after taking account of transaction costs, the market would have to be slow to adjust prices to the arrival of new information; that is, it would have to be
inefficient. This is referred to as the weak-form efficient market hypothesis (EMH). The two sets of tests of the weak-form EMH are (1) the statistical analysis of prices to determine if prices moved in trends or were a random walk, and (2) the analysis of specific trading rules to determine if their use could beat a buy-and-hold policy after considering transactions costs and risk. Almost all the studies testing the weak-form EMH using statistical analysis have found that prices do not move in trends based on statistical tests of autocorrelation and runs. These results support the EMH.

Regarding the analysis of specific trading rules, as discussed in Chapter 6, numerous technical trading rules exist that have not been or cannot be tested. Still, the vast majority of the results for the trading rules that have been tested support the EMH.

### 15.3.2 Challenges to Technical Trading Rules

An obvious challenge to technical analysis is that the past price patterns or relationships between specific market variables and stock prices may not be repeated. As a result, a technique that previously worked might miss subsequent market turns. This possibility leads most technicians to follow several trading rules and to seek a consensus of all of them to predict the future market pattern.

Other critics contend that many price patterns become self-fulfilling prophecies. For example, assume that many analysts expect a stock selling at $40 a share to go to $50 or more if it should rise above its current pattern and break through its channel at $45. As soon as it reaches $45, enough technicians will buy to cause the price to rise to $50, exactly as predicted. In fact, some technicians may place a limit order to buy the stock at such a breakout point. Under such conditions, the increase will probably be only temporary and the price will return to its true equilibrium.

Another problem with technical analysis is that the success of a particular trading rule will encourage many investors to adopt it. It is contended that this popularity and the resulting competition will eventually neutralize the technique. If numerous investors focus on a specific technical trading rule, some of them will attempt to anticipate the price pattern and either ruin the expected historical price pattern or eliminate profits for most traders by causing the price to change faster than expected. For example, suppose it becomes known that technicians who employ short-selling data have been enjoying high rates of return. Based on this knowledge, other technicians will likely start using these data and thus accelerate the stock price pattern following changes in short selling. As a result, this profitable trading rule may no longer be profitable after the first few investors react.

Further, as we will see when we examine specific trading rules, most of them require a great deal of subjective judgment. Two technical analysts looking at the same price pattern may arrive at widely different interpretations of what has happened and, therefore, will come to different investment decisions. This implies that the use of various techniques is neither completely mechanical nor obvious. Finally, as we will discuss in connection with several trading rules, the standard values that signal investment decisions can change over time. Therefore, in some instances technical analysts adjust the specified values that trigger investment decisions to conform to the new environment. In other cases, trading rules have been abandoned because they no longer work.

### 15.4 Technical Trading Rules and Indicators

To illustrate the specific technical trading rules, Exhibit 15.2 shows a typical stock price cycle that could be an example for the overall stock market or for an individual stock. The graph shows a peak and trough, along with a rising trend channel, a flat trend channel, a declining trend channel, and indications of when a technical analyst would ideally want to trade.
Mutual Fund Cash Positions

Mutual funds hold some part of their portfolio in cash for one of several reasons. One is that they need cash to liquidate shares submitted by fundholders. Another is that new investments in the mutual fund may not have been invested. Third, the portfolio manager might be bearish on the market and want to increase the fund’s defensive cash position.

Mutual fund ratios of cash as a percentage of the total assets in their portfolios (the cash ratio, or liquid asset ratio) are reported in the press, including monthly figures in Barron’s. This percentage of cash has varied in recent years from a low point of about 4 percent to a high point near 11 percent, although there appears to be a declining trend to the series.

Contrary-opinion technicians believe that mutual funds usually are wrong at peaks and troughs. Thus, they expect mutual funds to have a high percentage of cash near a market trough—the time when they should be fully invested to take advantage of the impending market rise. At the market peak, these technicians expect mutual funds to be almost fully invested with a low percentage of cash when they should be selling stocks and realizing gains. Therefore, contrary-opinion technicians watch for the mutual fund cash position to approach one of the extremes and act contrary to the mutual funds. Specifically, they would tend to buy when the cash ratio approaches 11 percent and to sell when the cash ratio approaches 4 percent.

An alternative rationale for this buy-sell decision is that a high cash position is a bullish indicator because of potential buying power. Irrespective of the reason for a large cash balance, these technicians believe the large cash balance will eventually be invested and will cause stock prices to increase. Alternatively, a low cash ratio would mean that the institutions have bought heavily and are left with little potential buying power. As of June 2011, this ratio was at 6.5 percent, which would be a neutral signal.

Credit Balances in Brokerage Accounts

Credit balances result when investors sell stocks and leave the proceeds with their brokers, expecting to reinvest them shortly. The amounts are reported by the SEC and the NYSE in Barron’s. Because technical analysts view these credit balances as potential purchasing power, a decline in these balances is considered bearish because it indicates lower purchasing power as the market approaches a peak. Alternatively, a buildup of credit balances indicates an increase in buying power and is a bullish signal. As of June 2011, the balances have been increasing for several months and relative to the prior year, which is bullish.

Investment Advisory Opinions

Many technicians believe that if a large proportion of investment advisory services are bearish, this signals the approach of a market trough and the onset of a bull market. Because most advisory services tend to be trend followers, the number of bears usually is greatest when market bottoms are approaching. This trading rule is specified in terms of the percent of advisory services that are bearish/bullish given the number of services expressing an opinion.

A 35 percent bearish or 20 percent bullish reading indicates a major market bottom (a bullish indicator), while a 35 percent bullish or 20 percent bearish reading suggests a major market top (a bearish signal). Exhibit 15.3 shows a time-series plot of the DJIA and the bearish sentiment index. As of June 2011, the percent bearish consensus index was at about 27 percent, which is a neutral rating.

Chicago Board Options Exchange (CBOE) Put-Call Ratio

Contrary-opinion technicians use put options, which give the holder the right to sell stock at a specified price for a given

1. Barron’s is a prime source for numerous technical indicators. For a readable discussion of relevant data and their use, see Martin E. Zweig (1987).

2. This ratio is compiled by Investors Intelligence, Larchmont, NY 10538. The technicians at B of A Merrill Lynch Global Research use this series as one of their “Investor Sentiment Indicators.” Notably, the percentage signals have changed over time.

15.4.1 Contrary-Opinion Rules

Many technical analysts rely on technical trading rules that assume that the majority of investors are wrong as the market approaches peaks and troughs. Therefore, these technicians try to determine when the majority of investors is either strongly bullish or bearish and then trade in the opposite direction.
**Mutual Fund Cash Positions** Mutual funds hold some part of their portfolio in cash for one of several reasons. One is that they need cash to liquidate shares submitted by fundholders. Another is that new investments in the mutual fund may not have been invested. Third, the portfolio manager might be bearish on the market and want to increase the fund’s defensive cash position.

Mutual funds’ ratios of cash as a percentage of the total assets in their portfolios (the cash ratio, or liquid asset ratio) are reported in the press, including monthly figures in *Barron’s*. This percentage of cash has varied in recent years from a low point of about 4 percent to a high point near 11 percent, although there appears to be a declining trend to the series.

Contrary-opinion technicians believe that mutual funds usually are wrong at peaks and troughs. Thus, they expect mutual funds to have a high percentage of cash near a market trough—the time when they should be fully invested to take advantage of the impending market rise. At the market peak, these technicians expect mutual funds to be almost fully invested with a low percentage of cash when they should be selling stocks and realizing gains. Therefore, contrary-opinion technicians watch for the mutual fund cash position to approach one of the extremes and act contrary to the mutual funds. Specifically, they would tend to buy when the cash ratio approaches 11 percent and to sell when the cash ratio approaches 4 percent.

An alternative rationale for this buy-sell decision is that a high cash position is a bullish indicator because of potential buying power. Irrespective of the reason for a large cash balance, these technicians believe the large cash balance will eventually be invested and will cause stock prices to increase. Alternatively, a low cash ratio would mean that the institutions have bought heavily and are left with little potential buying power. As of June 2011, this ratio was at 6.5 percent, which would be a neutral signal.

**Credit Balances in Brokerage Accounts** Credit balances result when investors sell stocks and leave the proceeds with their brokers, expecting to reinvest them shortly. The amounts are reported by the SEC and the NYSE in *Barron’s*. Because technical analysts view these credit balances as potential purchasing power, a decline in these balances is considered bearish because it indicates lower purchasing power as the market approaches a peak. Alternatively, a buildup of credit balances indicates an increase in buying power and is a bullish signal. As of June 2011, the balances have been increasing for several months and relative to the prior year, which is bullish.

**Investment Advisory Opinions** Many technicians believe that if a large proportion of investment advisory services are bearish, this signals the approach of a market trough and the onset of a bull market. Because most advisory services tend to be trend followers, the number of bears usually is greatest when market bottoms are approaching. This trading rule is specified in terms of the percent of advisory services that are bearish/bullish given the number of services expressing an opinion. A 35 percent bearish or 20 percent bullish reading indicates a major market bottom (a bullish indicator), while a 35 percent bullish or 20 percent bearish reading suggests a major market top (a bearish signal). Exhibit 15.3 shows a time-series plot of the DJIA and the bearish sentiment index. As of June 2011, the percent bearish consensus index was at about 27 percent, which is a neutral rating.

**Chicago Board Options Exchange (CBOE) Put-Call Ratio** Contrary-opinion technicians use put options, which give the holder the right to sell stock at a specified price for a given

---

1 *Barron’s* is a prime source for numerous technical indicators. For a readable discussion of relevant data and their use, see Martin E. Zweig (1987).

2 This ratio is compiled by Investors Intelligence, Larchmont, NY 10538. The technicians at B of A Merrill Lynch Global Research use this series as one of their “Investor Sentiment Indicators.” Notably, the percentage signals have changed over time.
time period, as signals of a bearish attitude. A higher put-call ratio indicates a pervasive bearish attitude for investors, which technicians consider a bullish indicator.

This ratio has historically fluctuated between 0.80 and 0.20 and was typically substantially less than 1 because investors tend to be bullish and avoid selling short or buying puts. Readings of 0.60 and above are considered bullish, while readings of 0.30 and below are bearish signals. As of June 2011, the ratio was about 0.70, implying that investors are quite bearish, which would be a strong bullish sign for contrary-opinion technicians.

**Futures Traders Bullish on Stock-Index Futures** Another relatively popular contrary-opinion measure is the percentage of speculators in stock-index futures who are bullish regarding stocks based on a survey of individual futures traders. These technicians would consider it a bearish sign when more than 70 percent of the speculators are bullish, and a bullish sign when this ratio declines to 30 percent or lower.

As we have shown, contrary-opinion technicians have several measures of how the majority of investors are investing that prompt them to take the opposite action. They generally employ several of these series to provide a consensus regarding investors’ sentiment.

**15.4.2 Follow the Smart Money**

Some technical analysts have created a set of indicators and corresponding rules that they believe indicate the behavior of smart, sophisticated investors. We discuss three such indicators in this section.

**Confidence Index** Published by Barron’s, the Confidence Index (CI) is the ratio of Barron’s average yield on the “Best grade Bonds” list to the average yield on the Dow Jones “Intermediate Grade Bonds” list. This index measures the change in yield spread over time between high-grade and intermediate grade bonds. Because the yields on high-grade bonds always should be lower than those on intermediate grade bonds, this ratio should approach 100 as the spread between the two sets of bonds gets smaller.

Technicians believe the ratio is a bullish indicator because, during periods of high confidence, investors are willing to invest in lower-quality bonds for the added yield, which causes a decrease

---

3Historical data for this index are contained in the *Dow Jones Investor’s Handbook*, Princeton, N.J (Dow Jones Books, annual). Current figures appear in Barron’s.
in the yield spread between the intermediate grade bonds and best grade bonds. Therefore, this ratio of yields—the Confidence Index—will increase. In contrast, when investors are pessimistic, the yield spread will increase, and there is a decline in the Confidence Index.

Unfortunately, this interpretation assumes that changes in the yield spread are caused almost exclusively by changes in investor demand for different quality bonds. In fact, the yield differences have frequently changed because of changes in the supply of bonds. For example, a large issue of high-grade AT&T bonds could cause a temporary increase in yields on all high-grade bonds, which would reduce the yield spread, and increase the Confidence Index without any change in investors’ attitudes. Therefore, this change in supply generates a false signal of a change in confidence. As of June 2011, the CI has been declining for several months and is down about 5 percent from its high point, which would be mildly bearish.

**T-Bill–Eurodollar Yield Spread** A popular measure of investor attitude or confidence on a global basis is the spread between T-bill yields and Eurodollar rates measured as the ratio of T-bill/Eurodollar yields. It is reasoned that, at times of international crisis, this spread widens as the smart money flows to safe-haven U.S. T-bills, which causes a decline in this ratio. It is contended that the stock market typically experiences a trough shortly thereafter.

**Debit Balances in Brokerage Accounts (Margin Debt)** Debit balances in brokerage accounts represent borrowing (margin debt) by knowledgeable investors from their brokers. Hence, these balances indicate the attitude of sophisticated investors who engage in margin transactions. Therefore, an increase in debit balances implies buying by these sophisticated investors and is considered a bullish sign, while a decline in debit balances would indicate selling and would be a bearish indicator.

Monthly data on margin debt is reported in Barron’s. Unfortunately, this index does not include borrowing by investors from other sources such as banks. Also, because it is an absolute value, technicians can only look for changes in the trend of borrowing—that is, increases are bullish, and declines are bearish. As of June 2011, these balances have been increasing for several weeks and are above the prior year figures, which would be a bullish sign.

**15.4.3 Momentum Indicators**
In addition to contrary-opinion and smart-money signals, several indicators of overall market momentum are used to make aggregate market decisions.

**Breadth of Market** The breadth of market series measures the number of issues that have increased each day and the number of issues that have declined. It helps explain what caused a change in direction in a composite market index such as the S&P 500 Index. As we discussed in Chapter 5, most stock-market indexes are heavily influenced by the stocks of large firms because the indexes are value weighted. Therefore, a stock-market index can experience an overall increase while the majority of the individual issues are not increasing, which means that most stocks are not participating in the rising market. Such a divergence can be detected by examining the advance-decline figures for all stocks on the exchange, along with the overall market index.

The advance-decline index is typically a cumulative index of net advances or net declines. Specifically, each day major newspapers publish figures on the number of issues on the NYSE that advanced, declined, or were unchanged. The figures for a five-day sample, as would be reported in Barron’s, are shown in Exhibit 15.4. These figures, along with changes in the DJIA at the bottom of the table, indicate a strong market advance because the DJIA was increasing and the net advance figure was strong, indicating that the market increase was broadly based. Even the results on Day 3, when the market declined 15 points, were encouraging since it was a small overall decline and the individual stock issues were split just about 50–50, which points toward a fairly even environment.
means that the net effect on price is in that direction, but the price change alone does not indicate the breadth of the excess demand or supply. Therefore, the technician looks for a price increase on heavy volume relative to the stock's normal trading volume as an indication of bullish activity. Conversely, a price decline with heavy volume is considered bearish. A generally bullish pattern would be when price increases are accompanied by heavy volume and small price reversals occur with light trading volume.

Technicians also use a ratio of upside-downside volume as an indicator of short-term momentum for the aggregate stock market. Each day the stock exchanges announce the volume of trading in stocks that experienced an increase divided by the volume of trading in stocks that declined. These data are reported daily in *The Wall Street Journal* and weekly in *Barron’s*. This ratio is used as an indicator of market momentum. Specifically, while values above 1.00 are generally bullish, technicians believe that an upside-downside volume value of 1.75 or more indicates an overbought position that is bearish. Alternatively, a value of 0.75 and lower supposedly reflects an oversold position and is considered bullish. The moving average value as of June 2011 is in the range of 105–110, which is mildly positive but on balance neutral.

**Support and Resistance Levels**

A *support level* is the price range at which the technician would expect a substantial increase in the demand for a stock. Generally, a support level will develop after a stock has enjoyed a meaningful price increase and the stock experiences profit taking. Technicians reason that at some price below the recent peak other investors who did not buy during the first price increase (waiting for a small reversal) will get into the stock. When the price reaches this support price, demand surges, and price and volume begin to increase again.

A *resistance level* is the price range at which the technician would expect an increase in the supply of stock and a price reversal. A resistance level develops after a significant decline from a higher price level. After the decline, the stock begins to recover, but the prior decline in price leads some investors who acquired the stock at a higher price to look for an opportunity to sell it near their breakeven points. Therefore, the supply of stock owned by these nervous investors is overhanging the market. When the price rebounds to the target price set by these investors, this overhanging supply of stock comes to the market, and there is a price decline on heavy volume.

It is also possible to envision a rising trend of support and resistance levels for a stock. For example, the rising support prices would be a set of higher prices where investors over time would see the price increase and would take the opportunity to buy when there is a "pull "

**Sources:** New York Stock Exchange and *Barron’s*.

**Stocks above Their 200-Day Moving Average** Technicians often compute moving averages of an index to determine its general trend. To examine individual stocks, the 200-day *moving average* of prices has been fairly popular. From these moving-average indexes for numerous stocks, Media General Financial Services calculates how many stocks currently are trading above their 200-day moving-average index, and this is used as an indicator of general investor sentiment. The market is considered to be *overbought* and subject to a negative correction when more than 80 percent of the stocks are trading above their 200-day moving average. In contrast, if less than 20 percent of the stocks are selling above their 200-day moving average, the market is considered to be *oversold*, which means investors should expect a positive correction. As of June 2011, the percent of stocks selling above their 200-day moving average has been about 46 percent, which would be considered a neutral signal.

### 15.4.4 Stock Price and Volume Techniques

In the introduction to this chapter, we examined a hypothetical stock price chart that demonstrated market peaks and troughs along with rising and declining trend channels and breakouts from channels that signal new price trends or reversals of the price trends. While price patterns alone are important, most technical trading rules consider both stock price and corresponding volume movements.

**Dow Theory** Any discussion of technical analysis using price and volume data should begin with a consideration of the Dow Theory because it was among the earliest work on this topic and remains the basis for many technical indicators. Dow described stock prices as moving in trends analogous to the movement of water. He postulated three types of price movements over time: (1) major trends that are like *tides* in the ocean, (2) intermediate trends that resemble waves, and (3) short-run movements that are like *ripples*. Followers of the Dow Theory attempt to detect the direction of the major price trend (tide), recognizing that intermediate movements (waves) may occasionally move in the opposite direction. They recognize that a major market advance does not go straight up, but rather includes small price declines as some investors decide to take profits.

Exhibit 15.5 shows the typical bullish pattern. The technician would look for every recovery to reach a new peak above the prior peak, and this price rise should be accompanied by heavy trading volume. Alternatively, each profit-taking reversal that follows an increase to a new peak should have a trough above the prior trough, with relatively light trading volume during the profit-taking reversals. When this pattern of price and volume movements changes, the major trend may be entering a period of consolidation (a flat trend) or a major reversal.

**Importance of Volume** As noted, technicians watch volume changes along with price movements as indicators of changes in supply and demand. A price movement in one direction
means that the net effect on price is in that direction, but the price change alone does not indicate the breadth of the excess demand or supply. Therefore, the technician looks for a price increase on heavy volume relative to the stock’s normal trading volume as an indication of bullish activity. Conversely, a price decline with heavy volume is considered bearish. A generally bullish pattern would be when price increases are accompanied by heavy volume and small price reversals occur with light trading volume.

Technicians also use a ratio of upside-downside volume as an indicator of short-term momentum for the aggregate stock market. Each day the stock exchanges announce the volume of trading in stocks that experienced an increase divided by the volume of trading in stocks that declined. These data are reported daily in The Wall Street Journal and weekly in Barron’s. This ratio is used as an indicator of market momentum. Specifically, while values above 1.00 are generally bullish, technicians believe that an upside-downside volume value of 1.75 or more indicates an overbought position that is bearish. Alternatively, a value of 0.75 and lower supposedly reflects an oversold position and is considered bullish. The moving average value as of June 2011 is in the range of 105–110, which is mildly positive but on balance neutral.

**Support and Resistance Levels** A support level is the price range at which the technician would expect a substantial increase in the demand for a stock. Generally, a support level will develop after a stock has enjoyed a meaningful price increase and the stock experiences profit taking. Technicians reason that at some price below the recent peak other investors who did not buy during the first price increase (waiting for a small reversal) will get into the stock. When the price reaches this support price, demand surges, and price and volume begin to increase again.

A resistance level is the price range at which the technician would expect an increase in the supply of stock and a price reversal. A resistance level develops after a significant decline from a higher price level. After the decline, the stock begins to recover, but the prior decline in price leads some investors who acquired the stock at a higher price to look for an opportunity to sell it near their breakeven points. Therefore, the supply of stock owned by these nervous investors is overhanging the market. When the price rebounds to the target price set by these investors, this overhanging supply of stock comes to the market, and there is a price decline on heavy volume.

It is also possible to envision a rising trend of support and resistance levels for a stock. For example, the rising support prices would be a set of higher prices where investors over time would see the price increase and would take the opportunity to buy when there is a “pull
back” due to profit taking. In this latter case, there would be a succession of higher support and resistance levels over time.

Exhibit 15.6 contains the daily stock prices for CVS Caremark Corporation, with support and resistance lines. The graphs show a rising pattern since CVS Caremark has experienced strong price increases during this period. At present, the resistance level is at about $39 and is rising, while the support level is about $36.50 and is also rising. The bullish technician would look for future prices to rise in line with this channel. If prices fell significantly below the rising support line on strong volume, it would signal a possible trend reversal and would be considered a bearish signal. In contrast, an increase above the resistance price line, a “breakout,” on strong volume would be bullish.

**Moving-Average Lines** Earlier, we discussed how technicians use a moving average of past stock prices as an indicator of the long-run trend and how they examine current prices relative to this trend for signals of a change. We also noted that a 200-day moving average is a relatively popular measure for individual stocks and the aggregate market. In this discussion, we add a 50-day moving-average price line (short-term trend) and consider large volume.

Exhibit 15.7 is a daily stock price chart for Goldman Sachs Group (GS) for the year ending June 15, 2011 with 50-day and 200-day moving-average (MA) lines. As noted, MA lines are meant to reflect the overall trend for the price series with the shorter MA line (the 50-day versus 200-day) reflecting shorter trends. Two comparisons involving the MA lines are considered important. The first comparison is the specific prices to the shorter-run 50-day MA line. If the overall price trend of a stock or the market has been down, the moving-average price line generally would lie above current prices. If prices reverse and break through the moving-average

![Exhibit 15.6 Daily Stock Price and Volume for CVS Caremark Corporation with Indications of Support and Resistance Levels](image-url)

*Source: Reproduced with permission of Yahoo! Inc. ©2011 Yahoo! Inc. YAHOO! and the YAHOO! logo are registered trademarks of Yahoo! Inc.*
line from below accompanied by heavy trading volume, most technicians would consider this a positive change and speculate that this breakthrough could be a preliminary signal of a reversal of the declining trend. In contrast, if the price of a stock had been rising, the moving-average line would also be rising, but it would be below current prices. If current prices declined and broke through the moving-average line from above accompanied by heavy trading volume, this would be considered a preliminary bearish pattern that would possibly signal a reversal of the long-run rising trend.

The second comparison is between the 50- and 200-day MA lines. Specifically, when these two lines cross, it confirms a change in the overall trend. Specifically, if the 50-day MA line crosses the 200-day MA line from below on good volume, this would be a bullish indicator (buy signal) because it confirms a reversal in trend from negative to positive. In contrast, when the 50-day line crosses the 200-day line from above, it confirms a change to a negative trend and would be a sell signal. These two crossings are shown in Exhibit 15.7 for Goldman Sachs Group. Following the buy signal in November 2010, there were continuing rising prices into January 2011, followed by generally falling prices in March, in April, and into May, when the 50-day MA broke through the 200-day MA from above on strong volume, which was a strong sell signal.

The price line continued to decline after the sell signal to about $115–116, where it has been fluctuating. A technician would look for the price to initially stop declining, then “build a base” prior to eventually breaking through the 50-day MA line followed by a confirmation when the 50-day MA line would break above the 200-day MA line.

As noted, for a bullish trend the 50-day MA line should be above the 200-day MA line. Notably, if this positive gap between the 50-day and 200-day lines gets too large (which happens with a fast run-up in price), a technician might consider this an indication that the stock is...
temporarily overbought, which is bearish in the short run. A *bearish* trend is when the 50-day MA line is below the 200-day MA line. Still, if the gap gets very large on the downside, it might be considered a signal of an oversold stock, which is bullish for the short run.

**Relative Strength** Technicians believe that once a trend begins, it will continue until some major event causes a change in direction. They believe this is also true of *relative* performance. If an individual stock or an industry group is outperforming the market, technicians believe it will continue to do so.

Therefore, technicians compute weekly or monthly **relative-strength (RS) ratios** for individual stocks and industry groups. The RS ratio is equal to the price of a stock or an industry index divided by the value for some stock-market index such as the S&P 500.\(^5\) If this ratio increases over time, it shows that the stock or industry is outperforming the overall stock market, and a technician would expect this superior performance to continue. Relative-strength ratios work during declining as well as rising markets. In a declining market, if a stock’s price declines less than the market does, the stock’s relative-strength ratio will continue to rise. Technicians believe that if this ratio is stable or increases during a bear market, the stock should do well during the subsequent bull market.

Investment firms publish relative-strength charts for individual stocks relative to the market (e.g., S&P Industrials Index). Using Walgreens as an example, Exhibit 15.8 describes how to read the charts. Finally, some technicians construct graphs of stocks relative to the stock’s industry index in addition to the comparison relative to the market.

**Bar Charting** Technicians use charts that show daily, weekly, or monthly time series of stock prices. For a given interval, the technical analyst plots the high and low prices and connects the two points vertically to form a bar. Typically, he or she will also draw a small horizontal line across this vertical bar to indicate the closing price. Finally, almost all bar charts include the volume of trading at the bottom of the chart so that the technical analyst can relate the price and volume movements.

**Candlestick Charts** Candlestick charts are basically an extension of the bar chart discussed previously. In addition to high, low, and closing prices for each trading day, they also include the opening price and indicate the change from open to close by shading whether the market or individual stock went down (dark shading) or up (white bar) for the day. The result for the Dow Jones Industrial Average shown in Exhibit 15.9 provides additional information and insight regarding the stock market movements over time.

**Multiple-Indicator Charts** Thus far, we have presented charts that deal with only one trading technique, such as moving-average lines or relative-strength rules. In the real world, it is fairly typical for technical charts to contain several indicators that can be used together—like the two MA lines (50- and 200-day) and the RS line—because they can provide added support to the analysis. Technicians include as many price and volume indicators as are reasonable on one chart and then, based on the performance of several technical indicators, try to arrive at a consensus about the future movement for the stock.

**Point-and-Figure Charts** Another popular graph is the point-and-figure chart. Unlike the bar chart, which typically includes all ending prices and volumes to show a trend, the point-and-figure chart includes only significant price changes, regardless of their timing. The technician determines what price interval to record as significant (one point, two points, and so on) and when to note price reversals.

To demonstrate how a technical analyst would use such a chart, suppose we want to chart a volatile stock that is currently selling for $40 a share. Because of its volatility, we believe that anything

\(^5\)In contrast to these relative to market or industry ratios, there are ratios that are relative to the stock itself, which is fundamentally a momentum indicator. These are not the same.
less than a two-point price change is not significant. Also, we consider anything less than a four-point reversal, meaning a movement in the opposite direction, quite minor. Therefore, we would set up a chart similar to the one in Exhibit 15.10, but our new chart would start at 40; it would also progress in two-point increments. If the stock moved to $42, we would place an X in the box above 40 and do nothing else until the stock rose to $44 or dropped to $38 (a four-point reversal from its high of $42). If it dropped to $38, we would move a column to the right, which indicates a reversal.

Exhibit 15.8 Daily Stock Prices for Walgreens with 50-day Moving Average and Relative Strength Compared to S&P Industrials with 50-day Moving Average

The Walgreen stock charts in this report display the following elements:
1. A line chart of the daily close of the Walgreen company stock price: July 2010 - June 2011, with the stock price indicated to the left.
2. A line of the 50-day moving average of the Walgreen company stock price.
3. A relative-strength line of Walgreen stock price compared to the S&P Industrials index.
4. A 50-day moving average of relative strength

Source: http://finance.yahoo.com
less than a two-point price change is not significant. Also, we consider anything less than a four-point reversal, meaning a movement in the opposite direction, quite minor. Therefore, we would set up a chart similar to the one in Exhibit 15.10, but our new chart would start at 40; it would also progress in two-point increments. If the stock moved to $42, we would place an X in the box above 40 and do nothing else until the stock rose to $44 or dropped to $38 (a four-point reversal from its high of $42). If it dropped to $38, we would move a column to the right, which indicates a reversal.
15.5.2 Technical Analysis of Foreign Exchange Rates

On numerous occasions, we have discussed the importance of changes in foreign exchange rates on the rates of return on foreign securities. Because of the importance of these relationships, bond and stock traders in world markets examine the time-series data of various currencies such as the British pound and the euro. They also analyze the spread between currencies, such as the difference between the Japanese yen and the British pound. Finally, they would typically examine the time series for the U.S. dollar trade-weighted exchange rate.

15.6 TECHNICAL ANALYSIS OF BOND MARKETS

Thus far, we have emphasized the use of technical analysis in stock markets. These techniques can also be applied to the bond market. The theory and rationale for technical analysis of bonds are the same as for stocks, and many of the same trading rules are used. A major difference is that it was generally not possible to consider the volume of trading of bonds until volume was reported starting in 2004.

Exhibit 15.12 demonstrates the use of technical analysis techniques applied to bond-yield series. Specifically, the graph contains a time-series plot of yields for the U.S. 10-year note with a medium-term momentum series. As shown starting in July 2010, 10-year Treasury yields have experienced a decline, an increase, and then another decline through July 2011.

<table>

...in direction, and begin again at 38 (fill in boxes at 42 and 40). If the stock price dropped to $34, we would enter an X at 36 and another at 34. If the stock then rose to $38 (another four-point reversal), we would move to the next column and begin at 38, going up (fill in 34 and 36). If the stock then went to $46, we would fill in more Xs as shown and wait for further increases or a reversal.

Depending on how fast the prices rise and fall, this process might take anywhere from two to six months. Given these figures, the technician would attempt to determine trends just as with the bar chart. As always, the technician would look for breakouts to either higher or lower price levels. A long horizontal movement with many reversals but no major trends up or down would be considered a period of consolidation, wherein the stock is moving from buyers to sellers and back again with no strong consensus about its direction. Once the stock breaks out and moves up or down after a period of consolidation, technical analysts anticipate a major move because previous trading set the stage for it. In other words, the longer the period of consolidation, the larger the expected subsequent move (up or down) when there is finally a breakout.

Point-and-figure charts provide a compact record of movements because they only consider significant price changes for the stock being analyzed. Therefore, some technicians contend they are easier to work with and give more vivid pictures of price movements.

15.5 TECHNICAL ANALYSIS OF FOREIGN MARKETS

Our discussion thus far has concentrated on U.S. markets, but analysts have discovered that these techniques apply to foreign markets as well. Merrill Lynch, for instance, prepares separate technical analysis publications for individual countries such as Japan, Germany, and the United Kingdom as well as a summary of all world markets. The examples that follow show that when analyzing non-U.S. markets, many techniques are limited to price and volume data rather than the more detailed U.S. market information. The reason is that the detailed information available on the U.S. market through the SEC, the several stock exchanges, and various investment services is not always available for other countries.

15.5.1 Foreign Stock Market Indexes

Exhibit 15.11 contains the daily time-series plot for the Japanese TOPIX Index. This chart shows a choppy flat performance from early 2006 to about July 2007, followed by a clear downtrend through September 2008 that is confirmed by the momentum series. This is followed by a short period of positive momentum, then a period of choppy flat performance with constant momentum that would be considered “base building” in anticipation of a recovery. B of A Merrill Lynch publishes similar charts for several other countries and currencies.
15.5.2 Technical Analysis of Foreign Exchange Rates

On numerous occasions, we have discussed the importance of changes in foreign exchange rates on the rates of return on foreign securities. Because of the importance of these relationships, bond and stock traders in world markets examine the time-series data of various currencies such as the British pound and the euro. They also analyze the spread between currencies, such as the difference between the Japanese yen and the British pound. Finally, they would typically examine the time series for the U.S. dollar trade-weighted exchange rate.

15.6 Technical Analysis of Bond Markets

Thus far, we have emphasized the use of technical analysis in stock markets. These techniques can also be applied to the bond market. The theory and rationale for technical analysis of bonds are the same as for stocks, and many of the same trading rules are used. A major difference is that it was generally not possible to consider the volume of trading of bonds until volume was reported starting in 2004.

Exhibit 15.12 demonstrates the use of technical analysis techniques applied to bond-yield series. Specifically, the graph contains a time-series plot of yields for the U.S. 10-year note with a medium-term momentum series. As shown starting in July 2010, 10-year Treasury yields have experienced a decline, an increase, and then another decline through July 2011.
The important segment for the technician would begin in late 2010 when rates increased from about 2.40 percent to about 3.70 percent followed by a decline to about 2.80 percent in July 2011. These rate changes were confirmed by the momentum graph below the interest rate chart. Notably, these declines continued into September 2011 when 10 year Treasury rates broke through 2.00 percent and reached historically low values of 1.92 percent. The point is, such a technical graph provides important insights to a bond-portfolio manager interested in adjusting his or her bond portfolio.

Numerous investors believe in and use the principles of technical analysis. The fact is, the large investment houses provide extensive support for technical analysis, and a large proportion of the discussion related to securities markets in the media is based on a technical view of the market. How they answer two main questions separate technical analysts and efficient market advocates. First, in the information dissemination process, does everybody get the information at about the same time? Second, how quickly do investors adjust security prices to reflect new information? From Chapter 6, we know the answers from efficient market advocates. In contrast, technical analysts believe that news takes time to travel from the insider and expert to the individual investor. They also believe that price adjustments are not instantaneous. As a result, they contend that security prices move in trends that persist and, therefore, they can use past price trends and volume information along with other market indicators to determine future price trends.

Technical trading rules fall into four general categories: contrary-opinion rules, follow-the-smart-money tactics, momentum indicators, and stock price and volume techniques. These techniques and trading rules can be applied to both domestic and foreign markets. They can also be used to analyze currency exchange rates and determine the prevailing sentiment in the bond market.

Most technicians employ several indicators and attempt to derive a consensus to guide their decision to buy, sell, or do nothing.

**Exhibit 15.12 Time-Series Plot of Yields for the U.S. 10-Year Note with Momentum Series for the Yields**

Source: Compiled by author.
The important segment for the technician would begin in late 2010 when rates increased from about 2.40 percent to about 3.70 percent followed by a decline to about 2.80 percent in July 2011. These rate changes were confirmed by the momentum graph below the interest rate chart. Notably, these declines continued into September 2011 when 10 year Treasury rates broke through 2.00 percent and reached historically low values of 1.92 percent. The point is, such a technical graph provides important insights to a bond-portfolio manager interested in adjusting his or her bond portfolio.

**SUMMARY**

- Numerous investors believe in and use the principles of technical analysis. The fact is, the large investment houses provide extensive support for technical analysis, and a large proportion of the discussion related to securities markets in the media is based on a technical view of the market.
- How they answer two main questions separate technical analysts and efficient market advocates. First, in the information dissemination process, does everybody get the information at about the same time? Second, how quickly do investors adjust security prices to reflect new information? From Chapter 6, we know the answers from efficient market advocates. In contrast, technical analysts believe that news takes time to travel from the insider and expert to the individual investor. They also believe that price adjustments are not instantaneous. As a result, they contend that security prices move in trends that persist and, therefore, they can use past price trends and volume information along with other market indicators to determine future price trends.
- Technical trading rules fall into four general categories: contrary-opinion rules, follow-the-smart-money tactics, momentum indicators, and stock price and volume techniques. These techniques and trading rules can be applied to both domestic and foreign markets. They can also be used to analyze currency exchange rates and determine the prevailing sentiment in the bond market.
- Most technicians employ several indicators and attempt to derive a consensus to guide their decision to buy, sell, or do nothing.⁶

**SUGGESTED READINGS**

*The study by Jerome Baaesl, George Shows, and Edward Thorp (1982) provides an analysis using numerous indicators.*
6. Assume a significant decline in credit balances at brokerage firms. Discuss why a technician would consider this bullish or bearish.

7. If the bearish sentiment index of advisory service opinions were to increase to 61 percent, discuss why a technician would consider this bullish or bearish.

8. Discuss why an increase in debit balances is considered bullish or bearish.

9. Describe the Dow Theory and its three components. Which component is most important? What is the reason for an intermediate reversal?

10. Describe a bearish price and volume pattern, and discuss why it is considered bearish.

11. Discuss the logic behind the breadth of market index. How is it used to identify a peak in stock prices?

12. During a 10-day trading period, the cumulative net advance index goes from 1,572 to 1,053. During this same period of time, the DJIA goes from 11,200 to 12,100. As a technician, discuss what this set of events would mean to you.

13. Explain the reasoning behind a support level and a resistance level.

14. What is the purpose of computing a moving-average line for a stock? Describe a bullish pattern using a 50-day moving-average line and the stock volume of trading. Discuss why this pattern is considered bullish.

15. Assuming a stock price and volume chart that also contains a 50-day and a 200-day MA line, describe a bearish pattern with the two MA lines and discuss why it is bearish.

16. Explain how you would construct a relative-strength ratio for an individual stock or an industry group. What would it mean to say a stock experienced good relative strength during a bear market?

17. Discuss why most technicians follow several technical rules and attempt to derive a consensus.

PROBLEMS

1. Select a stock on the NYSE and construct a daily high, low, and close bar chart for it that includes its volume of trading for 10 trading days.

2. Compute the relative-strength ratio for the stock in Problem 1 relative to the S&P 500 Index. Prepare a table that includes all the data and indicates the computations as follows:

<table>
<thead>
<tr>
<th>Day</th>
<th>Stock</th>
<th>S&amp;P 500</th>
<th>Stock Price/S&amp;P 500</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

3. Plot the relative-strength ratio computed in Problem 2 on your bar chart. Discuss whether the stock's relative strength is bullish or bearish.

4. Currently, Charlotte Art Importers is selling at $23 per share. Although you are somewhat dubious about technical analysis, you want to know how technicians who use point-and-figure charts would view this stock. You decide to note one-point movements and three-point reversals. You gather the following historical price information:

<table>
<thead>
<tr>
<th>Date</th>
<th>Price</th>
</tr>
</thead>
<tbody>
<tr>
<td>4/1</td>
<td>23</td>
</tr>
<tr>
<td>4/4</td>

5. If the mutual fund cash position were to increase close to 12 percent, would a technician consider this cash position bullish or bearish? Give two reasons for this opinion.
6. Assume a significant decline in credit balances at brokerage firms. Discuss why a technician would consider this bullish or bearish.

7. If the bearish sentiment index of advisory service opinions were to increase to 61 percent, discuss why a technician would consider this bullish or bearish.

8. Discuss why an increase in debit balances is considered bullish or bearish.

9. Describe the Dow Theory and its three components. Which component is most important? What is the reason for an intermediate reversal?

10. Describe a bearish price and volume pattern, and discuss why it is considered bearish.

11. Discuss the logic behind the breadth of market index. How is it used to identify a peak in stock prices?

12. During a 10-day trading period, the cumulative net advance index goes from 1,572 to 1,053. During this same period of time, the DJIA goes from 11,200 to 12,100. As a technician, discuss what this set of events would mean to you.

13. Explain the reasoning behind a support level and a resistance level.

14. What is the purpose of computing a moving-average line for a stock? Describe a bullish pattern using a 50-day moving-average line and the stock volume of trading. Discuss why this pattern is considered bullish.

15. Assuming a stock price and volume chart that also contains a 50-day and a 200-day MA line, describe a bearish pattern with the two MA lines and discuss why it is bearish.

16. Explain how you would construct a relative-strength ratio for an individual stock or an industry group. What would it mean to say a stock experienced good relative strength during a bear market?

17. Discuss why most technicians follow several technical rules and attempt to derive a consensus.

### PROBLEMS

1. Select a stock on the NYSE and construct a daily high, low, and close bar chart for it that includes its volume of trading for 10 trading days.

2. Compute the relative-strength ratio for the stock in Problem 1 relative to the S&P 500 Index. Prepare a table that includes all the data and indicates the computations as follows:

<table>
<thead>
<tr>
<th>Closing Price</th>
<th>Relative-Strength Ratio</th>
</tr>
</thead>
<tbody>
<tr>
<td>Day</td>
<td>Stock</td>
</tr>
<tr>
<td>----------------</td>
<td>--------</td>
</tr>
<tr>
<td>4/1</td>
<td>23½</td>
</tr>
<tr>
<td>4/4</td>
<td>28½</td>
</tr>
<tr>
<td>4/5</td>
<td>28</td>
</tr>
<tr>
<td>4/6</td>
<td>28</td>
</tr>
<tr>
<td>4/7</td>
<td>29½</td>
</tr>
<tr>
<td>4/8</td>
<td>30½</td>
</tr>
<tr>
<td>4/11</td>
<td>30½</td>
</tr>
<tr>
<td>4/12</td>
<td>32½</td>
</tr>
<tr>
<td>4/13</td>
<td>32</td>
</tr>
</tbody>
</table>

3. Plot the relative-strength ratio computed in Problem 2 on your bar chart. Discuss whether the stock’s relative strength is bullish or bearish.

4. Currently, Charlotte Art Importers is selling at $23 per share. Although you are somewhat dubious about technical analysis, you want to know how technicians who use point-and-figure charts would view this stock. You decide to note one-point movements and three-point reversals. You gather the following historical price information:

<table>
<thead>
<tr>
<th>Date</th>
<th>Price</th>
<th>Date</th>
<th>Price</th>
<th>Date</th>
<th>Price</th>
</tr>
</thead>
<tbody>
<tr>
<td>4/1</td>
<td>23½</td>
<td>4/18</td>
<td>33</td>
<td>5/3</td>
<td>27</td>
</tr>
<tr>
<td>4/4</td>
<td>28½</td>
<td>4/19</td>
<td>35½</td>
<td>5/4</td>
<td>26½</td>
</tr>
<tr>
<td>4/5</td>
<td>28</td>
<td>4/20</td>
<td>37</td>
<td>5/5</td>
<td>28</td>
</tr>
<tr>
<td>4/6</td>
<td>28</td>
<td>4/21</td>
<td>38½</td>
<td>5/6</td>
<td>28½</td>
</tr>
<tr>
<td>4/7</td>
<td>29½</td>
<td>4/22</td>
<td>36</td>
<td>5/9</td>
<td>28½</td>
</tr>
<tr>
<td>4/8</td>
<td>30½</td>
<td>4/25</td>
<td>35</td>
<td>5/10</td>
<td>28½</td>
</tr>
<tr>
<td>4/11</td>
<td>30½</td>
<td>4/26</td>
<td>35½</td>
<td>5/11</td>
<td>29½</td>
</tr>
<tr>
<td>4/12</td>
<td>32½</td>
<td>4/27</td>
<td>33½</td>
<td>5/12</td>
<td>30½</td>
</tr>
<tr>
<td>4/13</td>
<td>32</td>
<td>4/28</td>
<td>32½</td>
<td>5/13</td>
<td>29½</td>
</tr>
</tbody>
</table>
Plot the point-and-figure chart, using Xs for uptrends and Os for downtrends. How would a technician evaluate these movements? Discuss why you would expect a technician to buy, sell, or hold the stock based on this chart.

5. Assume the following daily closings for the Dow Jones Industrial Average:

<table>
<thead>
<tr>
<th>Day</th>
<th>DJIA</th>
<th>Day</th>
<th>DJIA</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>13,010</td>
<td>7</td>
<td>13,220</td>
</tr>
<tr>
<td>2</td>
<td>13,100</td>
<td>8</td>
<td>13,130</td>
</tr>
<tr>
<td>3</td>
<td>13,165</td>
<td>9</td>
<td>13,250</td>
</tr>
<tr>
<td>4</td>
<td>13,080</td>
<td>10</td>
<td>13,315</td>
</tr>
<tr>
<td>5</td>
<td>13,070</td>
<td>11</td>
<td>13,240</td>
</tr>
<tr>
<td>6</td>
<td>13,150</td>
<td>12</td>
<td>13,310</td>
</tr>
</tbody>
</table>

a. Calculate a four-day moving average for Days 4 through 12.
b. Assume that the index on Day 13 closes at 13,300. Would this signal a buy or sell decision?

6. The cumulative advance-decline line reported in Barron’s at the end of the month is 21,240. During the first week of the following month, the daily report for the Exchange is as follows:

<table>
<thead>
<tr>
<th>Day</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
<th>5</th>
</tr>
</thead>
<tbody>
<tr>
<td>Issues traded</td>
<td>3,544</td>
<td>3,533</td>
<td>3,540</td>
<td>3,531</td>
<td>3,521</td>
</tr>
<tr>
<td>Advances</td>
<td>1,737</td>
<td>1,579</td>
<td>1,759</td>
<td>1,217</td>
<td>1,326</td>
</tr>
<tr>
<td>Declines</td>
<td>1,289</td>
<td>1,484</td>
<td>1,240</td>
<td>1,716</td>
<td>1,519</td>
</tr>
<tr>
<td>Unchanged</td>
<td>518</td>
<td>470</td>
<td>541</td>
<td>598</td>
<td>596</td>
</tr>
</tbody>
</table>

a. Compute the daily net advance-decline line for each of the five days.
b. Compute the cumulative advance-decline line for each day and the final value at the end of the week.

---

THOMSON REUTERS

Use the Thomson One—Business School Edition Online Database to answer the following questions.

1. Examine the recent (past six months) price charts for Walgreens, Intel, and Merck (or any three firms of your choosing). What channels, buy/sell points, and patterns do you see in them?

2. What do the daily price and volume charts of the Dow Jones Industrial and S&P 500 for the past year imply for future price trends in the overall market?

3. For a stock of your choice, obtain daily price data for the past three years and download it into a spreadsheet. Compute and graph 5-day and 10-day moving averages of the price data, along with the daily price data. How successful were the signals generated by the moving-average lines?

4. Compute a table of relative strength for Walgreens over the past 6 months. What does the daily relative strength measure indicate for trends in Walgreen Co.’s stock?

5. Using daily data for the most recent two months, construct a point-and-figure chart for Walgreens.
Equity Portfolio Management Strategies

After you read this chapter, you should be able to answer the following questions:

- What are the two generic equity portfolio management styles?
- What are three techniques for constructing a passive index portfolio?
- How does the goal of a passive equity portfolio manager differ from the goal of an active manager?
- What is a portfolio’s tracking error and how is it useful in the construction of a passive equity investment?
- What is the difference between an index mutual fund and an exchange-traded fund?
- What are the three themes that active equity portfolio managers can use?
- What stock characteristics do momentum-oriented investors look for?
- How can an investor measure the tax efficiency of an actively managed portfolio?
- What stock characteristics differentiate value-oriented and growth-oriented investment styles?
- What is style analysis and what does it indicate about a manager’s investment performance?
- What techniques do active managers use in an attempt to outperform their benchmarks?
- What are the differences between the integrated, strategic, tactical, and insured approaches to asset allocation?

Recent chapters have reviewed how to analyze industries and companies, how to estimate a stock’s intrinsic value, and how technical analysis can assist in stock picking. Some equity portfolios are constructed one stock at a time. Research staffs analyze the economy, industries, and companies; evaluate firms’ strategies and competitive advantages; and recommend individual stocks for purchase or for sale.

Other equity portfolios are constructed using quantitative methods. Computers analyze relationships between stocks and market sectors to identify undervalued stocks. Quantitative screens and factor models are used to construct portfolios of stocks with such attributes as low P/E ratios, low price/book ratios, small capitalization, or high dividend yield; those neglected by analysts; or stocks whose returns are strongly correlated with economic variables, such as interest rates.

Managers of equity portfolios can also increase an investor’s wealth through their sector and asset allocation decisions. For example, a manager acting as a market timer might split his funds into two index portfolios—one containing stocks and the other containing bonds—and then shift the allocation between these portfolios depending on which asset class he believes will perform the best during the coming period. This strategy, which is formally known as tactical asset allocation, benefits from correctly predicting broad market movements rather than trends for individual companies. Similarly, insured asset allocation attempts to limit investment losses by shifting funds between an existing equity portfolio and a risk-free security depending on changing market conditions.
16.1 Passive versus Active Management

Equity portfolio management strategies can be placed into either a passive or an active category. One way to distinguish between these strategies is to decompose the total actual return that the portfolio manager attempts to produce:

\[
\text{Total Actual Return} = [\text{Expected Return}] + [\text{"Alpha"}]
\]

\[
= [\text{Risk-Free Rate + Risk Premium}] + [\text{"Alpha"}]
\]

Passive portfolio managers just try to capture the expected return consistent with the risk level of their portfolios. In contrast, active managers attempt to “beat the market” by forming portfolios capable of producing actual returns that exceed risk-adjusted expected returns. The difference between the actual and expected return is often called the portfolio’s alpha, and it represents the amount of value that the active manager has added (if positive) or subtracted (if negative) to the investment process.

Passive equity portfolio management typically holds stocks so the portfolio’s returns will track those of a benchmark index over time. Accordingly, this approach to investing is generally referred to as indexing, and there is no attempt on the manager’s part to generate alpha. While indexing is often thought to be a long-term buy-and-hold strategy, occasional rebalancing of the portfolio is necessary as the composition of the underlying benchmark changes and cash distributions must be reinvested. However, since the purpose is to mimic an index, the passive manager is judged by how well he or she tracks the target—that is, minimizes the deviation between stock portfolio and index returns.

Conversely, active equity portfolio management is an attempt by the manager to outperform an equity benchmark on a risk-adjusted basis. The active manager can employ any of several specific investment strategies to do this, but, broadly speaking, there are two main ways to try to add alpha: tactical adjustments (e.g., equity style or sector timing) or security selection (i.e., stock-picking) skills. So-called hybrid investment strategies that may appear to fall into the middle ground between the passive and active categories (e.g., enhanced indexing) are really just more modest variations of an active approach to equity portfolio management. Further, hedge funds are actively managed portfolios that often pursue a “pure alpha” (i.e., absolute return) strategy in which the manager seeks to isolate the alpha component of return; these strategies are discussed in Chapter 24.

When deciding to follow either an active or a passive strategy (or some combination of the two), an investor must assess the trade-off between the low-cost but less-exciting alternative of indexing versus the potentially more lucrative alternative of active investing, which almost certainly will have higher management fees and trading costs. Sharpe (1991) argued that these higher expenses will always make active management the inferior alternative. Sorensen, Miller, and Samak (1998) noted that the critical factor in this evaluation is the stock-picking skill of the portfolio manager and showed that the optimal allocation to indexing declines as managerial skill increases. Alford, Jones, and Winkelmann (2003) support this position by arguing that a disciplined approach to active management—which they term structured portfolio management—is likely to be the most effective method for investors. Harlow and Brown (2006) showed that the active versus passive management decision for many investors comes...
that the passive portfolio will inevitably underperform its index over time, even if the manager minimizes turnover in the portfolio for every other reason. The extent of this underperformance can range from 0.05 to 0.25 percent in developed stock markets to 3 percent for portfolios mimicking less liquid indexes (e.g., emerging markets).

### 16.2.1 Index Portfolio Construction Techniques

There are three basic techniques for constructing a passive index portfolio: full replication, sampling, and quadratic optimization. The most obvious technique is **full replication**, wherein all the securities in the index are purchased in proportion to their weights in the index. This technique helps ensure close tracking, but the need to buy many securities will increase transaction costs that will detract from performance. Additionally, the reinvestment of dividends will also result in high commissions when many firms pay small dividends at different times in the year.

The second technique, **sampling**, addresses the problem of having to buy numerous stock issues. With sampling, a portfolio manager would only need to buy a representative sample of stocks that comprise the benchmark index. Stocks with larger index weights are purchased according to their weight in the index; smaller issues are purchased so their aggregate characteristics (e.g., beta, industry distribution, and dividend yield) approximate the underlying benchmark. With fewer stocks to purchase, larger positions can be taken in the issues acquired, which should lead to proportionately lower transaction costs. Further, the reinvestment of dividends will be less problematic because fewer securities need to be purchased to rebalance the portfolio. The disadvantage of sampling is that portfolio returns will almost certainly not track the returns for the benchmark index as closely as with full replication.

Rather than obtaining a sample based on industry or security characteristics, **quadratic optimization** (or programming) techniques can be used to construct a passive portfolio. Historical information on price changes and correlations between securities are input to a computer program that determines the composition of a portfolio that will minimize return deviations from the benchmark. A problem with this technique is that it relies on historical price changes and correlations and, if these factors change over time, the portfolio may experience very large differences from the benchmark.

Sometimes customized passive portfolios, called **completeness funds**, are constructed to complement active portfolios that do not cover the entire market. For example, a large pension fund may allocate some of its holdings to active managers expected to outperform the market. Many times, these active portfolios are overweighted in certain market sectors or stock types. In this case, the pension fund sponsor may want the remaining funds to be invested passively to "fill the holes" left vacant by the active managers.

For example, suppose a pension fund hires three active managers to invest part of the fund's money. One manager emphasizes small-capitalization U.S. stocks, the second invests only in Pacific Rim countries, and the third invests in U.S. stocks with low P/E ratios. To ensure adequate diversification, the pension fund may want to passively invest the remaining assets in a completeness fund that will have a customized benchmark that includes large- and mid-capitalization U.S. stocks, U.S. stocks with normal to high P/E ratios, and international stocks outside the Pacific Rim.

Still other passive portfolios and benchmarks exist for investors with certain unique needs and preferences. Some investors may want their funds to be invested only in stocks that pay dividends or in a company that produces a product or service that the investor deems socially responsible. Mossavar-Rahmani (1988) and Dialynas (2001) show that benchmarks can be produced that reflect these desired attributes, and passive portfolios can be constructed to fill the holes left vacant by the active managers. Finally, notice the substantial rebound that all of these markets experienced following the capital market crisis in 2008.

### 16.2 An Overview of Passive Equity Portfolio Management Strategies

Passive equity portfolio management attempts to design a set of stock holdings that replicates the performance of a specific benchmark. A passive manager earns a fee by constructing a portfolio that closely tracks the returns to a particular equity index meeting the client’s needs and objectives. If the manager tries to outperform the benchmark, he or she clearly violates the passive premise of the portfolio.

Chapter 5 contained a summary of many of the different market indexes that a passive manager can attempt to replicate. Domestic equity indexes include the S&P 500, the NASDAQ Composite index, and the Wilshire 5000. Benchmarks also exist for various sectors of the stock market, such as those for small capitalization stocks (Russell 2000), for value- or growth-oriented stocks (Russell Growth Index and the Russell Value Index), for numerous developed world regions (such as the EAFE Index), and for collections of smaller countries (emerging markets). Fernholz, Garvy, and Hannon (1998), as well as Khorana, Nelling, and Trester (1998), have noted that as passive investing has grown in popularity, money managers have created an index fund for virtually every broad market category.

In Chapter 6, we presented several reasons for investing in a passive equity portfolio. Consistent evidence indicates that stock markets throughout the world are often fairly efficient. For many active managers, the annual costs of trying to beat the market (1 to 2 percent of the portfolio’s assets) are difficult to overcome. However, passive strategies are also not costless to employ. Because of cash flows into and out of an index fund, as well as events that change the composition of the benchmark itself (e.g., mergers, bankruptcies, index rebalancing), the passive manager will inevitably need to buy and sell securities over time. These transactions...
mean that the passive portfolio will inevitably underperform its index over time, even if the manager minimizes turnover in the portfolio for every other reason. The extent of this underperformance can range from 0.05 to 0.25 percent in developed stock markets to 3 percent for portfolios mimicking less liquid indexes (e.g., emerging markets).

16.2.1 Index Portfolio Construction Techniques

There are three basic techniques for constructing a passive index portfolio: full replication, sampling, and quadratic optimization. The most obvious technique is full replication, wherein all the securities in the index are purchased in proportion to their weights in the index. This technique helps ensure close tracking, but the need to buy many securities will increase transaction costs that will detract from performance. Additionally, the reinvestment of dividends will also result in high commissions when many firms pay small dividends at different times in the year.

The second technique, sampling, addresses the problem of having to buy numerous stock issues. With sampling, a portfolio manager would only need to buy a representative sample of stocks that comprise the benchmark index. Stocks with larger index weights are purchased according to their weight in the index; smaller issues are purchased so their aggregate characteristics (e.g., beta, industry distribution, and dividend yield) approximate the underlying benchmark. With fewer stocks to purchase, larger positions can be taken in the issues acquired, which should lead to proportionately lower transaction costs. Further, the reinvestment of dividends will be less problematic because fewer securities need to be purchased to rebalance the portfolio. The disadvantage of sampling is that portfolio returns will almost certainly not track the returns for the benchmark index as closely as with full replication.

Rather than obtaining a sample based on industry or security characteristics, quadratic optimization (or programming) techniques can be used to construct a passive portfolio. Historical information on price changes and correlations between securities are input to a computer program that determines the composition of a portfolio that will minimize return deviations from the benchmark. A problem with this technique is that it relies on historical price changes and correlations and, if these factors change over time, the portfolio may experience very large differences from the benchmark.

Sometimes customized passive portfolios, called completeness funds, are constructed to complement active portfolios that do not cover the entire market. For example, a large pension fund may allocate some of its holdings to active managers expected to outperform the market. Many times, these active portfolios are overweighted in certain market sectors or stock types. In this case, the pension fund sponsor may want the remaining funds to be invested passively to “fill the holes” left vacant by the active managers.

For example, suppose a pension fund hires three active managers to invest part of the fund’s money. One manager emphasizes small-capitalization U.S. stocks, the second invests only in Pacific Rim countries, and the third invests in U.S. stocks with low P/E ratios. To ensure adequate diversification, the pension fund may want to passively invest the remaining assets in a completeness fund that will have a customized benchmark that includes large- and mid-capitalization U.S. stocks, U.S. stocks with normal to high P/E ratios, and international stocks outside the Pacific Rim.

Still other passive portfolios and benchmarks exist for investors with certain unique needs and preferences. Some investors may want their funds to be invested only in stocks that pay dividends or in a company that produces a product or service that the investor deems socially responsible. Mossavar-Rahmani (1988) and Dialynas (2001) show that benchmarks can be produced that reflect these desired attributes, and passive portfolios can be constructed to
track the performance of the customized benchmark over time so that investors’ special needs can be satisfied.

16.2.2 Tracking Error and Index Portfolio Construction

If the goal of forming a passive portfolio is to replicate a particular equity index, the success of such a fund lies not in the absolute returns it produces but in how closely its returns match those of the benchmark. That is, the goal of the passive manager should be to minimize the portfolio’s return volatility relative to the index. Said differently, the manager should try to minimize tracking error.

As Ammann and Zimmermann (2001) note, tracking error can be defined as the extent to which return fluctuations in the managed portfolio are not correlated with return fluctuations in the benchmark. A flexible and straightforward way of measuring tracking error can be developed as follows. Let:

\[ w_i = \text{investment weight of Asset } i \text{ in the managed portfolio} \]
\[ R_{it} = \text{return to Asset } i \text{ in Period } t \]
\[ R_{bm} = \text{return to the benchmark portfolio in Period } t \]

so that the Period \( t \) return to managed portfolio is:

\[ R_{pt} = \sum_{i=1}^{N} w_i R_{it} \]

where:

\[ N = \text{number of assets in the managed portfolio} \]

With these definitions, the Period \( t \) return differential between the managed portfolio and the benchmark is:

\[ \Delta_t = \sum_{i=1}^{N} w_i R_{it} - R_{bm} = R_{pt} - R_{bm} \]

Given the returns to the managed portfolio and the benchmark, \( \Delta \) is a function of the \( N \) investment weights that the manager selects. Also, not all of the assets in the benchmark need be included in the managed portfolio (i.e., \( w = 0 \) for some assets).

For a sample of \( T \) return observations, the variance of \( \Delta \) can be calculated as follows:

\[ \sigma_{\Delta}^2 = \frac{\sum_{t=1}^{T} (\Delta_t - \bar{\Delta})^2}{(T - 1)} \]

Finally, the standard deviation of the return differential is:

\[ \sigma_{\Delta} = \sqrt{\sigma_{\Delta}^2} = \text{periodic tracking error} \]

so that annualized tracking error (TE) can be calculated as:

\[ TE = \sigma_{\Delta} \sqrt{P} \]

where \( P \) is the number of return periods in a year (e.g., \( P = 12 \) for monthly returns, \( P = 252 \) for daily returns).
Suppose an investor has formed a portfolio designed to track a particular benchmark. Over the last eight quarters, the returns to this portfolio, as well as the index returns and the return difference between the two, were:

<table>
<thead>
<tr>
<th>Period</th>
<th>Manager</th>
<th>Index</th>
<th>Difference ((\Delta))</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>2.3%</td>
<td>2.7%</td>
<td>-0.4%</td>
</tr>
<tr>
<td>2</td>
<td>-3.6</td>
<td>-4.6</td>
<td>1.0</td>
</tr>
<tr>
<td>3</td>
<td>11.2</td>
<td>10.1</td>
<td>1.1</td>
</tr>
<tr>
<td>4</td>
<td>1.2</td>
<td>2.2</td>
<td>-1.0</td>
</tr>
<tr>
<td>5</td>
<td>1.5</td>
<td>0.4</td>
<td>1.1</td>
</tr>
<tr>
<td>6</td>
<td>3.2</td>
<td>2.8</td>
<td>0.4</td>
</tr>
<tr>
<td>7</td>
<td>8.9</td>
<td>8.1</td>
<td>0.8</td>
</tr>
<tr>
<td>8</td>
<td>-0.8</td>
<td>0.6</td>
<td>-1.4</td>
</tr>
</tbody>
</table>

The periodic average and standard deviation of the manager’s return differential (i.e., “delta”) relative to the benchmark are:

\[
\text{Average } \Delta = \frac{\sum (-0.4 + 1.0 + \cdots + 0.8 - 1.4)}{8} = 0.2\%
\]

\[
\sigma = \sqrt{\frac{(-0.4 - 0.2)^2 + (1.0 - 0.2)^2 + \cdots + (-1.4 - 0.2)^2 + \sqrt{8 - 1}}{8}} = 1.0\%
\]

Thus, the manager’s annualized tracking error for this two-year period is 2.0 percent (= 1.0 percent \(\times\) \(\sqrt{4}\)).

Generally speaking, there is an inverse relationship between a passive portfolio’s tracking error relative to its index and the time and expense necessary to create and maintain the portfolio. For example, full replication of the S&P 500 would have virtually no tracking error but would involve positions in 500 different stocks and require frequent rebalancing. As smaller samples are used, the expense of forming the managed portfolio would decline but the potential tracking error is likely to increase. Thus, the art of being a manager of a passive equity portfolio lies in balancing the costs (larger tracking error) and the benefits (easier management, lower trading commissions) of using smaller samples. Exhibit 16.2 estimates the tracking error that occurs from such sampling.

Alford, Jones, and Winkelmann (2003) have also shown that tracking error can be a useful way to categorize a fund’s investment style. They argue that money managers can be classified...
using the following chart with regard to the tracking errors of their portfolios compared to the relevant benchmark:

<table>
<thead>
<tr>
<th>Investment Style</th>
<th>Tracking Error Range</th>
</tr>
</thead>
<tbody>
<tr>
<td>Passive</td>
<td>Less than 1.0% (0.5% or lower is normal)</td>
</tr>
<tr>
<td>Structured</td>
<td>Between 1.0% and 3.0%</td>
</tr>
<tr>
<td>Active</td>
<td>Over 3.0% (5.0% to 15.0% is normal)</td>
</tr>
</tbody>
</table>

They also document that structured portfolio managers, who can be viewed as active managers with the tightest controls on the permissible level of their tracking errors, tend to produce superior risk-adjusted returns to those active managers whose investment mandates allow them to stray further from their indexes.

**16.2.3 Methods of Index Portfolio Investing**

Although investors can construct their own passive investment portfolios that mimic a particular equity index, there are at least two prepackaged ways of accomplishing this goal that are typically more convenient and less expensive. These are (1) buying shares in an index mutual fund or (2) buying shares in an exchange-traded fund (ETF).

**Index Funds** As we discuss in Chapter 24, mutual funds represent established security portfolios managed by professional investment companies (e.g., Fidelity, Vanguard, Putnam) in which investors can participate. The investment company is responsible for deciding how the fund is managed. For an indexed portfolio, the fund manager will typically attempt to replicate the composition of the particular index exactly, meaning that he or she will buy the exact securities comprising the index in their exact weights and then alter those positions anytime the composition of the index itself is changed. Since changes to most equity indexes occur sporadically, index funds tend to generate low trading and management expense ratios. A prominent example of an index fund is Vanguard’s 500 Index Fund (VFINX), which is designed to mimic the S&P 500 index. Exhibit 16.3 provides a descriptive overview of this fund and indicates that its historical return performance is virtually indistinguishable from that of the benchmark.

The advantage of index mutual funds is that they provide an inexpensive way for investors to acquire a diversified portfolio that emphasizes the desired market or industry within the context of a traditional money management product. As with any mutual fund, the disadvantages are that investors can only liquidate their positions at the end of the trading day (i.e., no intraday trading), usually cannot short sell, and may have unwanted tax repercussions if the fund has an unforeseen need to sell a portion of its holdings, thereby realizing capital gains.

**Exchange-Traded Funds** ETFs are a more recent development in the world of indexed investment products than index mutual funds. Essentially, ETFs are depository receipts that give investors a pro rata claim on the capital gains and cash flows of the securities that are held in deposit by the financial institution that issued the certificates. That is, a portfolio of securities is placed on deposit at a financial institution or into a unit trust, which then issues a single type of certificate representing ownership of the underlying portfolio. In that way, ETFs are similar to the American depository receipts (ADRs) described in Chapter 3.

There are several notable example of ETFs, including (1) Standard & Poor’s 500 Depository Receipts (SPDRs, or “spiders,” as they are sometimes called), which are based on a basket of all the securities held in that index; (2) iShares, which recreate indexed positions in several global developed and emerging equity markets, including countries such as Australia, Mexico, Malaysia, the United Kingdom, France, Germany, Japan, and China; and (3) sector ETFs, which invest in baskets of stocks from specific industry sectors, including consumer services, industrial, technology, financial services, energy, utilities, and cyclical/transportation. Exhibit 16.4 shows descriptive and return data for the SPDR Trust certificates. Notice, however, that the returns to these shares do not track the index quite as closely as did the VFINX fund.
Vanguard 500 Index Fund is an open-end fund incorporated in the USA. The fund’s objective is to track the performance of the Standard & Poor's 500 Index, which is dominated by the stocks of large U.S. companies. The fund invests substantially all of its assets in the stocks that make up the index.

Exhibit 16.3 Details of the Vanguard 500 Index Trust Mutual Fund

A. Description

Vanguard 500 Index Fund is an open-end fund incorporated in the USA. The fund’s objective is to track the performance of the Standard & Poor's 500 Index, which is dominated by the stocks of large U.S. companies. The fund invests substantially all of its assets in the stocks that make up the index.

B. Historical Return Performance

Backpage
A significant advantage of ETFs over index mutual funds is that they can be bought and sold (and short sold) like common stock through an organized exchange or in an over-the-counter market. Further, they are backed by a sponsoring organization (e.g., for SPDRs, the sponsor is PDR Services LLC, a limited liability company wholly owned by NYSE Euronext exchange where SPDR shares trade) that can alter the composition of the underlying portfolio to reflect changes in the composition of the index. Other advantages relative to index funds include an often smaller management fee, the ability for continuous trading while markets are open, and the ability to time capital gain tax realizations. ETF disadvantages include the brokerage commission and the inability to reinvest dividends, except on a quarterly basis.

D. Historical Return Performance

Exhibit 16.5 shows the percentage of U.S.-domiciled mutual funds that were able to produce annual returns in excess of the S&P 500 Index over a period of about a quarter century.

### 16.3 AN OVERVIEW OF ACTIVE EQUITY PORTFOLIO MANAGEMENT STRATEGIES

The goal of active equity management is to earn a return that exceeds the return of a passive benchmark portfolio, net of transaction costs, on a risk-adjusted basis. The job of an active equity manager is not easy. If transaction costs and fees total 1.5 percent of the portfolio’s assets annually, the portfolio has to earn a return 1.5 percentage points above the passive benchmark just to keep pace with it. Further, if the manager’s strategy involves overweighting specific market sectors in anticipation of price increases, the risk of the active portfolio may exceed that of the passive benchmark, so the active portfolio’s return will have to exceed the benchmark by an even wider margin to compensate.

Exhibit 16.5 shows the percentage of U.S.-domiciled mutual funds that were able to produce annual returns in excess of the S&P 500 Index over a period of about a quarter century.
For the majority of this period, the average fund manager was not able to outperform the broad index; the percentage of active funds whose return exceeded that of the index was less than 50 percent in 64 of the 98 quarters represented in the sample. However, the display also indicates that the percentage of active managers beating the market was never zero and occasionally rose as high as 70 percent, which is impressive given that there were more than 4,500 domestic equity funds by the end of 2010. Indeed, evidence provided by Brown and Goetzmann (1995) and Chen, Jegadeesh, and Wermers (2000) shows that fund managers possess significant stock-picking skills that can translate into superior and persistent investment returns.

Exhibit 16.6 provides a broad overview of the different strategies that investment managers might adopt in forming their portfolios, as well as the investment philosophy that underlies each strategy. The passive strategies we just considered are based (at least implicitly) on the notion that capital markets are efficient and so equity portfolios should be invested to mimic broad indexes and not be traded actively. The realm of active management, however, is one in which managers are effectively betting against markets being perfectly efficient. For convenience, Exhibit 16.6 characterizes these bets as falling into three general categories: (1) fundamental, (2) technical, and (3) market anomalies and security attributes.

16.3.1 Fundamental Strategies
As we saw in Chapter 11, the top-down investment process begins with an analysis of broad country and asset class allocations and progresses down through sector allocation decisions to the bottom level, where individual securities are selected. Alternatively, a bottom-up process simply emphasizes the selection of securities without any initial market or sector analysis. Active equity management based on fundamental analysis can start from either direction, depending on what the manager thinks is mispriced relative to his or her valuation models. Generally, active fundamental managers use three generic themes. First, they can try to time the equity market by shifting funds into and out of stocks, bonds, and T-bills depending on broad market forecasts and estimated risk premiums. Second, they can shift funds among different equity sectors and industries (e.g., financial stocks, technology stocks, consumer
cycicals) or among investment styles (e.g., large capitalization, small capitalization, value, growth) to catch the next hot concept before the rest of the market. Third, equity managers can look at individual issues in an attempt to find undervalued stocks.

An asset class rotation strategy shifts funds in and out of the stock market depending on the manager’s perception of how the stock market is valued compared to the various alternative asset classes. Formally, such a strategy is called **tactical asset allocation** and will be described in more detail later in the chapter. A **sector rotation strategy** positions the portfolio to take advantage of the market’s next move. Often this means emphasizing or overweighting (relative to the benchmark portfolio) certain economic sectors or industries in response to the next expected phase of the business cycle. Exhibit 16.7 suggests how sector rotators may position their portfolios to take advantage of stock market trends during the economic cycle.

In general, asset and sector rotation strategies can be extremely profitable but also very risky for a manager to follow. This is shown in Exhibit 16.8, which lists the annual returns in each of several asset and sector classes from 1991 to 2010. The chart documents the tremendous volatility that existed during this period. For instance, bonds, which comprised the best-performing asset class in 2002, made up the worst class in the following four years. Conversely, large-cap growth stocks were one of the best places to invest for six years (i.e., 1994–1999), but this period was bracketed by years when this sector performed quite poorly. The message from this display is clear: While there are impressive gains to be made by correctly timing the hottest (or the coldest) market sectors, a manager must be right substantially more than he or she is wrong. Because this is an extremely difficult thing to do consistently, many investors choose to interpret Exhibit 16.8 as ultimately extolling the virtue of asset and sector class diversification.

A fundamental stock picker operating on a pure bottom-up basis will form a portfolio of equities that can be purchased at a substantial discount to what his or her valuation model indicates they are worth. As we discussed in Chapter 14, these valuation models might be based on absolute judgments about the future of the company (i.e., discounted cash flow) or relative assessments of how attractive the stock is compared with shares in otherwise similar firms (i.e., relative price multiples). In either case, it is usually true that the active manager will find stock picking to be a more reliable, although less profitable, way to invest than market timing.

---

**Exhibit 16.7 The Stock Market and the Business Cycle**

---

Finally, a recent trend in fundamental equity management is the development of the so-called 130/30 strategy. Fowler (2007) explains that funds based on this approach are allowed to take long positions up to 130 percent of the portfolio’s original capital and have short positions up to 30 percent. Relative to "long only" portfolios, these enhanced active funds let managers exploit their expertise in two ways. First, as Jacobs and Levy (2007) note, the use of the short positions creates the leverage needed to extend the long holdings beyond the original capital limit, potentially increasing both risk and expected returns compared to the fund’s benchmark. Second, 130/30 strategies enable managers to make full use of their fundamental research to buy stocks they identify as undervalued as well as short those that are overvalued. Thus, these strategies expand the ways in which investors can capture available alpha opportunities.

### 16.3.2 Technical Strategies

Earlier we discussed the role that technical analysis plays in the stock evaluation process. As we saw, assessing past stock price trends to surmise what information they imply about future price movements was one of the primary tools of this analytical approach. Active managers can form equity portfolios on the basis of past stock price trends by assuming that one of two things will happen: (1) past stock price trends will continue in the same direction, or (2) they will reverse themselves. A contrarian investment strategy is based on the belief that the best time to buy (sell) a stock is when the majority of other investors are the most bearish (bullish) about it. The contrarian investor will attempt to always purchase the stock when it is near its lowest price and sell it (or even short sell it) when it nears its peak. The belief is that stock returns are mean reverting, indicating that, over time, stocks will be priced so as to produce returns consistent with their risk-adjusted expected (i.e., mean) returns. DeBondt and Thaler (1985) demonstrated the potential benefits of forming active portfolios based on this notion. They showed that investing on an overreaction hypothesis could provide consistently superior returns. Exhibit 16.9 summarizes the performance of a market overreaction investment strategy.

Finally, a recent trend in fundamental equity management is the development of the so-called 130/30 strategy. Fowler (2007) explains that funds based on this approach are allowed to take long positions up to 130 percent of the portfolio’s original capital and have short positions up to 30 percent. Relative to “long only” portfolios, these enhanced active funds let managers exploit their expertise in two ways. First, as Jacobs and Levy (2007) note, the use of the short positions creates the leverage needed to extend the long holdings beyond the original capital limit, potentially increasing both risk and expected returns compared to the fund’s benchmark. Second, 130/30 strategies enable managers to make full use of their fundamental research to buy stocks they identify as undervalued as well as short those that are overvalued. Thus, these strategies expand the ways in which investors can capture available alpha opportunities.

16.3.2 Technical Strategies

Earlier we discussed the role that technical analysis plays in the stock evaluation process. As we saw, assessing past stock price trends to surmise what information they imply about future price movements was one of the primary tools of this analytical approach. Active managers can form equity portfolios on the basis of past stock price trends by assuming that one of two things will happen: (1) past stock price trends will continue in the same direction, or (2) they will reverse themselves.

A contrarian investment strategy is based on the belief that the best time to buy (sell) a stock is when the majority of other investors are the most bearish (bullish) about it. The contrarian investor will attempt to always purchase the stock when it is near its lowest price and sell it (or even short sell it) when it nears its peak. The belief is that stock returns are mean reverting, indicating that, over time, stocks will be priced so as to produce returns consistent with their risk-adjusted expected (i.e., mean) returns. DeBondt and Thaler (1985) demonstrated the potential benefits of forming active portfolios based on this notion. They showed that investing on an overreaction hypothesis could provide consistently superior returns. Exhibit 16.9 summarizes

---

**Exhibit 16.9 Abnormal Returns to a Market Overreaction Investment Strategy**

![Graph showing abnormal returns to a market overreaction investment strategy](image)

accelerating earnings and sells (or short sells) stocks with disappointing earnings. The notion behind this strategy is that, ultimately, a company’s share price will follow the direction of its earnings, which is one measure of the firm’s economic success. In judging the degree of momentum in a firm’s earnings, it is often the case in practice that investors will compare the company’s actual EPS to some level of what was expected. Two types of expected earnings are used most frequently: (1) those generated by a statistical model and (2) the consensus forecast of professional stock analysts. Panel B of Exhibit 16.10 shows that earnings momentum strategies were generally successful, although not to the same degree as price momentum strategies.

In our examination of market efficiency in Chapter 6, we saw several anomalies that suggested a role for active equity management. Two of these— the weekend effect and the January effect—involved investing during particular times of the year. While conceptually viable, these anomalies do not produce particularly effective portfolio strategies. That is, managers investing in stocks only in January are not likely to be able to justify their annual fees, while the number of transactions implied by the weekend effect (i.e., buy every Monday, sell every Friday) generally makes for a cost-ineffective portfolio. However, whether or not these calendar-related anomalies produce successful active portfolios, they still are useful rules for trades that an investor plans to make anyway.

A more promising approach to active anomaly investing involves forming portfolios based on various characteristics of the companies themselves. Two characteristics we have seen to matter in the stock market are the total capitalization of the firm’s outstanding equity (i.e., firm size) and the financial position of the firm, as indicated by its various financial ratios (e.g., P/E, P/BV). Over time, firms with smaller market capitalizations produce bigger risk-adjusted returns than those with large market capitalizations. Also, over time, firms with lower P/E and P/BV ratios produce bigger risk-adjusted returns than those with higher levels of those ratios. In fact, we saw in Chapter 9 that low and high levels of these ratios are used in practice to define value and growth stocks, respectively.

Another reason why these firm-specific attributes may be important to active investors is that the term sector considered earlier in the context of rotation strategies also can be defined by different stock attributes. Because the market seems to favor some attributes more than others, sector rotation may involve overweighting stocks with certain characteristics, such as small- or large-capitalization stocks, high- or low-P/E stocks, or stocks classified more generally as value or growth stocks. For example, Panel A of Exhibit 16.11 shows the difference in returns to portfolios invested in small- and large-cap stocks on a monthly basis from 1991–2010. The graph shows the large-cap portfolio return minus the small-cap return, so any net return above the horizontal axis indicates a period when the former outperformed the latter. Notice the consistent firm size rotation and spread in returns that occurred in this period; in given months, both large- and small-cap stocks outperformed the other by over 30 percent. Keep in mind, however, that small-cap stocks are almost always riskier than large-cap stocks. This is shown in Panel B of Exhibit 16.11 as the difference in the standard deviations of the large- and small-cap portfolios.

Similar analysis reveals the potential benefits of forming active global portfolios around financial ratios. Over a 20-year period, Fama and French (1998) divided the stocks in 13 world markets using several different ratios, including P/E and P/BV. They formed portfolios of stocks based on the highest and lowest 30 percent of each ratio and measured returns and standard deviations. For each country and each ratio, Exhibit 16.12 reports the average annual return differential between the lowest-ratio portfolio and the highest-ratio portfolio, as well as the difference in standard deviation for those two portfolios. Over time, portfolios with the lowest P/E and P/BV ratios produced the highest returns everywhere in the world except Italy. Those low-ratio portfolios also tended to be more volatile, although this finding was far less pronounced. The data appear to justify the price momentum strategy in that the portfolios with the highest (lowest) level of price momentum generated the highest (lowest) subsequent returns. Also, the last column shows that a momentum-based hedge fund that was long in the best-trend portfolio and short in the worst-trend one would also have been quite profitable.

### 16.3.3 Anomalies and Attributes

Price momentum strategies could be either based on pure price trend analysis or supported by the underlying economic fundamentals of the company. An earnings momentum strategy is a somewhat more formal active portfolio approach that purchases and holds stocks that have
accelerating earnings and sells (or short sells) stocks with disappointing earnings. The notion behind this strategy is that, ultimately, a company’s share price will follow the direction of its earnings, which is one measure of the firm’s economic success. In judging the degree of momentum in a firm’s earnings, it is often the case in practice that investors will compare the company’s actual EPS to some level of what was expected. Two types of expected earnings are used most frequently: (1) those generated by a statistical model and (2) the consensus forecast of professional stock analysts. Panel B of Exhibit 16.10 shows that earnings momentum strategies were generally successful, although not to the same degree as price momentum strategies.

In our examination of market efficiency in Chapter 6, we saw several anomalies that suggested a role for active equity management. Two of these—the weekend effect and the January effect—involved investing during particular times of the year. While conceptually viable, these anomalies do not produce particularly effective portfolio strategies. That is, managers investing in stocks only in January are not likely to be able to justify their annual fees, while the number of transactions implied by the weekend effect (i.e., buy every Monday, sell every Friday) generally makes for a cost-ineffective portfolio. However, whether or not these calendar-related anomalies produce successful active portfolios, they still are useful rules for trades that an investor plans to make anyway.

A more promising approach to active anomaly investing involves forming portfolios based on various characteristics of the companies themselves. Two characteristics we have seen to matter in the stock market are the total capitalization of the firm’s outstanding equity (i.e., firm size) and the financial position of the firm, as indicated by its various financial ratios (e.g., P/E, P/BV). Over time, firms with smaller market capitalizations produce bigger risk-adjusted returns than those with large market capitalizations. Also, over time, firms with lower P/E and P/BV ratios produce bigger risk-adjusted returns than those with higher levels of those ratios. In fact, we saw in Chapter 9 that low and high levels of these ratios are used in practice to define value and growth stocks, respectively.

Another reason why these firm-specific attributes may be important to active investors is that the term sector considered earlier in the context of rotation strategies also can be defined by different stock attributes. Because the market seems to favor some attributes more than others, sector rotation may involve overweighting stocks with certain characteristics, such as small- or large-capitalization stocks, high- or low-P/E stocks, or stocks classified more generally as value or growth stocks. For example, Panel A of Exhibit 16.11 shows the difference in returns to portfolios invested in small- and large-cap stocks on a monthly basis from 1991–2010. The graph shows the large-cap portfolio return minus the small-cap return, so any net return above the horizontal axis indicates a period when the former outperformed the latter. Notice the consistent firm size rotation and spread in returns that occurred in this period; in given months, both large- and small-cap stocks outperformed the other by over 30 percent. Keep in mind, however, that small-cap stocks are almost always riskier than large-cap stocks. This is shown in Panel B of Exhibit 16.11 as the difference in the standard deviations of the large- and small-cap portfolios.

Similar analysis reveals the potential benefits of forming active global portfolios around financial ratios. Over a 20-year period, Fama and French (1998) divided the stocks in 13 world markets using several different ratios, including P/E and P/BV. They formed portfolios of stocks based on the highest and lowest 30 percent of each ratio and measured returns and standard deviations. For each country and each ratio, Exhibit 16.12 reports the average annual return differential between the lowest-ratio portfolio and the highest-ratio portfolio, as well as the difference in standard deviation for those two portfolios. Over time, portfolios with the lowest P/E and P/BV ratios produced the highest returns everywhere in the world except Italy. Those low-ratio portfolios also tended to be more volatile, although this finding was far less
strategy, while earnings momentum is ultimately a fundamental approach to investing so it should not be surprising that they can lead to forming very different types of portfolios. That is, a price momentum investor might be attracted to a stock with consistently strong, positive returns regardless of why they occurred. In contrast, the earnings momentum investor is likely to be attracted to stocks for companies that generate earnings in excess of market expectations, even if the past returns for those stocks have been negative.

To examine these differences in more specific terms, we performed two separate computer screenings of the stocks in the Russell 1000 Index during a recent period. In the first, the stocks were ranked from highest to lowest in terms of their returns over the past six months, the characteristic likely to be appealing to a price momentum investor. In the second screen, the stocks were ranked from highest to lowest by their earnings surprise (i.e., the percentage difference between the firm’s actual earnings and the consensus forecast of professional stock analysts) over the prior year, which is what an earnings momentum investor would be interested in knowing. Financial data for 10 of the top-ranked stocks from each screening are shown in Exhibit 16.13.

The stocks most likely to be included in a price momentum-based portfolio all share the feature that they have had strong positive price increases over the prior three-month, six-month, and one-year periods. However, there appear to be few other similarities between these securities. In particular, the earnings surprise component is actually negative for four of the stocks listed, even though the average earnings per share for these companies is forecast to rise from $3.92 to $4.95. Thus, the price momentum investor is making a bet on the continuation of past price trends, perhaps for reasons that have more to do with the psychology of other investors than with the underlying economic position of the companies themselves.

On the other hand, the earnings momentum-based manager will be attracted to stocks for companies that consistently produce earnings that surpass analyst expectations. The 10 positions shown at the bottom of Exhibit 16.13 all have demonstrated that ability over the past year. Additionally, eight of these stocks have a forecasted future level of earnings that is higher than their current level.

uniform across countries. As we will see shortly, these results are important for understanding the differences between the value and growth investment styles.

16.3.4 Forming Momentum-Based Stock Portfolios: Two Examples

As we have just seen, in the world of active equity portfolio management the concept of momentum investing can mean two things: price momentum and earnings momentum. However, the justifications for these strategies are very different—price momentum is a technical...
strategy, while earnings momentum is ultimately a fundamental approach to investing—so it
should not be surprising that they can lead to forming very different types of portfolios. That
is, a price momentum investor might be attracted to a stock with consistently strong, positive
returns regardless of why they occurred. In contrast, the earnings momentum investor is likely
to be attracted to stocks for companies that generate earnings in excess of market expectations,
even if the past returns for those stocks have been negative.

To examine these differences in more specific terms, we performed two separate computer
screenings of the stocks in the Russell 1000 Index during a recent period. In the first, the
stocks were ranked from highest to lowest in terms of their returns over the past six months,
the characteristic likely to be appealing to a price momentum investor. In the second screen,
the stocks were ranked from highest to lowest by their earnings surprise (i.e., the percentage
difference between the firm’s actual earnings and the consensus forecast of professional stock
analysts) over the prior year, which is what an earnings momentum investor would be inter-
ested in knowing. Financial data for 10 of the top-ranked stocks from each screening are
shown in Exhibit 16.13.

The stocks most likely to be included in a price momentum-based portfolio all share
the feature that they have had strong positive price increases over the prior three-month,
six-month, and one-year periods. However, there appear to be few other similarities between
these securities. In particular, the earnings surprise component is actually negative for four
of the stocks listed, even though the average earnings per share for these companies is
forecast to rise from $3.92 to $4.95. Thus, the price momentum investor is making a bet on the
continuation of past price trends, perhaps for reasons that have more to do with the psy-
chology of other investors than with the underlying economic position of the companies
themselves.

On the other hand, the earnings momentum-based manager will be attracted to stocks for
companies that consistently produce earnings that surpass analyst expectations. The 10 posi-
tions shown at the bottom of Exhibit 16.13 all have demonstrated that ability over the past
year. Additionally, eight of these stocks have a forecasted future level of earnings that is higher
than current earnings. However, many of these stocks have also experienced negligible or negative returns at some point over the prior 12 months, which could mean that the stock disappointed investors in some other way in the past. Despite this, the belief of the earnings momentum investor is that firms whose fundamental economic position allows them to beat expectations will eventually see their stock prices increase to reflect that performance. Thus, the trading strategy in an earnings momentum portfolio is simple: Buy (and hold) stocks with positive earnings momentum, and sell those stocks when that momentum deteriorates or turns negative.

Two final points should be mentioned. First, notice that only one stock (AVP) was ranked at the top of both the price-momentum and the earnings-momentum screens. This supports the earlier observation that these two active strategies tend to produce different collections of stocks. Second, the stocks listed in Exhibit 16.13 were selected in a purely mechanical manner without any additional insight from a professional money manager who might override the computer screen for any of several reasons. For instance, an earnings momentum manager following a “Growth at a Reasonable Price” (i.e., GARP) discipline might be more attracted to positive earnings surprise stocks that also sell at lower PEG ratios (FST, EL) than to those that appear to be more expensive by that measure (NLY, CBL).

16.3.5 Tax Efficiency and Active Equity Management

We saw earlier that the primary intention of an actively managed equity portfolio is to produce a return that exceeds that of its passive benchmark. Of course, to accomplish that goal the active manager must form a portfolio that differs from the index itself, which usually requires trading stocks into and out of the fund on a frequent basis. Compared to a passively managed portfolio, there are two potential costs associated with these additional stock trades. First, the active fund will incur additional transaction costs, which will reduce the net return to the portfolio. Second, selling stocks that have appreciated in price will create a capital gain on which investors may have to pay taxes.

While the negative effect on returns due to high transaction fees are shared by all investors, the tax consequences of active equity management are a concern only for those investors who hold their portfolio in a taxable account. Many investors— institutions such as pension funds and university endowment funds or individuals with tax-deferred retirement plans— do not have to worry about paying additional taxes on the trades of an active portfolio manager. Reichenstein (2006) as well as Horan and Adler (2009) note, though, that many other investors— particularly individuals not investing through a retirement plan— do need to worry about the tax efficiency of the active portfolio because this is an expense that they will ultimately bear.

The fund’s portfolio turnover is an indirect measure of the amount of trading that could lead to a higher tax bill for a taxable investor. The portfolio turnover ratio is typically measured as the total dollar value of the securities sold from the portfolio in a year divided by the average dollar value of the assets managed by the fund. For instance, an active manager that sold $75 million worth of stocks in a year from a portfolio that averaged $100 million in assets under management would have a turnover ratio of 75 percent. In essence, the manager has replaced three out of every four stocks in the portfolio at some point during the year. While the turnover ratio is a good indicator of overall trading activity, it does not necessarily indicate that the majority of those trades generated capital gains that in turn created taxable events. Many of those trades might have been transacted at losses that actually offset the gains created by other sales.

A more direct measure of how well portfolio managers balance the capital gains and losses resulting from their trades is the tax cost ratio. As developed by Morningstar, Inc., a leading provider of investment analysis in the mutual fund industry, this statistic compares a fund’s 5-year EPS Surprise [Act-Est] to Est PEG.
than current earnings. However, many of these stocks have also experienced negligible or negative returns at some point over the prior 12 months, which could mean that the stock disappointed investors in some other way in the past. Despite this, the belief of the earnings momentum investor is that firms whose fundamental economic position allows them to beat expectations will eventually see their stock prices increase to reflect that performance. Thus, the trading strategy in an earnings momentum portfolio is simple: Buy (and hold) stocks with positive earnings momentum, and sell those stocks when that momentum deteriorates or turns negative.

Two final points should be mentioned. First, notice that only one stock (AVP) was ranked at the top of both the price-momentum and the earnings-momentum screens. This supports the earlier observation that these two active strategies tend to produce different collections of stocks. Second, the stocks listed in Exhibit 16.13 were selected in a purely mechanical manner without any additional insight from a professional money manager who might override the computer screen for any of several reasons. For instance, an earnings momentum manager following a “Growth at a Reasonable Price” (i.e., GARP) discipline might be more attracted to positive earnings surprise stocks that also sell at lower PEG ratios (FST, EL) than to those that appear to be more expensive by that measure (NLY, CBL).

### 16.3.5 Tax Efficiency and Active Equity Management

We saw earlier that the primary intention of an actively managed equity portfolio is to produce a return that exceeds that of its passive benchmark. Of course, to accomplish that goal the active manager must form a portfolio that differs from the index itself, which usually requires trading stocks into and out of the fund on a frequent basis. Compared to a passively managed portfolio, there are two potential costs associated with these additional stock trades. First, the active fund will incur additional transaction costs, which will reduce the net return to the portfolio. Second, selling stocks that have appreciated in price will create a capital gain on which investors may have to pay taxes.

While the negative effect on returns due to high transaction fees are shared by all investors, the tax consequences of active equity management are a concern only for those investors who hold their portfolio in a taxable account. Many investors—such as pension funds and university endowment funds or individuals with tax-deferred retirement plans—do not have to worry about paying additional taxes on the trades of an active portfolio manager. Reichenstein (2006) as well as Horan and Adler (2009) note, though, that many other investors—particularly individuals not investing through a retirement plan—do need to worry about the tax efficiency of the active portfolio because this is an expense that they will ultimately bear.

The fund’s portfolio turnover is an indirect measure of the amount of trading that could lead to a higher tax bill for a taxable investor. The portfolio turnover ratio is typically measured as the total dollar value of the securities sold from the portfolio in a year divided by the average dollar value of the assets managed by the fund. For instance, an active manager that sold $75 million worth of stocks in a year from a portfolio that averaged $100 million in assets under management would have a turnover ratio of 75 percent. In essence, the manager has replaced three out of every four stocks in the portfolio at some point during the year. While the turnover ratio is a good indicator of overall trading activity, it does not necessarily indicate that the majority of those trades generated capital gains that in turn created taxable events. Many of those trades might have been transacted at losses that actually offset the gains created by other sales.

A more direct measure of how well portfolio managers balance the capital gains and losses resulting from their trades is the tax cost ratio. As developed by Morningstar, Inc., a leading provider of investment analysis in the mutual fund industry, this statistic compares a fund’s
growth stock managers when selling their services to clients. Exhibit 16.15 indicates how pervasive these styles have become. Using the classifications of Morningstar, Inc., the number of available growth- and value-oriented funds grew dramatically, particularly toward the end of the reporting period. The chart shows that the available number of growth fund products expanded by more than 18 percent per year over this period, with large-cap portfolios being the most prevalent. Value fund availability did not increase quite as much but still expanded substantially.

The distinction between value and growth investing can be best appreciated by considering the thought process of a representative manager for each style. In Chapter 11, we saw that the price/earnings ratio for any company can be expressed as:

\[ P/E = \frac{\text{Current Price per Share}}{\text{Earnings per Share}} \]

where the earnings per share (EPS) measure can be based on either current or forecasted firm performance. Value and growth managers will focus on different aspects of this equation when evaluating stocks. Specifically, a growth-oriented investor will:

1. Focus on the EPS component (i.e., the denominator) of the P/E ratio and its economic determinants;
2. Look for companies that he or she expects to exhibit rapid EPS growth in the future; and
3. Often implicitly assume that the P/E ratio will remain constant over the near term, meaning that the stock price will rise as forecasted earnings growth is realized.

On the other hand, a value-oriented investor will:

1. Focus on the price component (i.e., the numerator) of the P/E ratio; he or she must be convinced that the price of the stock is "cheap" by some means of comparison;
2. Not care a great deal about current earnings or the fundamental drivers of earnings growth; and
3. Often implicitly assume that the P/E ratio is below its natural level and that the market will soon "correct" this situation by increasing the stock price with little or no change in earnings.

The pretax return (PTR) with this same return adjusted for taxes (TAR), assuming that investors pay taxes on net short-term and long-term capital gains at the highest rate.

\[ \text{Tax Cost Ratio} = \left[ 1 - \left( 1 + \frac{\text{TAR}}{1 + \text{PTR}} \right) \right] \times 100 \]

Ptak (2002) explains that the tax cost ratio represents the percentage of an investor’s assets that are lost to taxes on a yearly basis due to the trading strategy employed by the fund manager. Notice that even if there is high turnover in a portfolio, TAR need not be significantly below PTR if the manager was able to “harvest” enough capital losses to balance out the capital gains associated by other trades.

For example, Exhibit 16.14 lists tax efficiency statistics for both a passive (the Vanguard 500 Index Fund we saw earlier) and an active (MFS Research Fund) mutual fund. Compared to the index fund, the active fund had a higher expense ratio (which includes all management, operating, and administrative fees as a percentage of the funds assets) as well as a higher turnover ratio (73% vs. 12%). Thus, MFRX was clearly a more expensive fund to investors with substantially more stock trading than VFINX. Despite those additional expenses, it outperformed the benchmark fund on a pretax basis over the one-year period (15.46% vs. 14.91%) and five-year period (3.56% vs. 2.21%) shown. However, once the tax efficiency of the trades in the two funds is considered, the story changes. Specifically, notice that there is very little difference between the pretax and tax-adjusted returns for VFINX, meaning that what little trading there was in the index fund was fairly balanced in the creation of capital gains and losses. This leads to a five-year tax cost ratio for VFINX of just 0.32% (= [1 - (1.0188/1.0221)] × 100). Conversely, the trades in MFRX were far less tax efficient; its five-year tax cost ratio was 1.41%, meaning that taxable investors in the fund saw their positions reduced by almost 150 basis points per year due to taxes. This tax efficiency gap was even more dramatic for the one-year period in 2010.

16.4 Value versus Growth Investing: A Closer Look

An important development in active equity management during the last several years has been the creation of portfolio strategies based on value- and growth-oriented investment styles. It is now common for money management firms to define themselves as “value stock managers” or
In summary, a growth investor focuses on the current and future economic story of a company, with less regard to share valuation. The value investor focuses on share price in anticipation of a market correction and, possibly, improving company fundamentals.

The conceptual difference between value and growth investing may be reasonably straightforward, but classifying individual stocks into the appropriate style is not always simple in practice. Since detailed company valuations are time-consuming to produce, most analysts rely on more easily obtained financial indicators—such as P/E and P/BV ratios, dividend yields, and EPS growth rates—to define both individual equity holdings and style benchmark portfolios. Exhibit 16.16 shows one approach for classifying firms according to style and market capitalization. Notice that value stocks are relatively cheap (e.g., low P/BV, high yield) and have modest growth opportunities (e.g., regulated firms), while growth stocks tend to be more expensive, reflecting their superior earnings potential (e.g., technology firms).

To get a better feel for the types of portfolios these two investment styles might produce, Exhibit 16.17 lists representative samples of the top holdings for the Harbor Capital Appreciation (HACAX) growth-oriented mutual fund and the T. Rowe Price Value (TRVLX) mutual fund as of September 30, 2010. Both funds feature large-cap companies, but they differ in their investment approach in other important ways. HACAX’s biggest holdings emphasize technology (AAPL, GOOG, CSCO) firms, while TRVLX invests more on the financial (JPM, WFC) side among a variety of diverse holdings (PFE, GE, LUV). On average, the stocks in the HACAX portfolio tend to have higher P/E and P/BV ratios and greater future growth potential than those in TRVLX. Both portfolios appear to have comparable levels of risk (i.e., beta), but TRVLX holds stocks that tend to pay higher dividends. Interestingly, both portfolios hold IBM and Schlumberger among their top holdings, although these stocks would seem to be a better fit with HACAX’s other positions. This underscores the room for investor judgment involved in classifying companies along the value-growth dimension.

Although investors appear to pay somewhat more attention to growth-oriented strategies, research has shown that a value approach to portfolio management tends to provide superior returns. In particular, Capaul, Rowley, and Sharpe (1993) studied the long-term performance of value and growth portfolios (defined by relative P/BV ratios) in six countries: the United States, Canada, Japan, Europe, Australia, and New Zealand. Exhibit 16.15 indicates how pervasive these styles have become. Using the classifications of Morningstar, Inc., the number of available growth- and value-oriented funds grew dramatically, particularly toward the end of the reporting period. The chart shows that the available number of growth fund products expanded by more than 18 percent per year over this period, with large-cap portfolios being the most prevalent. Value fund availability did not increase quite as much but still expanded substantially.

The distinction between value and growth investing can be best appreciated by considering the thought process of a representative manager for each style. In Chapter 11, we saw that the price/earnings ratio for any company can be expressed as:

\[
P/E \text{ Ratio} = \frac{\text{Current Price per Share}}{\text{Earnings per Share}}
\]

where the earnings per share (EPS) measure can be based on either current or forecasted firm performance. Value and growth managers will focus on different aspects of this equation when evaluating stocks. Specifically, a growth-oriented investor will:

- Focus on the EPS component (i.e., the denominator) of the P/E ratio and its economic determinants;
- Look for companies that he or she expects to exhibit rapid EPS growth in the future; and
- Often implicitly assume that the P/E ratio will remain constant over the near term, meaning that the stock price will rise as forecasted earnings growth is realized.

On the other hand, a value-oriented investor will:

- Focus on the price component (i.e., the numerator) of the P/E ratio; he or she must be convinced that the price of the stock is “cheap” by some means of comparison;
- Not care a great deal about current earnings or the fundamental drivers of earnings growth; and
- Often implicitly assume that the P/E ratio is below its natural level and that the market will soon “correct” this situation by increasing the stock price with little or no change in earnings.

“growth stock managers” when selling their services to clients. Exhibit 16.15 indicates how pervasive these styles have become. Using the classifications of Morningstar, Inc., the number of available growth- and value-oriented funds grew dramatically, particularly toward the end of the reporting period. The chart shows that the available number of growth fund products expanded by more than 18 percent per year over this period, with large-cap portfolios being the most prevalent. Value fund availability did not increase quite as much but still expanded substantially.

The distinction between value and growth investing can be best appreciated by considering the thought process of a representative manager for each style. In Chapter 11, we saw that the price/earnings ratio for any company can be expressed as:

\[
P/E \text{ Ratio} = \frac{\text{Current Price per Share}}{\text{Earnings per Share}}
\]

where the earnings per share (EPS) measure can be based on either current or forecasted firm performance. Value and growth managers will focus on different aspects of this equation when evaluating stocks. Specifically, a growth-oriented investor will:

- Focus on the EPS component (i.e., the denominator) of the P/E ratio and its economic determinants;
- Look for companies that he or she expects to exhibit rapid EPS growth in the future; and
- Often implicitly assume that the P/E ratio will remain constant over the near term, meaning that the stock price will rise as forecasted earnings growth is realized.

On the other hand, a value-oriented investor will:

- Focus on the price component (i.e., the numerator) of the P/E ratio; he or she must be convinced that the price of the stock is “cheap” by some means of comparison;
- Not care a great deal about current earnings or the fundamental drivers of earnings growth; and
- Often implicitly assume that the P/E ratio is below its natural level and that the market will soon “correct” this situation by increasing the stock price with little or no change in earnings.

This motivation is based on an excellent overview of value- and growth-oriented investment styles that can be found in Christopherson and Williams (1993).
In summary, a growth investor focuses on the current and future economic “story” of a company, with less regard to share valuation. The value investor focuses on share price in anticipation of a market correction and, possibly, improving company fundamentals.

The conceptual difference between value and growth investing may be reasonably straightforward, but classifying individual stocks into the appropriate style is not always simple in practice. Since detailed company valuations are time-consuming to produce, most analysts rely on more easily obtained financial indicators—such as P/E and P/BV ratios, dividend yields, and EPS growth rates—to define both individual equity holdings and style benchmark portfolios. Exhibit 16.16 shows one approach for classifying firms according to style and market capitalization. Notice that value stocks are relatively cheap (e.g., low P/BV, high yield) and have modest growth opportunities (e.g., regulated firms), while growth stocks tend to be more expensive, reflecting their superior earnings potential (e.g., technology firms).

To get a better feel for the types of portfolios these two investment styles might produce, Exhibit 16.17 lists representative samples of the top holdings for the Harbor Capital Appreciation (HACAX) growth-oriented mutual fund and the T. Rowe Price Value (TRVLX) mutual fund as of September 30, 2010. Both funds feature large-cap companies, but they differ in their investment approach in other important ways. HACAX’s biggest holdings emphasize technology (AAPL, GOOG, CSCO) firms, while TRVLX invests more on the financial (JPM, WFC) side among a variety of diverse holdings (PFE, GE, LUV). On average, the stocks in the HACAX portfolio tend to have higher P/E and P/BV ratios and greater future growth potential than those in TRVLX. Both portfolios appear to have comparable levels of risk (i.e., beta), but TRVLX holds stocks that tend to pay higher dividends. Interestingly, both portfolios hold IBM and Schlumberger among their top holdings, although these stocks would seem to be a better fit with HACAX’s other positions. This underscores the room for investor judgment involved in classifying companies along the value-growth dimension.

Although investors appear to pay somewhat more attention to growth-oriented strategies, research has shown that a value approach to portfolio management tends to provide superior returns. In particular, Capaul, Rowley, and Sharpe (1993) studied the long-term performance of value and growth portfolios (defined by relative P/BV ratios) in six countries: the United

As we have seen, there are many equity investment styles, including forming portfolios around stock characteristics such as market capitalization, leverage, industry sector, relative valuation, and growth potential. Style analysis attempts to explain the variability in the observed returns to a security portfolio in terms of the movements in the returns to a series of benchmark portfolios capturing the essence of a particular security characteristic. Effectively, style analysis determines the combination of long positions in a collection of passive indexes that best mimics the past performance of a security portfolio.

The process compares the past returns to a manager’s portfolio with those to a series of indexes representing different investment styles to determine the relationship between the fund and those specific styles. The more highly correlated a fund’s returns are with a given style index, the greater the weighting that style is given in the statistical assessment. The goals of style analysis are to better understand the underlying influences responsible for the portfolio’s performance and to properly classify the manager’s strategy when comparing him or her with other managers. Thus, regardless of whatever investment objective a manager might profess to follow, style analysis allows the portfolio to speak for itself.

Exhibit 16.20 shows a simple style grid that could be used to classify a manager’s performance along two dimensions: firm size (large cap, mid cap, small cap) and relative value (value, blend, growth) characteristics. An investor whose portfolio produced returns best mimicked by the returns to indexes representing a small-cap value style (such as Manager A) would be plotted in the lower left quadrant of the grid. These grids also establish the implicit investment style for popular stock market indicators. For example, Exhibit 16.21 shows the style plot points for the S&P 500, S&P Midcap, Wilshire 5000, NASDAQ Composite, Russell 3000 (R3), Russell 2000

States, the United Kingdom, Japan, France, Germany, and Switzerland. They demonstrated that global value stocks outperformed global growth stocks by an average of 3.3 percent per year. More recent evidence provided by Chan and Lakonishok (2004) supports this conclusion. Exhibit 16.18, which shows the cumulative performance of a large-cap growth index (Russell 1000 Growth) and a large-cap value index (Russell 1000 Value), indicates that this performance advantage persisted in the U.S. market through December 2010. This is all the more notable for the fact that, except for the 2008 market crisis, much of this period was a particularly good time for the large-cap growth investment style.

It is tempting to conclude that value is unambiguously superior to growth as an investment style. However, although value investing produces higher average returns than growth investing, this does not occur with much consistency from one investment period to another. Panel A of Exhibit 16.19 shows that there are significant differences in the value-growth return spread (based on the rolling annual performance of the Russell 1000 Value and Growth Indexes) over time. The spread ranged from over 50 percent in favor of value investing to more than 30 percent to the advantage of the growth style. Knewston, Sias, and Whidbee (2010) show how investors can benefit from timing this style rotation. Conversely, Panel B indicates that the spread between value and growth return standard deviations, while itself volatile, is generally negative, meaning that the growth strategy is usually riskier than the value approach.
16.5 An Overview of Style Analysis

As we have seen, there are many equity investment styles, including forming portfolios around stock characteristics such as market capitalization, leverage, industry sector, relative valuation, and growth potential. Style analysis attempts to explain the variability in the observed returns to a security portfolio in terms of the movements in the returns to a series of benchmark portfolios capturing the essence of a particular security characteristic. Effectively, style analysis determines the combination of long positions in a collection of passive indexes that best mimics the past performance of a security portfolio.

The process compares the past returns to a manager’s portfolio with those to a series of indexes representing different investment styles to determine the relationship between the fund and those specific styles. The more highly correlated a fund’s returns are with a given style index, the greater the weighting that style is given in the statistical assessment. The goals of style analysis are to better understand the underlying influences responsible for the portfolio’s performance and to properly classify the manager’s strategy when comparing him or her with other managers. Thus, regardless of whatever investment objective a manager might profess to follow, style analysis allows the portfolio to speak for itself.

Exhibit 16.20 shows a simple style grid that could be used to classify a manager’s performance along two dimensions: firm size (large cap, mid cap, small cap) and relative value (value, blend, growth) characteristics. An investor whose portfolio produced returns best mimicked by the returns to indexes representing a small-cap value style (such as Manager A) would be plotted in the lower left quadrant of the grid. These grids also establish the implicit investment style for popular stock market indicators. For example, Exhibit 16.21 shows the style plot points for the S&P 500, S&P Midcap, Wilshire 5000, NASDAQ Composite, Russell 3000 (R3), Russell 2000
Notice that the S&P 500 can be characterized as a large-cap, blend (i.e., between value and growth) fund. As such, it may not be the appropriate performance benchmark for someone managing a mid-cap, growth-oriented portfolio.

Source: Rolling 12-month returns to Russell 1000 Value and Growth Indexes.
Formally, style analysis relies on the constrained least squares procedure, with the returns to the manager's portfolio as the dependent variable and the returns to the style index portfolios as the independent variables. There are often three constraints employed: (1) no intercept term is specified, (2) the coefficients must sum to one, and (3) all the coefficients must be non-negative. As developed by Sharpe (1992), returns-based style analysis is simply an application of an asset class factor model:

\[ R_{pt} = \sum_{j=1}^{n} b_{pj} F_{jt} + e_{pt} \]

where:
- \( R_{pt} \) = the \( t \)th period return to the portfolio of Manager \( p \)
- \( F_{jt} \) = the \( t \)th period return to the \( j \)th style factor
- \( b_{pj} \) = the sensitivity of Portfolio \( p \) to Style \( j \)
- \( e_{pt} \) = the portion of the return variability in Portfolio \( p \) not explained by variability in the set of factors

As with any regression equation, the coefficient of determination can be defined as:

\[ R^2 = 1 - \frac{\sigma^2(e_{pt})}{\sigma^2(R_{pt})} \]

Because of the way the factor model is designed, \( R^2 \) can be interpreted as the percentage of Manager \( p \)'s return variability due to the portfolio's style, with \( 1 - R^2 \) due to his or her selection skills.

The benchmark portfolios selected as style analysis factors should be consistent with the manager's pronounced style. A different set of indexes might be specified for a domestic equity fund than for a global bond fund. Also, an effective benchmark portfolio should be easy to measure, have an investable proxy, and be as uncorrelated as possible with other style indexes.

To illustrate how this process can be implemented, the investment styles of the two mutual funds we considered earlier—Harbor Capital Appreciation Fund and T. Rowe Price Value Fund—were analyzed over a five-year interval ending in June 2011. Both portfolios performed well during the period, generating average annual returns that exceeded their respective benchmarks by more than 2.00%. However, Exhibit 16.22 shows that the managers of these portfolios followed very different styles. The bar charts indicate how each portfolio's returns were correlated with the underlying style factors. Accordingly, the style of HACAX is most closely related to the U.S. Large Growth Stock Index, while TRVLX is most closely connected with a value stock index, with some growth stock and global equity exposure as well. Also, security selection accounted for a relatively small amount of TRVLX return variability (2.2 percent) but was more of a consideration (5.3 percent) in the HACAX portfolio.

Finally, style analysis can also show whether a manager maintains a consistent investment style over time. This can be accomplished by reestimating the optimal combination of mimicking style indexes as additional performance data become available and then overlaying the plot points on the same grid. Exhibit 16.23 shows the connected sequence of plot points—or "snail trails," as they are sometimes called—for four different mutual funds managed by a leading investment company. Two of these funds (I and II) have well-defined style mandates and have been able to achieve relatively stable investment policies. The other two—III and IV—have exhibited considerable style drift, which in both cases is due to their flexible investment missions. Of course, an investor needs to be cautious about a manager whose portfolio exhibits unintentional style drift.

---

Source: Based on Fidelity Management and Research Company data.

(R2), and Russell 1000 (R1), among others. Notice that the S&P 500 can be characterized as a large-cap, blend (i.e., between value and growth) fund. As such, it may not be the appropriate performance benchmark for someone managing a mid-cap, growth-oriented portfolio.

---

2Exhibit 16.21 also plots the investment style for various subsets of the Russell indexes. For example, R1V and R1G are, respectively, the value and growth components of the Russell 1000. They are created by ranking the 1,000 companies in the index by their price-to-book ratios and assigning those with the lowest (highest) ratios to the value (growth) subindex.
Formally, style analysis relies on the constrained least squares procedure, with the returns to the manager’s portfolio as the dependent variable and the returns to the style index portfolios as the independent variables. There are often three constraints employed: (1) no intercept term is specified, (2) the coefficients must sum to one, and (3) all the coefficients must be non-negative. As developed by Sharpe (1992), returns-based style analysis is simply an application of an asset class factor model:

\[ R_{pt} = [b_{p1}F_{1t} + b_{p2}F_{2t} + \cdots + b_{pn}F_{nt}] + e_{pt} \]

where:
- \( R_{pt} \) = the \( t \)th period return to the portfolio of Manager \( p \)
- \( F_{jt} \) = the \( t \)th period return to the \( j \)th style factor
- \( b_{pj} \) = the sensitivity of Portfolio \( p \) to Style \( j \)
- \( e_{pt} \) = the portion of the return variability in Portfolio \( p \) not explained by variability in the set of factors

As with any regression equation, the coefficient of determination can be defined as:

\[ R^2 = 1 - \frac{\sigma^2(e_p)}{\sigma^2(R_p)} \]

Because of the way the factor model is designed, \( R^2 \) can be interpreted as the percentage of Manager \( p \)’s return variability due to the portfolio’s style, with \( (1 - R^2) \) due to his or her selection skills.

The benchmark portfolios selected as style analysis factors should be consistent with the manager’s pronounced style. A different set of indexes might be specified for a domestic equity fund than for a global bond fund. Also, an effective benchmark portfolio should be easy to measure, have an investable proxy, and be as uncorrelated as possible with other style indexes.

To illustrate how this process can be implemented, the investment styles of the two mutual funds we considered earlier—Harbor Capital Appreciation Fund and T. Rowe Price Value Fund—were analyzed over a five-year interval ending in June 2011. Both portfolios performed well during the period, generating average annual returns that exceeded their respective benchmarks by more than 2.00%. However, Exhibit 16.22 shows that the managers of these portfolios followed very different styles. The bar charts indicate how each portfolio’s returns were correlated with the underlying style factors. Accordingly, the style of HACAX is most closely related to the U.S. Large Growth Stock Index, while TRVLX is most closely connected with a value stock index, with some growth stock and global equity exposure as well. Also, security selection accounted for a relatively small amount of TRVLX return variability (2.2 percent) but was more of a consideration (5.3 percent) in the HACAX portfolio.

Finally, style analysis can also show whether a manager maintains a consistent investment style over time. This can be accomplished by reestimating the optimal combination of mimicking style indexes as additional performance data become available and then overlaying the plot points on the same grid. Exhibit 16.23 shows the connected sequence of plot points—or “snail trails,” as they are sometimes called—for four different mutual funds managed by a leading investment company. Two of these funds (I and II) have well-defined style mandates and have been able to achieve relatively stable investment policies. The other two—III and IV—have exhibited considerable style drift, which in both cases is due to their flexible investment missions. Of course, an investor needs to be cautious about a manager whose portfolio exhibits unintentional style drift.
16.6 Asset Allocation Strategies

An equity portfolio does not stand in isolation; it is part of an investor’s overall investment portfolio. Many times the equity portfolio is part of a balanced portfolio that also contains holdings in various long- and short-term debt securities (such as bonds and Treasury bills). In such situations, the portfolio manager must consider more than just the composition of the equity or the bond component of the portfolio. The manager also must determine the appropriate mix of asset categories in the entire portfolio. There are four general strategies for determining the asset mix of a portfolio: integrated, strategic, tactical, and insured asset allocation methods.
This integrated approach to portfolio formation is illustrated in Exhibit 16.24. Sharpe (1987, 1990) describes three key steps to integrated asset allocation. First, both capital market conditions and investor-specific objectives and constraints (e.g., risk tolerance, investment horizon, tax status) are established before the asset mix is determined. These processes are summarized in boxes C2 and I2, respectively, with the outcomes of those processes in boxes C3 and I3. An example of C3 might be the Markowitz efficient frontier containing portfolios of optimal risk–expected return combinations; the end product of I3 might be captured in an investment policy statement.

The second step in the integrated asset allocation process combines the information from the first step to select the single best portfolio for the investor in question. This is captured by the optimizer box in M1, with the resulting asset mix being shown in M2. One simple way of seeing how M1 might work is to calculate the expected utility (EU) using the following formula:

\[
\text{EU}_{pk} = \text{ER}_p - \sigma^2_p - RT_k
\]

where \(\text{ER}_p\) and \(\sigma^2_p\) are the expected return and variance for Portfolio \(p\) (which come from C3) and \(RT_k\) is the risk-tolerance factor for Investor \(k\) (which comes from I3). The risk-tolerance factor is intended to capture the essence of an investor’s attitude toward risk bearing. Notice that the higher this number, the more risk tolerant the investor is and the less Portfolio \(p\) has.

**Fund IV**

### 16.6.1 Integrated Asset Allocation

The *integrated asset allocation* strategy separately examines (1) capital market conditions and (2) the investor’s objectives and constraints. These factors are combined to establish the portfolio asset mix that offers the best opportunity for meeting the investor’s needs. The actual portfolio returns are used as inputs to an iterative process in which changes in the investor’s objectives, constraints, and capital market expectations are noted. The optimal portfolio is then revised based on this update.
This integrated approach to portfolio formation is illustrated in Exhibit 16.24. Sharpe (1987, 1990) describes three key steps to integrated asset allocation. First, both capital market conditions and investor-specific objectives and constraints (e.g., risk tolerance, investment horizon, tax status) are established before the asset mix is determined. These processes are summarized in boxes C2 and I2, respectively, with the outcomes of those processes in boxes C3 and I3. An example of C3 might be the Markowitz efficient frontier containing portfolios of optimal risk–expected return combinations; the end product of I3 might be captured in an investment policy statement.

The second step in the integrated asset allocation process combines the information from the first step to select the single best portfolio for the investor in question. This is captured by the optimizer box in M1, with the resulting asset mix being shown in M2. One simple way of seeing how M1 might work is to calculate the expected utility (EU) of each prospective asset mix using the following formula:

\[ EU_{pk} = ER_p - \left( \frac{\sigma_p^2}{RT_k} \right) = ER_p - (\text{Risk Penalty}) \]

where \( ER_p \) and \( \sigma_p^2 \) are the expected return and variance for Portfolio \( p \) (which come from C3) and \( RT_k \) is the risk-tolerance factor for Investor \( k \) (which comes from I3). The risk-tolerance factor is intended to capture the essence of an investor’s attitude toward risk bearing. Notice that the higher this number, the more risk tolerant the investor is and the less Portfolio \( p \) has
One way to think of the strategic allocation process is as being equivalent to the integrated asset allocation process shown in Exhibit 16.24 but without the feedback loops. That is, the manager will determine the long-term asset allocation that is best suited for a particular investor by optimizing information from both the capital market and that investor. However, once this asset mix is established, the manager does not attempt to adjust the allocation according to temporary changes in market and investor circumstances. Thus, as Ezra (1998) points out, the strategic allocation should define the basic nature of the trade-off between opportunity and safety that confronts the investor.

As an example, Brown, Garlappi, and Tiu (2010) examined the asset allocation patterns of college and university endowment funds in the United States and Canada. Exhibit 16.26 shows both the average actual and strategic (i.e., target) investment proportions for their fund sample in 2002 and 2005. There are several interesting things to note. First, endowment fund managers made some dramatic adjustments in the targeted investment proportions over these years; for instance, the strategic allocations to both U.S. equity (49.6% to 44.7%) and U.S. fixed-income (25.1% to 21.5%) declined significantly. Second, managers made an explicit decision to shift these assets to investments in the non-U.S. equity and hedge fund categories. Finally, planned investments in the rest of the asset classes listed remained relatively stable, which is consistent with the idea of a strategic allocation as a long-term view.

### 16.6.3 Tactical Asset Allocation

Unlike an investor’s strategic allocation, which is set with a long-term focus and modified infrequently, tactical asset allocation frequently adjusts the asset class mix in the portfolio to take advantage of changing market conditions. With tactical asset allocation, these adjustments are driven solely by perceived changes in the relative values of the various asset classes; the investor’s risk tolerance and investment constraints are assumed to be constant over time. In Exhibit 16.24, this is equivalent to an integrated approach to asset allocation that removes the feedback loop involving investor-specific information (i.e., I2).

Tactical asset allocation is often based on the premise of mean reversion: whatever a security’s return has been in the recent past, it will eventually revert to its long-term average (mean) value. This assessment is usually done on a comparative basis. For instance, suppose that the ratio of stock and bond returns is normally 1.2, reflecting the greater degree of risk in the equity market. If stock returns were suddenly double those of bond returns, the tactical investor might determine that bonds were now undervalued relative to stock. He should then overweight the fixed-income component of his portfolio, shifting, say, from a 60–40 percent initial strategic mix of stocks and bonds to a 50–50 percent split.

Notice that tactical asset allocation is an inherently contrarian method of investing. The investor adopting this approach will always be buying the asset class that is currently out of favor—on a relative basis, at least— and selling the asset class with the highest market value. In the preceding example, this was the case when the investor underweighted his stock allocation after stock prices rose substantially compared to bond prices. DuBois (1992) notes that how frequently the investor chooses to adjust the asset class mix in the portfolio will depend on several factors, such as the general level of volatility in the capital markets, relative equity and fixed-income risk premiums, and changes in the macroeconomic environment.

The endowment fund example in Exhibit 16.26 also shows the tactical adjustments made by managers. These adjustments can be measured as the difference between the actual and strategic (i.e., planned) allocation proportions and are listed in the last column. Notice that endowment fund managers went from being underweighted in the U.S. equity category in 2002 to being slightly overinvested by 2005 (−3.2% to +1.0%). This pattern was mirrored by an opposite movement for U.S. fixed income, which saw its tactical position fall from an overweight of +0.8% to an underweight of −1.0%. This means that endowment managers not only reduced their strategic allocations to fixed income between 2002 and 2005, but their actual investments in this category

</tbody>
</table>

its expected return “penalized” by its risk level. The optimal asset mix for any particular investor is then the one that generates the highest level of expected utility.

As an example, Panel A of Exhibit 16.25 shows the expected returns and variances for three different potential asset mixes (C3), while Panel B lists risk-tolerance factors for two investors (I3). Panel C shows the expected utility calculations that combine this information (M2). For instance, the expected utility generated by Portfolio A for Investor 1 is 5.6 (= 7 − 7/5), which is the largest value of the three potential allocations and therefore his optimal asset mix. By contrast, Investor 2 is more tolerant of risk and finds that Portfolio 2, which generates an expected utility level of 8.5 (= 9 − 20/40), is her optimal allocation. Notice that the risk-tolerance factor effectively deflates the risk penalty, allowing more risk-tolerant investors to pursue more volatile portfolios with higher expected returns.

The third stage of the integrated allocation process occurs after enough time has passed that the optimal portfolio’s actual performance can be compared with the manager’s original expectations. This evaluation process is represented by Box M3 in Exhibit 16.24. Following this assessment, the manager can make adjustments to the portfolio by including new information into the optimization process. Modifications to the initial asset mix can result from either a fundamental change in capital market conditions (e.g., increased inflation) or a change in the investor’s circumstances (e.g., increased risk tolerance). It is this feedback loop that makes portfolio management a dynamic process.

### 16.6.2 Strategic Asset Allocation

Strategic asset allocation is used to determine the long-term policy asset weights in a portfolio. Typically, long-term average asset returns, risk, and covariances are used as estimates of future capital market results. Efficient frontiers are generated using this historical information, and the investor decides which asset mix is appropriate for his or her needs during the planning horizon. This results in a constant-mix asset allocation with periodic rebalancing to adjust the portfolio to the specified asset weights.
One way to think of the strategic allocation process is as being equivalent to the integrated asset allocation process shown in Exhibit 16.24 but without the feedback loops. That is, the manager will determine the long-term asset allocation that is best suited for a particular investor by optimizing information from both the capital market and that investor. However, once this asset mix is established, the manager does not attempt to adjust the allocation according to temporary changes in market and investor circumstances. Thus, as Ezra (1998) points out, the strategic allocation should define the basic nature of the trade-off between opportunity and safety that confronts the investor.

As an example, Brown, Garlappi, and Tiu (2010) examined the asset allocation patterns of college and university endowment funds in the United States and Canada. Exhibit 16.26 shows both the average actual and strategic (i.e., target) investment proportions for their fund sample in 2002 and 2005. There are several interesting things to note. First, endowment fund managers made some dramatic adjustments in the targeted investment proportions over these years; for instance, the strategic allocations to both U.S. equity (49.6% to 44.7%) and U.S. fixed-income (25.1% to 21.5%) declined significantly. Second, managers made an explicit decision to shift these assets to investments in the non-U.S. equity and hedge fund categories. Finally, planned investments in the rest of the asset classes listed remained relatively stable, which is consistent with the idea of a strategic allocation as a long-term view.

### 16.6.3 Tactical Asset Allocation

Unlike an investor's strategic allocation, which is set with a long-term focus and modified infrequently, tactical asset allocation frequently adjusts the asset class mix in the portfolio to take advantage of changing market conditions. With tactical asset allocation, these adjustments are driven solely by perceived changes in the relative values of the various asset classes; the investor’s risk tolerance and investment constraints are assumed to be constant over time. In Exhibit 16.24, this is equivalent to an integrated approach to asset allocation that removes the feedback loop involving investor-specific information (i.e., I2).

Tactical asset allocation is often based on the premise of mean reversion: whatever a security’s return has been in the recent past, it will eventually revert to its long-term average (mean) value. This assessment is usually done on a comparative basis. For instance, suppose that the ratio of stock and bond returns is normally 1.2, reflecting the greater degree of risk in the equity market. If stock returns were suddenly double those of bond returns, the tactical investor might determine that bonds were now undervalued relative to stock. He should then overweight the fixed-income component of his portfolio, shifting, say, from a 60–40 percent initial strategic mix of stocks and bonds to a 50–50 percent split.

Notice that tactical asset allocation is an inherently contrarian method of investing. The investor adopting this approach will always be buying the asset class that is currently out of favor—on a relative basis, at least—and selling the asset class with the highest market value. In the preceding example, this was the case when the investor underweighted his stock allocation after stock prices rose substantially compared to bond prices. DuBois (1992) notes that how frequently the investor chooses to adjust the asset class mix in the portfolio will depend on several factors, such as the general level of volatility in the capital markets, relative equity and fixed-income risk premiums, and changes in the macroeconomic environment.

The endowment fund example in Exhibit 16.26 also shows the tactical adjustments made by managers. These adjustments can be measured as the difference between the actual and strategic (i.e., planned) allocation proportions and are listed in the last column. Notice that endowment fund managers went from being underweighted in the U.S. equity category in 2002 to being slightly overinvested by 2005 (−3.2% to +1.0%). This pattern was mirrored by an opposite movement for U.S. fixed income, which saw its tactical position fall from an overweight of +0.8% to an underweight of −1.0%. This means that endowment managers not only reduced their strategic allocations to fixed income between 2002 and 2005, but their actual investments in this category
the portfolio’s value lower wealth, consequently decreasing his or her ability to handle risk, which means the portfolio’s exposure to risky assets must decline. Often, insured asset allocation involves only two assets, such as common stocks and T-bills. As stock prices rise, the asset allocation increases the stock component. As stock prices fall, the stock component of the mix falls while the T-bill component increases. This is opposite of what would happen under tactical asset allocation. Insured asset allocation is like the integrated approach without the feedback loop on the capital market side (i.e., C2 in Exhibit 16.24). It is sometimes called a constant proportion strategy because of the shifts that occur as wealth changes.

16.6.5 Selecting an Active Allocation Method

Which asset allocation strategy is used depends on the perceptions of the variability in the client’s objectives and constraints and the perceived relationship between past and future capital market conditions. If you believe that capital market conditions are relatively constant over time, you might use insured asset allocation. If you believe that the client’s goals, risk preferences, and constraints are constant, you might use tactical asset allocation. Integrated asset allocation assumes that both the investor’s needs and the capital market conditions are variable and therefore must be constantly monitored. Under these conditions, the portfolio mix must be updated constantly to reflect these changes.

SUMMARY

- Passive equity portfolios attempt to track the returns of an established benchmark, such as the S&P 500, or one that meets the investor’s needs.
- Active portfolios attempt to add value relative to their benchmark by market timing and/or by seeking to buy undervalued stocks. Index mutual funds and exchange-traded funds are popular ways for small investors to make passive investments.
- Tracking error, which is defined as the standard deviation of the difference between the returns to a managed fund and a benchmark, is a convenient way to categorize various management styles. Portfolios with tracking errors of less than 1 percent are generally considered to be passive, while active equity strategies often have tracking errors in excess of 5 percent.
- There are several methods for constructing and managing a passive portfolio, including full replication of a benchmark or sampling. Several active management approaches exist, including sector rotation and price and earnings momentum strategies. Value- and growth-oriented strategies have become particularly popular in recent years, and style analysis helps the investor determine the exact investment style the manager is using. Investors should also consider the tax efficiency of an actively managed portfolio.

Since equity portfolios typically are used with other assets in an investor’s overall portfolio, we reviewed several common asset allocation strategies, including integrated asset allocation, strategic asset allocation, tactical asset allocation, and insured asset allocation. The basic difference between these strategies is whether they rely on current market expectations or long-run projections, as well as whether the investor’s objectives and constraints remain constant or change with market conditions.

SUGGESTED READINGS

fell short of those targets as well. Obviously, this is a strong view against fixed-income investments. Finally, not all of the tactical adjustments shown in Exhibit 16.26 were probably intentional. The underweight positions in the private equity categories are likely due to managers not being able to invest all of the money they had planned, which would also explain the overweight positions in their cash accounts. Private equity investments will be discussed in Chapter 24.

16.6.4 Insured Asset Allocation

Insured asset allocation likewise results in continual adjustments in the portfolio allocation, assuming that expected market returns and risks are constant over time, while the investor’s objectives and constraints change as his or her wealth position changes. For example, rising portfolio values increase the investor’s wealth and consequently his or her ability to handle risk, which means the investor can increase his or her exposure to risky assets. 1. Why have passive portfolio management strategies increased in use over time?

2. What is meant by an indexing portfolio strategy and what is the justification for this strategy? How might it differ from another passive portfolio?

3. Briefly describe four techniques considered active equity portfolio management strategies.

4. List two investment products that a manager following a passive investment strategy could use to make an investment in the Standard & Poor’s 500 Index. Briefly discuss which product is likely to be the most accurate method for tracking the index.

5. Discuss three strategies active managers can use to add value to their portfolios.

6. How do trading costs and market efficiencies affect the active manager? How may an active manager try to overcome these obstacles to success?

7. Discuss how the four asset allocation strategies differ from one another.

8. There has been a long-standing debate regarding the existence of a "value-growth" anomaly in financial economic research. Previous studies have shown that value stocks (i.e., stocks with low price-to-book ratios) have higher returns than growth stocks (i.e., stocks with high price-to-book ratios) in the United States and markets around the world, even after adjusting for a market-wide risk factor. What are some possible explanations for why value stocks might outperform growth stocks on a risk-adjusted basis? Is this value-growth "anomaly" consistent with the existence of an efficient stock market?

9. Describe the difference between a price momentum strategy and an earnings momentum strategy. Under what conditions would you expect the two approaches to produce similar portfolios?

10. What are the trade-offs involved when constructing a portfolio using a full replication versus a sampling method?

11. Because of inflationary expectations, you expect natural resource stocks, such as mining companies and oil firms, to perform well over the next three to six months. As an active portfolio manager, describe the various methods available to take advantage of this forecast.

**PROBLEMS**

*Management fees and administrative charges have not been deducted.*

Based on this data, Stewart concludes that Foreman is an actively managed fund, that Copeland is an index fund, and that Foreman outperformed Copeland for the year. A colleague tells Stewart that her conclusions may not be accurate and makes the following statements:

1. Even though Foreman has a low $R^2$ with the S&P 500 Index, Foreman may not be an actively managed fund.
2. Copeland may be an actively managed fund even though Copeland has low portfolio turnover.
3. Foreman may not have had superior risk-adjusted performance compared with Copeland for the year.

For each of these three statements, describe one circumstance in which the statement could be correct.

3. Consider the following trading and performance data for four different equity mutual funds:

<table>
<thead>
<tr>
<th>Fund W</th>
<th>Fund X</th>
<th>Fund Y</th>
<th>Fund Z</th>
</tr>
</thead>
<tbody>
<tr>
<td>Assets under Management, Avg. for Past 12 months (mil)</td>
<td>$289.4</td>
<td>$653.7</td>
<td>$1,298.4</td>
</tr>
<tr>
<td>Security Sales, Past 12 months (mil)</td>
<td>$37.2</td>
<td>$569.3</td>

<td>9.98%</td>
<td>10.65%</td>
<td>10.12%</td>
</tr>
<tr>
<td>Tax-adjusted Return, 3-year avg.</td>
<td>9.43%</td>
<td>8.87%</td>
<td>9.34%</td>
</tr>
</tbody>
</table>

a. Calculate the portfolio turnover ratio for each fund.
b. Which two funds are most likely to be actively managed and which two are most likely passive funds? Explain.
c. Calculate the tax cost ratio for each fund.
d. Which funds were the most and least tax efficient in the operations? Why?

4. Global Advisers Company (GAC) is an SEC-registered investment counseling firm involved solely in managing international securities portfolios. After much research on the developing economy and capital markets of the country of Otunia, GAC has decided to include an investment in the Otunia stock market in its Emerging Market Commingled Fund. However, GAC has not yet decided whether to invest actively or by indexing. Your opinion on the active versus indexing decision has been solicited. A summary of the research findings follows.

Otunia’s economy is fairly well diversified across agricultural and natural resources, manufacturing (both consumer and durable goods), and a growing finance sector. Transaction costs in securities markets are relatively large in Otunia because of high commissions and government “stamp taxes” on securities trades. Accounting standards and disclosure regulations are quite detailed, resulting in wide public availability of reliable information about companies’ financial performance.

Chapter 16: Equity Portfolio Management Strategies

---

### QUESTIONS

1. Why have passive portfolio management strategies increased in use over time?
2. What is meant by an indexing portfolio strategy and what is the justification for this strategy? How might it differ from another passive portfolio?
3. Briefly describe four techniques considered active equity portfolio management strategies.
4. List two investment products that a manager following a passive investment strategy could use to make an investment in the Standard & Poor’s 500 Index. Briefly discuss which product is likely to be the most accurate method for tracking the index.
5. Discuss three strategies active managers can use to add value to their portfolios.
6. How do trading costs and market efficiencies affect the active manager? How may an active manager try to overcome these obstacles to success?
7. Discuss how the four asset allocation strategies differ from one another.
8. There has been a long-standing debate regarding the existence of a “value-growth” anomaly in financial economic research. Previous studies have shown that value stocks (i.e., stocks with low price-to-book ratios) have higher returns than growth stocks (i.e., stocks with high price-to-book ratios) in the United States and markets around the world, even after adjusting for a market-wide risk factor. What are some possible explanations for why value stocks might outperform growth stocks on a risk-adjusted basis? Is this value-growth “anomaly” consistent with the existence of an efficient stock market?
9. Describe the difference between a price momentum strategy and an earnings momentum strategy. Under what conditions would you expect the two approaches to produce similar portfolios?

<td>19.0</td>
<td>18.8</td>
<td>19.7</td>
</tr>
</tbody>
</table>

a. Did either manager outperform the index, based on the average annual return differential that he or she produced relative to the benchmark? Demonstrate.

b. Calculate the tracking error for each manager relative to the index. Which manager did a better job of limiting his or her client’s unsystematic risk exposure? Explain.

**THOMSON REUTERS**

Use the Thomson One—Business School Edition Online Database to answer the following questions.

1. Consider four different stock market indexes representing different equity investment styles:

   - **Large-cap, Value:** Russell 1000 Value (FRUS1VA)
   - **Large-cap, Growth:** Russell 1000 Growth (FRUS1GR)
   - **Small-cap, Value:** Russell 2000 Value (FRUS2VA)
   - **Small-cap, Growth:** Russell 2000 Growth (FRUS2GR).

   Which of these investment styles would have been the most profitable to invest in over the following periods ending February 25, 2011: (a) the past three months, (b) the past year, and (c) the past five years? (Hint: You can calculate the growth of a $1 investment in all four strategies by taking the ratio of the beginning and ending index values for each of the respective investment periods.) Which strategy appears to have been the riskiest? Why?

2. Using the same companies represented in Panels A and B of Exhibit 16.17, update the financial information using the most recent data available. Given your analysis, would all of the various firms shown in the exhibit still qualify to be included in the same portfolio? In particular, should IBM now be classified as a value stock or a growth stock? (Note: Use the longest-term EPS growth forecast available in constructing your display.)

3. Use the “Search for Companies” function to create your own portfolio according to a specific investment style mandate (e.g., large-cap growth, high-return momentum, industry-specific) of your own choosing. Once you have established this portfolio, use the “Save Set” command to name and save the identity of the portfolio companies you have selected. Analyze your portfolio’s recent valuation, financial, and performance characteristics by accessing the various summary reports available under the “Portfolios” tab. (Note: You should experiment with the various search commands available in the company search menu in order to get acquainted with the multitude of portfolios that you can form, as well as the scope of the financial reports that can be created for those portfolios.)
This page intentionally left blank
For most investors, bonds receive limited attention and very little respect. This is surprising when one considers that the total market value of the bond market in the United States and in most other countries is substantially larger than the market value of the stock market. For example, at the end of 2010 the market value of all publicly issued bonds in the U.S. was more than $30 trillion, while the market value of all stocks was about $18 trillion. On a global basis, the values are about $61 trillion for bonds versus $43 trillion for stocks. Beyond the size factor, bonds have a reputation for low, unexciting rates of return. Although this may have been true 40 or 50 years ago, it certainly has not been true during the past 30 years. Specifically, the average annual compound rate of return on government/corporate bonds for the period 1980–2010 was over 8 percent versus almost 11 percent for common stocks. These rates of return along with corresponding standard deviations (6 percent for bonds versus 16 percent for stocks) and the relatively low correlation between stocks and bonds (about 0.21) indicate that there are substantial opportunities in bonds for individual and institutional investors to enhance their risk-return performance.

The chapters in this section are intended to provide (1) a basic understanding of bonds and the bond markets around the world, (2) background on analyzing returns and risks in the bond market, (3) insights regarding the valuation of bonds, including numerous new fixed-income securities with very unusual cash flow characteristics, and (4) an understanding of either active or passive bond portfolio management.

Chapter 17 describes the global bond market in terms of country participation and the makeup of the bond market in major countries. Also, we examine characteristics of bonds in alternative categories, such as government, corporate, and municipal. We also discuss the many new corporate bond instruments developed in the United States, such as asset-backed securities, zero-coupon bonds, high-yield bonds, and inflation protection securities. While the use of these securities globally has generally been limited to the large developed markets, it is certain that they will eventually be used around the world. Finally, we consider sources of price information needed by bond investors.

Chapter 18 is concerned with the analysis and valuation of bonds. This includes a detailed discussion of how one values a bond using a single discount rate or using spot rates. We also evaluate alternative rate of return measures for bonds. Subsequently, we consider what factors affect yields on bonds and what characteristics influence the volatility of bond returns, including the very important concept of bond duration, which is a measure of bond price volatility that is important in active and passive bond portfolio management. We also consider bond convexity and the impact it has on bond price volatility. Notably, these concepts are examined for option-free securities. We also consider how they apply to a growing set of securities with embedded options.

Chapter 19 considers how to use the background provided in Chapter 17 and Chapter 18 to create and manage a bond portfolio. We consider three major categories of portfolio strategies in detail. The first is passive portfolio management strategies, which include either a simple buy-and-hold strategy or indexing to one of the major benchmarks. The second category includes active management strategies that can involve one of five alternatives: interest rate participation, valuation analysis, credit analysis, yield spread analysis, or bond swaps. The third category includes matched funding strategies, which include constructing dedicated portfolios, constructing classical or contingent immunization portfolios, or horizon matching.

The fact that three fairly long chapters are devoted to the study of bonds attests to the importance of the topic and the extensive research done in this area. During the past 20 years, there have been more developments related to the valuation and portfolio management of bonds than of stocks. This growth of the fixed-income sector does not detract from the importance of equities but certainly enhances the significance of fixed-income securities. Finally, readers should keep in mind that this growth in size, sophistication, and specialization of the bond market implies numerous and varied career opportunities in the bond area, including trading these securities, valuation, credit analysis, and domestic and global portfolio management.

The third category includes matched funding strategies, which include constructing dedicated portfolios, constructing classical or contingent immunization portfolios, or horizon matching.

The fact that three fairly long chapters are devoted to the study of bonds attests to the importance of the topic and the extensive research done in this area. During the past 20 years, there have been more developments related to the valuation and portfolio management of bonds than of stocks. This growth of the fixed-income sector does not detract from the importance of equities but certainly enhances the significance of fixed-income securities. Finally, readers should keep in mind that this growth in size, sophistication, and specialization of the bond market implies numerous and varied career opportunities in the bond area, including trading these securities, valuation, credit analysis, and domestic and global portfolio management.
After you read this chapter, you should be able to answer the following questions:

- What are some of the basic features of bonds that affect their risk, return, and value?
- What is the current country structure of the world bond market, and how has the makeup of the global bond market changed in recent years?
- What are the major components of the world bond market and the international bond market?
- How does the makeup of the bond market differ in major countries?
- What are bond ratings, and what is their purpose? What is the difference between investment-grade bonds and high-yield (junk) bonds?
- What are the characteristics of bonds in the major bond categories, such as governments (including TIPS), agencies, municipalities, and corporates?
- What are the important characteristics of corporate bond issues developed in the United States during the past decade, such as mortgage-backed securities, other asset-backed securities, zero-coupon and deep discount bonds, high-yield bonds, and structured notes?
- How do you read the quotes available for the alternative bond categories (e.g., governments, municipalities, and corporates)?

The global bond market is large and diverse and represents an important investment opportunity. This chapter is concerned with publicly issued, long-term, nonconvertible debt obligations of public and private issuers in the United States and major global markets. In later chapters, we consider preferred stock and convertible bonds. An understanding of bonds is helpful in an efficient market because the existence of U.S. and foreign bonds increases the universe of investments available for the creation of a diversified portfolio.

In this chapter, we review some basic features of bonds and examine the structure of the world bond market. The bulk of the chapter involves an in-depth discussion of the major fixed-income investments. The chapter ends with a brief review of the price information sources for bond investors. The reader may also want to revisit Chapter 5, which contains a detailed description of the major bond indexes and how they relate to one another.

17.1 Basic Features of a Bond

Public bonds are long-term, fixed-obligation debt securities packaged in convenient, affordable denominations for sale to individuals and financial institutions. They differ from other debt, such as individual mortgages and privately placed debt obligations, because they are sold to the public rather than channeled directly to a single lender. Bond issues are considered fixed-income
securities because they impose fixed financial obligations on the issuers. Specifically, the issuer of a bond agrees to:

1. Pay a fixed amount of interest periodically to the holder of record
2. Repay a fixed amount of principal at the date of maturity

Normally, interest on bonds is paid every six months, although some bond issues pay in intervals as short as a month or as long as a year. The principal is due at maturity; this par value of the issue is rarely less than $1,000. A bond has a specified term to maturity, which defines the life of the issue. The public debt market typically is divided into three time segments based on an issue’s original maturity:

1. Short-term issues with maturities of one year or less. The market for these instruments is commonly known as the money market.
2. Intermediate-term issues with maturities in excess of 1 year but less than 10 years. These instruments are known as notes.
3. Long-term obligations with maturities in excess of 10 years, called bonds.

The lives of debt obligations change constantly as the issues progress toward maturity. Thus, issues that have been outstanding in the secondary market for any period of time eventually move from long term to intermediate to short term. This change in maturity is important because a major determinant of the price volatility of bonds is the remaining life (maturity) of the issue.

17.1.1 Bond Characteristics

A bond can be characterized based on (1) its intrinsic features, (2) its type, (3) its indenture provisions, or (4) the features that affect its cash flows and/or its maturity.

**Intrinsic Features** The coupon, maturity, principal value, and the type of ownership are important intrinsic features of a bond. The coupon of a bond indicates the income that the bond investor will receive over the life (or holding period) of the issue. This is known as interest income, coupon income, or nominal yield.

The term to maturity specifies the date or the number of years before a bond matures (or expires). There are two different types of maturity. The most common is a term bond, which has a single maturity date. Alternatively, a serial obligation bond issue has a series of maturity dates, perhaps 20 or 25. Each maturity, although a subset of the total issue, is really a small bond issue with generally a different coupon. Municipalities issue most serial bonds.

The principal, or par value, of an issue represents the original value of the obligation. This is generally stated in $1,000 increments from $1,000 to $25,000 or more. Principal value is not the same as the bond’s market value. The market prices of many issues rise above or fall below their principal values because of differences between their coupons and the prevailing market rate of interest. If the market interest rate is above the coupon rate, the bond will sell at a discount to par. If the market rate is below the bond’s coupon, it will sell at a premium above par. If the coupon is comparable to the prevailing market interest rate, the market value of the bond will be close to its original principal value.

Finally, bonds differ in terms of ownership. With a bearer bond, the holder, or bearer, is the owner, so the issuer keeps no record of ownership. Interest from a bearer bond is obtained by clipping coupons attached to the bonds and sending them to the issuer for payment. In contrast, the issuers of registered bonds maintain records of owners and pay the interest directly to the current owner of record.

**Types of Issues** In contrast to common stock, companies can have many different bond issues outstanding at the same time. Bonds can have different types of collateral and be either senior, unsecured, or subordinated (junior) securities. Secured (senior) bonds are backed by a legal claim on some specified property of the issuer in the case of default. For example,
mortgage bonds can be secured by real estate assets; equipment trust certificates, which are used by railroads and airlines, provide a senior claim on the firm’s equipment.

Unsecured bonds (debentures) are backed only by the promise of the issuer to pay interest and principal on a timely basis. As such, they are secured by the general credit of the issuer. Subordinate (junior) debentures possess a claim on income and assets that is subordinated to other debentures. Income issues are the most junior type because interest on them is paid only if it is earned. Although income bonds are unusual in the corporate sector, they are very popular municipal issues, where they are referred to as revenue bonds. Finally, refunding issues provide funds to prematurely retire another issue.

The type of issue has only a marginal effect on comparative yield because it is the creditworthiness of the issuer that determines bond quality. A study of corporate bond price behavior by Hickman (1958) found that whether the issuer pledged collateral did not become important until the bond issue approached default. The collateral and security characteristics of a bond influence yield differentials only when these factors affect the bond’s quality ratings.

Indenture Provisions The indenture is the contract between the issuer and the bondholder specifying the issuer’s legal requirements. A trustee (usually a bank) acting on behalf of the bondholders ensures that all the indenture provisions are met, including the timely payment of interest and principal. All the factors that dictate a bond’s features, its type, and its maturity are set forth in the indenture.

Features Affecting a Bond’s Maturity Investors should be aware of the three alternative call option features that can affect the life (maturity) of a bond. One extreme is a freely callable provision that allows the issuer to retire the bond at any time with a typical notification period of 30 to 60 days. The other extreme is a noncallable provision wherein the issuer cannot retire the bond prior to its maturity.1 Intermediate between these is a deferred call provision, which means the issue cannot be called for a certain period of time after the date of issue (e.g., 5 to 10 years). At the end of the deferred call period, the issue becomes freely callable. Callable bonds have a call premium, which is the amount above maturity value that the issuer must pay to the bondholder for prematurely retiring the bond.

A nonrefunding provision prohibits a call and premature retirement of an issue from the proceeds of a lower-coupon refunding bond. This is meant to protect the bondholder from a typical refunding, but it is not foolproof. An issue with a nonrefunding provision can be called and retired prior to maturity using other sources of funds, such as excess cash from operations, the sale of assets, or proceeds from a sale of common stock. This occurred on several occasions during the 1980s and 1990s when many issuers retired nonrefundable high-coupon issues early because they could get the cash from one of these other sources and felt that this was a good financing decision.

Another important indenture provision that can affect a bond’s maturity is the sinking fund, which specifies that a bond must be paid off systematically over its life rather than only at maturity. There are numerous sinking-fund arrangements, and the bondholder should recognize this as a feature that can change the stated maturity of a bond. The size of the sinking fund can be a percentage of a given issue or a percentage of the total debt outstanding, or it can be a fixed or variable sum stated on a dollar or percentage basis. Similar to a call feature, sinking fund payments may commence at the end of the first year or may be deferred for 5 or 10 years from date of the issue. The amount of the issue that must be repaid before maturity from a sinking fund can range from a nominal sum to 100 percent. Like a call, the sinking-fund feature typically carries a nominal premium but is generally smaller than the straight

---

1The main issuer of noncallable bonds between 1985 and 2011 was the U.S. Treasury. Corporate long-term bonds typically have contained some form of call provision, except during periods of relatively low interest rates (e.g., 1994–2001; 2010–2011) when the probability of exercising the option was very low. We discuss this notion in more detail in Chapter 18 in connection with the analysis of embedded options.
call premium (e.g., 1 percent). For example, a bond issue with a 20-year maturity might have a sinking fund that requires that 5 percent of the issue be retired every year beginning in year 10. The effect of this is that by year 20, half of the issue has been retired and the rest is paid off at maturity. Sinking-fund provisions have a small effect on comparative yields at the time of issue but have little subsequent impact on price behavior.

A sinking-fund provision is an obligation and must be carried out regardless of market conditions. Although a sinking fund allows the issuer to call bonds on a random basis, most bonds are retired for sinking-fund purposes through direct negotiations with institutional holders. Essentially, the trustee negotiates with an institution to buy back the necessary amount of bonds at a price slightly above the current market price.

17.1.2 Rates of Return on Bonds

The rate of return on a bond is computed in the same way as the rate of return on stock or any asset. It is determined by the beginning and ending price and the cash flows during the holding period. The major difference between stocks and bonds is that the interim cash flow on bonds (i.e., the interest) is contractual and accrues over time, as discussed subsequently, whereas the dividends on stock may vary. Therefore, the holding period return \( (HPR) \) for a bond will be:

\[
HPR_{i,t} = \frac{P_{i,t+1} + \text{Int}_{i,t}}{P_{i,t}}
\]

where:

- \( HPR_{i,t} \) = the holding period return for bond \( i \) during Period \( t \)
- \( P_{i,t+1} \) = the market price of bond \( i \) at the end of Period \( t \)
- \( P_{i,t} \) = the market price of bond \( i \) at the beginning of Period \( t \)
- \( \text{Int}_{i,t} \) = the interest paid or accrued on bond \( i \) during Period \( t \). Because the interest payment is contractual, it accrues over time, and if a bond owner sells the bond between interest payments, the sale price includes accrued interest.\(^2\)

The holding period yield \( (HPY) \) is:

\[
HPY = HPR - 1
\]

Note that the only contractual factor is the amount of interest payments. The beginning and ending bond prices are determined by market forces, as discussed in Chapter 11. Notably, the ending price is determined by market forces unless the bond is held to maturity, in which case the investor will receive the par value. These price variations in bonds mean that investors in bonds can experience capital gains or losses. Interest rate volatility has increased substantially since the 1960s, and this has caused large price fluctuations in bonds.\(^3\) As a result, capital gains or losses have become a major component of the rates of return on bonds.

17.2 The Global Bond Market Structure\(^4\)

The market for fixed-income securities is substantially larger than the listed equity exchanges (NYSE, TSE, LSE) because corporations tend to issue bonds rather than common stock. Figures released by Securities Industry and Financial Markets Association (SIFMA) indicate

\(^2\)The concept of accrued interest will be discussed further in Chapter 18, when we consider the valuation of bonds.

\(^3\)The analysis of bond price volatility is discussed in detail in Chapter 18.

Quasi Governments (Agencies) and Foreign Governments

Agency issues have become a major segment in the U.S. dollar and pound sterling market (over 12 percent) but are a smaller proportion in other countries (e.g., about 8 percent in Japan). These agencies represent political subdivisions of the government, although the securities are not typically direct obligations of the government. The U.S. agency market has two types of issuers: government-sponsored enterprises and federal agencies. The proceeds of agency bond issues are used to finance many legislative programs. Foreign government issues are from a country but not in its own currency (e.g., a Japanese government issue denominated in dollars and sold in the United States).

Securitized/Collateralized Issues

These can be either government agencies or corporate issues that are backed by cash flow securities such as mortgages or car loans. Collateralized securities can include several different issues and structured cash flows. As shown in Exhibit 17.2, this has become a major sector in the United States and is fairly strong in the Eurozone countries. Therefore, they will be discussed in detail in a subsequent section.

Corporations

The major nongovernmental issuer of debt is the corporate sector. The importance of this sector differs dramatically among countries. It is a slow growth component in the United States.

Source: Estimated by authors based on data from Bank of America Merrill Lynch Global Research.

that in the United States during 2010, less than 10 percent of all new security issues were equity, which included preferred as well as common stock. Corporations issue less common or preferred stock because firms derive most of their equity financing from internally generated funds (i.e., retained earnings). Also, although the equity market is strictly corporations, the bond market in most countries has four noncorporate sectors: the pure government sector (e.g., the Treasury in the United States), government agencies (e.g., FNMA), state and local government bonds (municipals), and international bonds (e.g., Yankees and Eurobonds in the United States).

The size of the global bond market and the distribution among countries can be gleaned from Exhibit 17.1, which lists the dollar value of debt outstanding and the percentage distribution for the major currencies for the years 2009–2010. There has been consistent overall growth, at the rate of 6 to 10 percent a year. Also, the currency trends are significant. Specifically, the U.S. dollar market went from 45 percent of the total world bond market in 2002 to about 43 percent in 2010. A significant change in 1999 was the creation of the Eurozone sector, which includes a large part of Europe (i.e., Germany, Italy, France) with the significant exception of the United Kingdom. Notably, this euro currency sector has held at about 30 percent over the last decade.

17.2.1 Participating Issuers

In a report from Bank of America Merrill Lynch Global Research, there are five different categories of bonds for each currency: (1) sovereign bonds (e.g., the U.S. Treasury), (2) quasi and foreign governments (including agency bonds), (3) securitized and collateralized bonds from governments or corporations, (4) directly issued corporate bonds, and (5) high-yield and/or emerging market bonds. The division of bonds among these five categories for three large currency markets and the Eurozone during 2010 is contained in Exhibit 17.2.

Sovereigns The market for government securities is the largest sector in Japan. It involves a variety of debt instruments issued to meet the growing needs of this government. It is generally a stable component for other currencies.
United States; a smaller sector in Japan and in the euro currency countries, and a significant part of the pound sterling market.

The market for corporate bonds is commonly subdivided into several segments: industrials, public utilities, transportation, and financial issues. The specific makeup varies among countries.

High-Yield/Emerging Market

This section includes both high-yield bonds (noninvestment grade) from corporations in developed countries, and both government and corporate issues from emerging market countries such as China and India, where the bonds can be either investment grade or high yield (noninvestment grade). Notably, the only currency where this sector is significant is the U.S. dollar market, where it constitutes over 7 percent. The other currencies have only nominal amounts currently, but these sectors are expected to experience significant growth in the future.

17.2.2 Participating Investors

Numerous individual and institutional investors with diverse investment objectives participate in the bond market. Individual investors are a minor portion because of the market’s complexity and the high minimum denominations of most issues. Institutional investors typically account for 90 to 95 percent of the trading, although different segments of the market are more institutionalized than others. For example, institutions are involved heavily in the agency market, but they are less active in the corporate sector.

A variety of institutions invest in the bond market. Life insurance companies invest in corporate bonds and, to a lesser extent, in Treasury and agency securities. Commercial banks invest in municipal bonds and government and agency issues. Property and liability insurance companies concentrate on municipal bonds and Treasuries. Private and government pension funds are heavily committed to corporates but also invest in Treasuries and agencies. Finally, fixed-income mutual funds have experienced significant growth, and their demand spans the full spectrum of the market as they develop bond funds that meet the needs of a variety of investors. As we will discuss in Chapter 24, municipal bond funds and corporate bond funds (including high-yield bonds) have experienced significant growth.

Alternative institutions tend to favor different sectors of the bond market based on two factors: (1) the tax code applicable to the institution, and (2) the nature of the institution’s liability structure. For example, because commercial banks are subject to normal taxation and have fairly short-term liability structures, they favor short- to intermediate-term municipals. Pension funds are virtually tax-free institutions with long-term commitments, so they prefer high-yielding, long-term government or corporate bonds. Such institutional investment preferences can affect the short-run supply and demand of loanable funds and impact interest rate changes.

17.2.3 Bond Ratings

Agency ratings are an integral part of the bond market because most corporate and municipal bonds are rated by one or more of the rating agencies. The exceptions are very small issues and bonds from certain industries, such as bank issues. These are known as nonrated bonds.

There are three major rating agencies: (1) Fitch Investors Service, (2) Moody’s, and (3) Standard and Poor’s.

This sector of the bond market is described in more detail later in this chapter. It is possible to distinguish another sector that exists in the United States but not in other countries—institutional bonds. These are corporate bonds issued by a variety of private, nonprofit institutions, such as schools, hospitals, and churches. They are not broken out because they are only a minute part of the U.S. market and do not exist elsewhere.

**Source:** Estimates by authors based on historical data from Bank of America Merrill Lynch Global Research.

**Quasi Governments (Agencies) and Foreign Governments** Agency issues have become a major segment in the U.S. dollar and pound sterling market (over 12 percent) but are a smaller proportion in other countries (e.g., about 8 percent in Japan). These agencies represent political subdivisions of the government, although the securities are not typically direct obligations of the government. The U.S. agency market has two types of issuers: government-sponsored enterprises and federal agencies. The proceeds of agency bond issues are used to finance many legislative programs. Foreign government issues are from a country but not in its own currency (e.g., a Japanese government issue denominated in dollars and sold in the United States).

**Securitized/Collateralized Issues** These can be either government agencies or corporate issues that are backed by cash flow securities such as mortgages or car loans. Collateralized securities can include several different issues and structured cash flows. As shown in Exhibit 17.2, this has become a major sector in the United States and is fairly strong in the Eurozone countries. Therefore, they will be discussed in detail in a subsequent section.

**Corporations** The major nongovernmental issuer of debt is the corporate sector. The importance of this sector differs dramatically among countries. It is a slow growth component in the
United States; a smaller sector in Japan and in the euro currency countries, and a significant part of the pound sterling market.

The market for corporate bonds is commonly subdivided into several segments: industrials, public utilities, transportation, and financial issues. The specific makeup varies among countries.5

**High-Yield/Emerging Market** This section includes both high-yield bonds (noninvestment grade) from corporations in developed countries, and both government and corporate issues from emerging market countries such as China and India, where the bonds can be either investment grade or high yield (noninvestment grade). Notably, the only currency where this sector is significant is the U.S. dollar market, where it constitutes over 7 percent. The other currencies have only nominal amounts currently, but these sectors are expected to experience significant growth in the future.

### 17.2.2 Participating Investors

Numerous individual and institutional investors with diverse investment objectives participate in the bond market. Individual investors are a minor portion because of the market’s complexity and the high minimum denominations of most issues. Institutional investors typically account for 90 to 95 percent of the trading, although different segments of the market are more institutionalized than others. For example, institutions are involved heavily in the agency market, but they are less active in the corporate sector.

A variety of institutions invest in the bond market. Life insurance companies invest in corporate bonds and, to a lesser extent, in Treasury and agency securities. Commercial banks invest in municipal bonds and government and agency issues. Property and liability insurance companies concentrate on municipal bonds and Treasuries. Private and government pension funds are heavily committed to corporates but also invest in Treasuries and agencies. Finally, fixed-income mutual funds have experienced significant growth, and their demand spans the full spectrum of the market as they develop bond funds that meet the needs of a variety of investors. As we will discuss in Chapter 24, municipal bond funds and corporate bond funds (including high-yield bonds) have experienced significant growth.

Alternative institutions tend to favor different sectors of the bond market based on two factors: (1) the tax code applicable to the institution, and (2) the nature of the institution’s liability structure. For example, because commercial banks are subject to normal taxation and have fairly short-term liability structures, they favor short- to intermediate-term municipals. Pension funds are virtually tax-free institutions with long-term commitments, so they prefer high-yielding, long-term government or corporate bonds. Such institutional investment preferences can affect the short-run supply and demand of loanable funds and impact interest rate changes.

### 17.2.3 Bond Ratings

Agency ratings are an integral part of the bond market because most corporate and municipal bonds are rated by one or more of the rating agencies. The exceptions are very small issues and bonds from certain industries, such as bank issues. These are known as nonrated bonds. There are three major rating agencies: (1) Fitch Investors Service, (2) Moody’s, and (3) Standard and Poor’s.

---

5This sector of the bond market is described in more detail later in this chapter. It is possible to distinguish another sector that exists in the United States but not in other countries—institutional bonds. These are corporate bonds issued by a variety of private, nonprofit institutions, such as schools, hospitals, and churches. They are not broken out because they are only a minute part of the U.S. market and do not exist elsewhere.
17.3.1 Domestic Government Bonds

United States

As shown in Exhibit 17.2, a significant percent of the U.S. dollar fixed-income market is U.S. Treasury obligations. The U.S. government, backed by the full faith and credit of the U.S. Treasury, issues Treasury bills (T-bills), which mature in less than one year, and two forms of long-term obligations: government notes, which have maturities of 10 years or less, and Treasury bonds, with maturities of 10 to 30 years. Current Treasury obligations are:

Chapter 17: Bond Fundamentals

Bond ratings provide the fundamental analysis for thousands of issues. The rating agencies analyze the issuing organization and the specific issue to determine the probability of default and inform the market of their analyses through their ratings.6

The primary question in bond credit analysis is whether the firm can service its debt in a timely manner over the life of a given issue. Consequently, the rating agencies consider expectations over the life of the issue, along with the historical and current financial position of the company. We consider default estimation further when we discuss high-yield (junk) bonds.

Studies by authors such as Belkaoui (1980) and Gentry, Whitford, and Newbold (1988) have examined the relationship between bond ratings and issue quality as indicated by financial variables. The results clearly demonstrated that bond ratings were positively related to profitability, size, and cash flow coverage, and they were inversely related to financial leverage and earnings instability.

The original ratings assigned to bonds have an impact on their marketability and effective interest rate. Generally, the three agencies’ ratings agree. When they do not, the issue is said to have a split rating.7 Seasoned issues are regularly reviewed to ensure that the assigned rating is still valid. If not, revisions are made either upward or downward. Revisions are usually done in increments of one rating grade. The ratings are based on both the company and the issue. After an evaluation of the creditworthiness of the total company is completed, a company rating is assigned to the firm’s most senior unsecured issue. All junior bonds receive lower ratings based on indenture specifications. Also, an issue could receive a higher rating than justified because of credit-enhancement devices, such as the attachment of bank letters of credit, surety, or indemnification bonds from insurance companies.

The agencies assign letter ratings depicting what they view as the risk of default of an obligation. The letter ratings range from AAA (Aaa) to D. Exhibit 17.3 describes the various ratings assigned by the major services. Except for slight variations in designations, the meaning and interpretation are basically the same. The agencies modify the ratings with + and – signs for Fitch and S&P or with numbers (1-2-3) for Moody’s. As an example, an A+ (A1) bond is at the top of the A-rated group, while A– (A3) is at the bottom of the A category.

The top four ratings—AAA (or Aaa), AA (or Aa), A, and BBB (or Baa)—are generally considered to be investment-grade securities. The next level of securities is known as speculative bonds and includes the BB- and B-rated obligations. The C categories are generally either income obligations or revenue bonds, many of which are trading flat. (Flat bonds are in arrears on their interest payments.) In the case of D-rated obligations, the issues are in outright default, and the ratings indicate the bonds’ relative salvage values.8

17.3 Alternative Bond Issues

We have described the basic features available for all bonds and the overall structure of the global bond market in terms of the issuers of bonds and investors in bonds. In this section, we provide a detailed discussion of the bonds available from the major issuers of bonds. The presentation is longer than you would expect because when we discuss each issuing unit, such as governments, municipalities, or corporations, we briefly consider the bonds available in several world financial centers, such as Japan, the United Kingdom, and the several major countries in the Eurozone.

---

7Split ratings are discussed in Billingsley, Lamy, Marr, and Thompson (1985); Ederington (1985); and Liu and Moore (1987). Studies that consider shopping for ratings, the acquisition of indicative ratings, and ratings bias are Mathis, McAndrews, and Rochet (2009) and Skreta and Veldkamp (2009).

8Bonds rated below investment grade are also referred to as “high-yield bonds” or “junk” bonds. These high-yield bonds are discussed in the subsequent section on corporate bonds.
come in denominations of $1,000 and $10,000. The interest income from the U.S. government securities is subject to federal income tax but exempt from state and local levies. These bonds are popular because of their high credit quality, substantial liquidity, and noncallable feature.

Short-term T-bills differ from notes and bonds because they are sold at a discount from par to provide the desired yield. The return is the difference between the purchase price and the par at maturity. In contrast, government notes and bonds carry semiannual coupons that specify the nominal yield of the obligations.

Government notes and bonds have unusual call features. First, the period specified for the deferred call feature on Treasury issues is very long and is generally measured relative to the maturity date rather than from date of issue. They generally cannot be called until five years prior to their maturity date. Notably, all U.S. Treasury issues since 1989 have been noncallable.

Treasury Inflation-Protected Securities (TIPS)

The Treasury began issuing these inflation-indexed bonds in January 1997 to appeal to investors who wanted or needed a real default-free rate of return. To ensure the investors will receive the promised yield in real terms, the bond principal and interest payments are indexed to the Consumer Price Index for All Urban Consumers (CPI-U), published by the Bureau of Labor Statistics. Because inflation is generally not known until several months after the fact, the index value used has a three-month lag built in—for example, for a bond issued on June 30, 2011, the beginning base index value used would be the CPI value as of March 30, 2011. Following the issuance of a TIPS bond, its principal value is adjusted every six months to reflect the inflation since the base period. In turn, the interest payment is computed based on this adjusted principal—that is, the interest payments equal the original coupon times the adjusted principal. The example in Exhibit 17.4 demonstrates how the principal and interest payments are computed. As shown in this example, both the interest payments and the principal payments are adjusted over time to reflect

17.3.1 Domestic Government Bonds

United States As shown in Exhibit 17.2, a significant percent of the U.S. dollar fixed-income market is U.S. Treasury obligations. The U.S. government, backed by the full faith and credit of the U.S. Treasury, issues Treasury bills (T-bills), which mature in less than one year, and two forms of long-term obligations: government notes, which have maturities of 10 years or less, and Treasury bonds, with maturities of 10 to 30 years. Current Treasury obligations
come in denominations of $1,000 and $10,000. The interest income from the U.S. government securities is subject to federal income tax but exempt from state and local levies. These bonds are popular because of their high credit quality, substantial liquidity, and noncallable feature.

Short-term T-bills differ from notes and bonds because they are sold at a discount from par to provide the desired yield. The return is the difference between the purchase price and the par at maturity. In contrast, government notes and bonds carry semiannual coupons that specify the nominal yield of the obligations.

Government notes and bonds have unusual call features. First, the period specified for the deferred call feature on Treasury issues is very long and is generally measured relative to the maturity date rather than from date of issue. They generally cannot be called until five years prior to their maturity date. Notably, all U.S. Treasury issues since 1989 have been noncallable.

Treasury Inflation-Protected Securities (TIPS) The Treasury began issuing these inflation-indexed bonds in January 1997 to appeal to investors who wanted or needed a real default-free rate of return. To ensure the investors will receive the promised yield in real terms, the bond principal and interest payments are indexed to the Consumer Price Index for All Urban Consumers (CPI-U), published by the Bureau of Labor Statistics. Because inflation is generally not known until several months after the fact, the index value used has a three-month lag built in—for example, for a bond issued on June 30, 2011, the beginning base index value used would be the CPI value as of March 30, 2011. Following the issuance of a TIPS bond, its principal value is adjusted every six months to reflect the inflation since the base period. In turn, the interest payment is computed based on this adjusted principal—that is, the interest payments equal the original coupon times the adjusted principal. The example in Exhibit 17.4 demonstrates how the principal and interest payments are computed. As shown in this example, both the interest payments and the principal payments are adjusted over time to reflect

---

9This section draws heavily from excellent articles by Shen (1998), Roll (2004), and Kothari and Shanken (2004).
the prevailing inflation, thereby ensuring that the investor receives a real rate of return on these bonds of 3.50 percent.

Notably, these bonds can also be used to derive the prevailing market estimate of the expected rate of inflation during the remaining maturity of the TIPS bond. For example, if we assume that when the bond is issued on July 15, 2008, it sells at par for a YTM of 3.50 percent, while a nominal Treasury note of equal maturity is sold at a YTM of 5.75 percent. This differential in promised YTM (5.75 − 3.50) implies that investors expect an average annual rate of inflation of 2.25 percent during this five-year period. If, a year later, the spread increased to 2.45 percent, it would indicate that investors expect a higher inflation rate during the next four years.\footnote{For a recent extended discussion of these securities, see Brynjolfsson, “Inflation Indexed Bonds,” in Fabozzi, ed. (2012).}

\textbf{Japan}\footnote{For additional discussion, see Viner (1988), Elton and Gruber (1990), and Fabozzi (1990a).} The second-largest country government bond market in the world is Japan’s. It is controlled by the Japanese government and the Bank of Japan (Japanese Central Bank). Japanese government bonds (JGBs) are an attractive investment vehicle for those favoring the Japanese yen because their quality is equal to that of U.S. Treasury securities (they are guaranteed by the government of Japan) and they are very liquid. There are three maturity segments: medium-term (2, 3, or 4 years), long-term (10 years), and super-long (private placements for 15 and 20 years). Bonds are issued in both registered and bearer form, although registered bonds can be converted to bearer bonds.

Medium-term bonds are issued monthly through a competitive auction system similar to that of U.S. Treasury bonds. Long-term bonds are authorized by the Ministry of Finance and issued monthly by the Bank of Japan through an underwriting syndicate consisting of major financial institutions. Most super-long bonds are sold through private placement to a few financial institutions. Very liquid federal government bonds account for over 50 percent of the Japanese bonds outstanding and over 80 percent of total bond trading volume in Japan.

At least 50 percent of the trading in Japanese government bonds will be in the so-called \textit{benchmark issue} of the time. The benchmark issue is selected from 10-year coupon bonds. (As of mid-2011, the benchmark issue was a 1.20 percent coupon bond maturing in 2021.) The designation of a benchmark issue is intended to assist smaller financial institutions in their trading of government bonds by ensuring these institutions that there is a liquid market in this particular security. Compared to the benchmark issue, the comparable most active U.S. bond within a class accounts for only about 10 percent of the volume.

The yield on this benchmark bond is typically about 30 basis points below other comparable Japanese government bonds, reflecting its superior marketability. The benchmark issue changes when a designated issue matures or because of a decision by the Bank of Japan.

\textbf{United Kingdom}\footnote{For further discussion, see European Bond Commission (1989).} The U.K. pound sterling government bond market is made up of jobbers and brokers who act as principals or agents with negotiated commission structures. In addition, there are 27 primary dealers similar to the U.S. Treasury market.

Maturities in this market range from short gilts (maturities of less than 5 years) to medium gilts (5 to 15 years) to long gilts (15 years and longer). Government bonds either have a fixed redemption date or a range of dates with redemption at the option of the government after giving appropriate notice. Government bonds are normally registered, although bearer delivery is available.

Gilts are issued through the Bank of England (the British central bank) using the tender method, whereby prospective purchasers tender offering prices at which they hope to be allotted bonds. The price cannot be less than the minimum tender price stated in the prospectus. If
the issue is oversubscribed, allotments are made first to those submitting the highest tenders and continue until a price is reached where only a partial allotment is required to fully subscribe the issue. All successful allottees pay the lowest allotment prices.

These issues are extremely liquid and are highly rated because they are guaranteed by the British government. All gilts are quoted and traded on the London Stock Exchange and pay interest semiannually.

**Eurozone** The combined value of the euro sovereign bond market is actually larger in U.S. dollar terms than the Japanese market because it includes several relatively significant markets including Germany, which was the third largest by itself, as well as France and Italy among others. Because the Eurozone includes numerous countries that were previously economically independent, the issuing process for alternative countries differs dramatically except that all of the bonds are denominated in euros. It is likely that over time the issuing process will become more uniform, but there will always be differences.

### 17.3.2 Government Agency Issues

In addition to pure government bonds, the federal government in each country can establish agencies that have the authority to issue their own bonds. The size and importance of these agencies differ among countries. Agency bonds are a large and growing sector of the U.S. bond market, a much smaller component of the bond markets in Japan and Germany, and nonexistent in the United Kingdom.

**United States** Agency securities are obligations issued by the U.S. government through either a government agency or a government-sponsored enterprise (GSE). Six government-sponsored enterprises and over two dozen federal agencies issue bonds. Exhibit 17.5 lists the more popular government-sponsored and federal agencies and their purposes.¹⁴

Agency issues usually pay interest semiannually, and the minimum denominations vary between $1,000 and $10,000. These obligations are not direct Treasury issues, yet they carry the full faith and credit of the U.S. government. Moreover, some of the issues are subject to state and local income tax, whereas others are exempt.¹⁵

One agency issue offers particularly attractive investment opportunities: GNMA (“Ginnie Mae”) pass-through certificates, which are obligations of the Government National Mortgage Association.¹⁶ These bonds represent an undivided interest in a pool of federally insured mortgages. The bondholders receive monthly payments from Ginnie Mae that include both principal and interest because the agency “passes through” mortgage payments made by the original borrower (the mortgagee) to Ginnie Mae.

The coupons on these pass-through securities are related to the interest charged on the pool of mortgages. The portion of the cash flow that represents the repayment of the principal is tax-free, but the interest income is subject to federal, state, and local taxes. The issues have minimum denominations of $25,000 with maturities of 25 to 30 years but an average life of only 12 years because, as mortgages in the pool are paid off, payments and prepayments are

---

¹³For additional information on the Eurobond market, see Molinas and Bales (2004).

¹⁴We will no longer distinguish between federal agency and government-sponsored obligations; instead, the term agency shall apply to either type of issue. For further discussion of these securities, see Cabana and Fabozzi, “Agency Securities,” in Fabozzi, ed. (2012).

¹⁵Federal National Mortgage Association (Fannie Mae) debentures, for example, are subject to state and local income tax, whereas the interest income from Federal Home Loan Bank bonds is exempt. In fact, a few issues are exempt from federal income tax as well (e.g., public housing bonds).

¹⁶For a further discussion of mortgage-backed securities, see Cabana and Fabozzi (2012); Bhattacharya and Berliner (2012); and Davidson, Cling, and Belbase (2012), all in Fabozzi, ed. (2012).
subsequently nationalized the two firms in 2009. As of mid-2011, there are ongoing discussions regarding the future of these firms or if they should simply be dissolved.

Japan

The agencies in Japan, referred to as government associate organizations, account for about 7 percent of the total Japanese yen bond market. This agency market includes public agency debt that is issued in a way similar to that of government debt.

United Kingdom

As shown in Exhibit 17.2, about 13 percent of the pound sterling market is agency and foreign government debt.

Eurozone

As shown in Exhibit 17.2, agency bonds and foreign government bonds are less than 8 percent of the Euro bonds outstanding.

17.3.3 Municipal Bonds

Municipal bonds are issued by states, counties, cities, and other political subdivisions. Again, the size of the municipal bond market (referred to as local authority in the United Kingdom) varies substantially among countries. It is about 9 percent of the total U.S. market, compared to less than 3 percent in Japan, nonexistent in the United Kingdom, and not specifically identified in the Eurozone data. Therefore, it is not broken out as a category in Exhibit 17.2. Because of the size and popularity of this market in the United States, we will discuss only the U.S. municipal bond market.

Municipalities in the United States issue two distinct types of bonds: general obligation bonds and revenue issues.

General obligation bonds (GOs) are essentially backed by the full faith and credit of the issuer and its entire taxing power. Revenue bonds, in turn, are serviced by the income generated from specific revenue-producing projects of the municipality, such as bridges, toll roads, hospitals, municipal coliseums, and waterworks. Revenue bonds generally provide higher returns than GOs because of their higher default risk. Should a municipality fail to generate sufficient income from a project designated to service a revenue bond, it has no legal debt service obligation until the income becomes sufficient, at which time the accrued interest will be paid.

GO municipal bonds tend to be issued on a serial basis so that the issuer’s cash flow requirements will be steady over the life of the obligation. Therefore, the principal portion of the total debt service requirement generally begins at a fairly low level and builds up over the life of the obligation. In contrast, most municipal revenue bonds are term issues, so the principal value is not due until the final maturity date.

The most important feature of municipal obligations is that the interest payments are exempt from federal income tax and from taxes for some states in which the obligation was issued. This means that their attractiveness varies with the investor’s tax bracket. You can convert the tax-free yield of a municipal to an equivalent taxable yield (ETY) using the following equation:

\[
ETY = \frac{i}{1-t}
\]

where:

- \(ETY\) = equivalent taxable yield
- \(i\) = coupon rate of the municipal obligations
- \(t\) = marginal tax rate of the investor

For a more detailed discussion of the municipal bond market, see Feldstein, Fabozzi, Grant, and Radner (2012); for discussion of the credit analysis of these bonds, see Feldstein, Grant, and Radner (2012); Both sources are in Fabozzi, ed. (2012).

An investor in the 35 percent marginal tax bracket would find that a 5 percent yield on a municipal bond selling close to its par value is equivalent to a 7.69 percent fully taxable yield according to the following calculation:

\[
ETY = \frac{i}{1-t}
\]

Because the tax-free yield is the major benefit of municipal bonds, an investor’s marginal tax rate is a primary concern in evaluating them. As a rough rule of thumb, using the tax rates expected in 2012, an investor must be in the 28 to 30 percent tax bracket before the lower yields available in municipal bonds are competitive with those from fully taxable bonds. However, although the interest payment on municipals is tax-free, any capital gains are not (which is why the ETY formula is correct only for a bond selling close to its par value).

Municipal Bond Insurance

A significant feature of the U.S. municipal bond market is municipal bond insurance, wherein an insurance company will guarantee to make principal and interest payments in the event that the issuer of a bond defaults. The insurance is placed on the bond at date of issue and is irrevocable over the life of the issue. The issuer purchases the insurance for the benefit of the investor, and the municipality benefits from lower interest costs due to lower credit risk, which causes an increase in the rating on the bond and increased marketability because more institutions can invest in the highly rated bond (typically AAA). Those who would benefit from the insurance are small government units that are not widely known and bonds with a complex capital structure.

The following discussion of the bond insurance companies has two components. The initial discussion considers the traditional history of bond insurance. This is followed by a discussion of the major problems encountered in this area during the 2007–2008 credit/liquidity crises.

As of 2008, approximately 40 percent of all new municipal bond issues were insured by six private bond insurance firms: the Municipal Bond Investors Assurance (MBIA), American Municipal Bond Assurance Corporation (AMBAC), the Financial Security Assurance (FSA), the Financial Guaranty Insurance Company (FGIC), Capital Guaranty Insurance Company (CGIC), and Connie Lee Insurance Company. These firms insured either general obligation or revenue bonds. To qualify for private bond insurance, the issue must initially carry an S&P rating of BBB or better. Traditionally, the rating agencies would give an AAA (Aaa) rating to bonds insured by these firms because the insurance firms typically had AAA ratings. A notable caveat was that if the ratings for one of these insurance companies was downgraded, all the bonds that it insured would be downgraded. Generally, insured bond issues enjoyed a more active secondary market and lower required yields.

As alluded to previously, this traditional environment for municipal bond insurance changed dramatically beginning in 2007–2008 as a consequence of the credit/liquidity crises that impacted all the insurance companies. Notably, the problems were not caused by credit events in the municipal bond market but by changes in the business model of the insurance companies. Specifically, these insurance firms entered the bond insurance business in the 1980s by insuring only municipal bonds, and they charged premium rates that reflected the fairly low default rates experienced by municipal bonds over time. This business line was very profitable for the insurance companies due to the continuing low default rates. Subsequently, the firms sold insurance on investment-grade corporate bonds at higher premiums.

18 For further discussion of municipal bond insurance, see Feldstein, Fabozzi, Grant, and Radner (2012) in Fabozzi, ed. (2012). For a discussion of the specific benefits of insurance to the issuer, see Kidwell, Sorenson, and Wachowicz (1987).

A notable caveat was that if the ratings for one of these insurance companies was downgraded, all the bonds that it insured would be downgraded. Generally, insured bond issues enjoyed a more active secondary market and lower required yields.\(^{18}\)

As alluded to previously, this traditional environment for municipal bond insurance changed dramatically beginning in 2007–2008 as a consequence of the credit/liquidity crises that impacted all the insurance companies. Notably, the problems were not caused by credit events in the municipal bond market but by changes in the business model of the insurance companies. Specifically, these insurance firms entered the bond insurance business in the 1980s by insuring only municipal bonds, and they charged premium rates that reflected the fairly low default rates experienced by municipal bonds over time. This business line was very profitable for the insurance companies due to the continuing low default rates. Subsequently, the firms sold insurance on investment-grade corporate bonds at higher premiums.

\(^{18}\)For further discussion of municipal bond insurance, see Feldstein, Fabozzi, Grant, and Radner (2012) in Fabozzi, ed. (2012). For a discussion of the specific benefits of insurance to the issuer, see Kidwell, Sorenson, and Wachowicz (1987).
due to their slightly higher historical default rates (about 2 percent cumulative default over 10 years for BBB-rated bonds). Again this was generally a profitable business with continuing low default rates. Finally, in the early 2000s they took a very large step and began insuring structured finance products including collateralized debt obligations (CDOs; to be described later) that contained a combination of many securities (including subprime mortgages). Unfortunately, the premiums charged for this insurance were relatively low, given the much higher risk involved. More important, the defaults experienced during 2007–2008 were substantially higher than envisioned, and the payments required by these insurance firms to cover the defaults on these securities were very large compared to the capital available to these insurance firms. As a result of these losses and the resulting capital impairment, the rating agencies downgraded the smaller insurance firms in early 2008 and the largest firms experienced significant downgrades in July 2008. As noted earlier, when these insurance companies are downgraded, all the bonds with an AAA rating because of the bond insurance also are downgraded. Therefore, the disruptive impact on the municipal bonds was enormous. For a period in 2008 and 2009, the typical negative spread on municipals relative to Treasuries became positive. As of mid-2011, the spread was not negative, but it was very small—about 11 basis points (2.88 percent for municipals vs. 2.99 percent for 10-year Treasuries).

17.3.4 Corporate Bonds

Again, the importance of corporate bonds varies across countries. The absolute dollar value of corporate bonds in the United States is substantial and has grown overall and as a percentage of U.S. long-term capital. At the same time, corporate debt as a percentage of total U.S. debt has stabilized at about 30 percent because of the faster growth of agency debt. The pure corporate sector in Japan is small and declining, and the ex-bank corporate sector in the Eurozone has grown to be over 14 percent. The proportion of corporate debt in the United Kingdom has increased to almost 30 percent.

U.S. Corporate Bond Market Utilities dominate the U.S. corporate bond market. Other important segments include industrials, rail and transportation issues, and financial issues. This market is very diverse and includes debentures, first-mortgage issues, convertible obligations, bonds with warrants, subordinated debentures, income bonds (similar to municipal revenue bonds), collateral trust bonds backed by financial assets, equipment trust certificates, and a variety of asset-backed securities (ABS), including mortgage-backed bonds (MBS).

If we ignore convertible bonds and bonds with warrants, the preceding list of obligations varies by the type of collateral behind the bond. Most bonds have semiannual interest payments, sinking funds, and a single maturity date. Maturities range from 25 to 40 years, with public utilities generally on the longer end and industrials preferring the 25- to 30-year range. Most corporate bonds provide for deferred calls after 5 to 10 years. The deferment period varies directly with the level of the interest rates. Specifically, during periods of higher interest rates, bond issues typically will carry a 7- to 10-year deferment, while during periods of lower interest rates, the deferment periods decline.

On the other hand, corporate notes—with maturities of five to seven years—are generally noncallable. Notes become popular when interest rates are high because issuing firms prefer to avoid long-term obligations during such periods. In contrast, during periods of very low interest rates, such as 1997, 2001–2004, and 2008–2010, many corporate issues did not include a call provision because corporations did not believe that they would be able to exercise the call option as rates were already very low and the firms did not want to pay the higher yield required for the call option.

Generally, the average yields for industrial bonds will be the lowest of the three major sectors, followed by utility returns. The difference in yield between utilities and industrials occurs
because utilities have the largest supply of bonds, so yields on their bonds must be higher to increase the demand for these bonds.\textsuperscript{19}

Other corporate bonds beyond debentures are discussed below.

**Mortgage Bonds** The issuer of a mortgage bond has granted to the bondholder a first mortgage lien on some piece of property or possibly all the firm’s property. Such a lien provides greater security to the bondholder in case of a default, and a lower interest rate for the issuing firm.

**Equipment Trust Certificates** Equipment trust certificates are issued by railroads (the biggest issuers), airlines, and other transportation firms with the proceeds used to purchase equipment (freight cars, railroad engines, and airplanes), which serves as the collateral for the debt. Maturities range from 1 to about 15 years. The fairly short maturities reflect the nature of the collateral, which is subject to substantial wear and tear and tends to deteriorate rapidly.

Equipment trust certificates are appealing to investors because of their attractive yields, low default record, and a fairly liquid secondary market.

**Collateral Trust Bonds** As an alternative to pledging fixed assets or property, a borrower can pledge financial assets, such as stocks, bonds, or notes, as collateral. These bonds are termed collateral trust bonds. These pledged financial assets are held by a trustee for the benefit of the bondholder.

**Mortgage Pass-Through Securities\textsuperscript{20}** Earlier, we discussed mortgage bonds backed by pools of mortgages. You will recall that the pass-through monthly payments are necessarily both interest and principal and that the bondholder is subject to early retirement of the bond if the mortgagees prepay because the house is sold or the mortgage refinanced. Therefore, when you acquire the typical mortgage pass-through bonds, you would be uncertain about the size and timing of the payments.

**Collateralized mortgage obligations (CMOs)**\textsuperscript{21} were developed in the early 1980s to offset some of the problems with the traditional mortgage pass-throughs. The main innovation of the CMO instrument is the segmentation of irregular mortgage cash flows to create short-term, medium-term, and long-term securities. Specifically, CMO investors own bonds that are serviced with the cash flows from mortgages; but, rather than the straight pass-through arrangement, the CMO substitutes a *sequential distribution process* that creates a series of bonds with varying maturities to appeal to a wider range of investors.

The prioritized distribution process is as follows:

- Several classes of bonds (these are referred to as *tranches*) are issued against a pool of mortgages, which are the collateral. For example, assume a CMO issue with four classes (tranches) of bonds. In such a case, the first three (e.g., Classes A, B, C) would pay interest at their stated rates beginning at their issue date, and the fourth class would be an accrual bond (referred to as a *Z bond*).

- The cash flows received from the underlying mortgages are applied first to pay the interest on most of the bonds (all except the accrual class) and then to retire the bonds sequentially, as discussed below.

- The classes of bonds are retired sequentially. All principal payments (both scheduled payments and prepayments) are directed first to the shortest-maturity class A bonds until they are completely retired. Then all principal payments are directed to the next

\textsuperscript{19}For a further discussion, see Fabozzi, Mann, and Cohen (2012) in Fabozzi, ed. (2012).

\textsuperscript{20}For a further discussion of mortgages and mortgage pass-through securities, see Bhattacharya and Berliner (2012) and Davidson, Cling, and Belbuse (2012), both in Fabozzi, ed. (2012).

\textsuperscript{21}For further discussion of CMOs, see Crawford (2012); three chapters by Lowell (2012); Mohabbi, Li, White, and Kwun (2012); and Hu and Goldstein (2012), all in Fabozzi (2012).
shortest-maturity bonds (i.e., the class B bonds). The process continues until all the classes have been paid off.

- During the early periods, the accrual bonds (the class Z bonds) pay no interest, but the interest accrues as additional principal, and the cash flow from the mortgages that collateralize these bonds is used to pay interest on and retire the bonds in the other classes. Subsequently, all remaining cash flows are used to pay off the accrued interest, to pay any current interest, and then to retire the Z bonds.

This prioritized sequential pattern means that the A-class bonds are fairly short term and each subsequent class is a little longer term until the Z-class bond, which is a long-term bond that functions like a zero-coupon or PIK bond for the initial years.

Besides creating bonds that pay interest in a more normal pattern (quarterly or semiannually) and that have more predictable maturities, these bonds are considered very high-quality securities (AAA) because of the structure and quality of the collateral. To obtain an AAA rating, CMOs are structured to ensure that the underlying mortgages will always generate enough cash to support the bonds issued, even under the most conservative prepayment and reinvestment rates. In fact, most CMOs are overcollateralized.

Further, the credit risk of the collateral is minimal because most are backed by mortgages guaranteed by a federal agency (GNMA) or by the FHLMC. Those mortgages that are not backed by agencies carry private insurance from one of the GSEs (Fannie Mae or Freddie Mac) for principal and interest and are rated AAA. Notably, even with this AAA rating, the yield on these CMOs typically has been higher than the yields on AA industrials. This premium yield has contributed to their popularity and growth.

**Covered Bonds**  As noted, the prepayment (maturity uncertainty) problem with straight mortgage pass-through securities was alleviated with the creation of CMOs. Subsequently, the significant credit crises during 2008–2009 almost destroyed the mortgage-backed market because of the numerous defaults on mortgages that caused even some highly rated securities to experience major price declines and heavy losses for numerous investors. In response to this event, some observers have suggested that the U.S. mortgage market consider issuing **covered bonds**, which have been issued for many years (since the 18th century) in Europe (e.g., Germany, Denmark, France, and Spain).

As discussed previously, in the case of a standard mortgage-backed security (MBS) or a collateralized mortgage obligation (CMO), the major credit backing for the bond is the pool of assets (the mortgages) held by the special purpose entity (SPE) that owns the pool of assets. Notably, the issuer (originator) of the MBS that put together the pool of assets is basically free from any risk once the assets (mortgages) have been sold to the SPE and the MBS bonds have been sold to the investors. In contrast, in the case of covered bonds, due to several unique transactions the MBS bonds are backed by both the pool of assets and the issuing firm. Specifically, the bond is still an obligation of the issuer, yet it is also backed by the claim over the collateral pool of mortgages that can withstand a claim by the creditors of the issuer if the issuer enters bankruptcy. Therefore, covered bonds are backed by both the credit of the issuer and the strength of the asset pool.

The specific set of transactions that must occur to create “structured covered bonds” are fairly complicated and beyond the scope of this chapter. For an excellent detailed discussion of what is done to create covered bonds, see Vinod Kothari, “Covered Bonds,” in Fabozzi (2012).

**Asset-Backed Securities (ABSs)**  A rapidly expanding segment of the securities market is that of asset-backed securities, which involve securitizing debt beyond the residential mortgages that we have discussed. This is an important concept because it substantially increases the liquidity of these individual debt instruments, whether they be commercial mortgages, car loans, credit card debt, student loans, or home equity loans. This general class of securities was introduced
in 1983. As of December 31, 2010, there was almost $4.0 trillion of asset-backed securities outstanding. This nonmortgage market is dominated by securities backed by automobile loans and credit card receivables.

**Certificates for Automobile Receivables (CARs)** CARs are securities collateralized by loans made to individuals to finance the purchase of cars. Auto loans are self-amortizing, with monthly payments and relatively short maturities (i.e., two to six years). These auto loans can either be direct loans from a lending institution or indirect loans that are originated by an auto dealer and sold to the ultimate lender. CARs typically have monthly or quarterly fixed interest and principal payments and expected weighted average lives of one to three years. The expected actual life of the instrument typically is shorter than the specified maturity because of early payoffs when cars are sold or traded in. The cash flows of CARs are comparable to short-term corporate debt, but they provide a significant yield premium over these securities. The popularity of these collateralized securities makes them important not only by themselves but also as an indication of the potential for issuing additional collateralized securities backed by other assets and/or other debt instruments.

**Credit Card–Backed Securities** Recently, the fastest-growing segment of the ABS market has been securities supported by credit card loans. Credit card receivables are a revolving credit ABS, in contrast to auto loan receivables that are referred to as an installment contract ABS, because of the nature of the loan. Specifically, whereas the mortgaged-backed and auto loan securities amortize principal, the principal payments from credit card receivables are not paid to the investor but are retained by the trustee to reinvest in additional receivables. This allows the issuer to specify a maturity for the security that is consistent with the needs of the issuer and the demands of the investors.

When buying a credit card ABS, the indenture specifies (1) the intended maturity for the security, (2) the “lockout period,” during which no principal will be paid, and (3) the structure for repaying the principal, which can be accomplished through a single-bullet payment, similar to a bond, or distributed monthly with the interest payment over a specified amortization period. For example, a 5-year credit card ABS could have a lockout period of 4 years followed by a 12-month amortization of the principal.

Beyond this standard arrangement, revolving credit securities are protected by early amortization events that can force early repayment if specific payout events occur that are detrimental to the investor (e.g., if there is an increase in the loss rate or if the issuer goes into bankruptcy or receivership). This early amortization feature protects the investor from credit problems, but it also causes an early payment that may not be desirable for the investor.

**Auction-Rate Securities** are issued by municipalities, hospitals, museums, and student loan authorities in an attempt to pay short-term rates for long-term funds. These securities have stated long maturities such as 20 or 30 years, but they typically have required yields like short-term securities because the coupon is constantly being set during frequent auctions every week to 35 days. At these auctions, the original investors can hold the security and get the new rate set at the auction. Alternatively, if they want to liquidate their position or don’t think the yield is high enough, they can sell the security at the auction. Investors, such as treasurers and pension funds, like these securities as short-term investment options because they are generally very liquid and provide yields that exceed what is available on T-bills.

This market was very popular prior to 2008 when it became very illiquid because there was a massive “flight to quality” and numerous auctions “failed,” meaning that there were not

---

22For further discussion of CARs, as well as equipment loans and student loans, see McElravey (2012) in Fabozzi (2012).

23For further discussion of credit card–backed securities, see McElravey (2012), in Fabozzi, ed. (2012).
enough bids to sell all the bonds available. As a result, investors could not liquidate their position, and issuers suffered because the required yield increased dramatically (e.g., from 4 percent to 15 percent). For a discussion of what transpired during this period, see Rappaport and Karmin (2008) and Smith, McGinty, and Rappaport (2008).

**Variable-Rate Notes** Introduced in the United States in the mid-1970s, variable-rate notes became popular during periods of high interest rates. As discussed by Fabozzi and Mann (2012), the typical variable-rate note possesses two unique features:

1. After the first 6 to 18 months of the issue’s life, during which a minimum rate is often guaranteed, the coupon rate floats, so that every six months it changes to follow some standard. Usually it is pegged 1 percent above a stipulated short-term rate. For example, the rate might be tied to the preceding three weeks’ average 90-day T-bill rate.
2. After the first year or two, the notes are redeemable at par, at the holder’s option, usually at six-month intervals.

Such notes represent a long-term commitment on the part of the borrower yet provide the lender with all the characteristics of a short-term obligation. They typically are available to investors in minimum denominations of $1,000. However, although the six-month redemption feature provides liquidity, the variable rates can cause these issues to experience wide swings in semiannual coupons.

**Collateralized Debt Obligations (CDOs)** CDOs are considered part of the asset-backed security market because they are backed by cash-flow generating assets similar to mortgages, car loans, or credit card accounts. They deserve special attention for four reasons: (1) their rapid growth since 2000, (2) the substantial diversity of assets that are used to back the securities, (3) the diversity of credit quality within a CDO issue in terms of credit rating, and (4) the significant problems generated by these securities caused by credit problems for the tranches with low credit ratings and liquidity problems for the tranches with high credit ratings.

As noted, in contrast to most ABSs that are backed by one specific type of asset (mortgages, car loans, etc.), the CDO is generally backed by a diversified pool of several assets including investment-grade or high-yield bonds, domestic bank loans, emerging market bonds, residential mortgages (some subprime) and commercial mortgages, and even other CDOs. The reason for creating many CDOs is to allow an institution to reduce its capital requirements by removing some high-risk loans from its balance sheet. Beyond a diverse set of assets, the CDO is typically structured into tranches similar to the CMOs, but in this case the tranches differ by credit quality—that is, the issuers use credit enhancement techniques to create tranches that are rated from AAA to BBB or lower. Similar to other ABSs, the issuer, in consultation with the rating agencies, determines what credit enhancements are required to attain a given rating for a tranche. Therefore, investors can benefit from higher returns but can also select their desired credit risk based on the ratings assigned.

The problems in these securities began in 2006 during the real estate “boom,” when mortgage loans were made to numerous individuals with very low credit scores resulting in subprime mortgage loans that were subsequently put into CDOs. In 2007 and 2008, a high proportion of these subprime loans defaulted, which reduced the value of these tranches. Even the highly rated tranches that were protected by credit enhancement techniques could not be traded—they were very illiquid because of a significant flight to quality to Treasury securities and away from complicated securities with credit ratings that were being questioned. As a result, there were significant price declines in a short period of time (from par value to 65 percent of par) because of either credit or liquidity problems.

**Zero-Coupon and Deep Discount Bonds** The typical corporate bond has a coupon and maturity. As discussed in Chapter 11, the value of the bond is the present value of the stream of
The high-yield bond market exploded in size and activity beginning in the early 1980s (recent data in Exhibit 17.6). Beginning in 1983, more large issues became common and the average size of an issue currently is over $460 million. Also, high-yield issues have become a significant percentage of the total new-issue bond market. As of 2011, the total outstanding high-yield debt constituted about 20 percent of outstanding corporate debt in the United States.

**Distribution of High-Yield Bond Ratings**

Exhibit 17.7 contains the distribution of ratings for all the bonds contained in the B of A Merrill Lynch High-Yield Bond Index as of December 31, 1992–May 31, 2011. As shown, the heavy concentration by market value is typically in the B-rated class that has a range of value from about 40 percent to 71 percent and averages about 55 percent for the annual periods 1992–2010. In contrast, both the high- and the low-rated categories have fairly volatile percentages depending on the business cycle—i.e., during a recession year (e.g., 2001, 2009) there is an increase in BBs and a decline in CCCs. Specifically, the BB rated segment varies from about 19 percent to 45 percent, and the CCC/NR segment varies from about 4 percent to 35 percent. This volatility in the percentages is also reflected in the relative standard deviations measured by the coefficients of variation.

**Ownership of High-Yield Bonds**

The major owners of high-yield bonds have been mutual funds, insurance companies, and pension funds. As of the end of 2010, over 100 mutual funds were either exclusively directed to invest in high-yield bonds or included such bonds in their portfolio. Notably, there has been a shift of ownership away from insurance companies and

---

25 These bonds will be discussed further in Chapter 18 in the section on volatility and duration and in Chapter 19 when we consider immunization.

---

25 Almost everyone would acknowledge that the development of the high-yield debt market has had a positive impact on the capital-raising ability of the economy. For an analysis of this impact, see Perry and Taggart (1988). Updates on the characteristics of this market are contained in Fridson (1994), Altman (1992), and Reilly, Wright, and Gentry (2009).
an international syndicate, and sold to non-U.S. investors outside the United States. The relative size of these two markets (foreign bonds versus Eurobonds) varies by country.

**United States**
The Eurodollar bond market in the U.S. has become much larger than the Yankee bond market. However, because the Eurodollar bond market is heavily affected by changes in the value of the U.S. dollar, it experiences slower growth during periods when the dollar is weak. Such periods create a desire for diversification by investors.

Yankee bonds are issued by foreign firms who register with the SEC and borrow U.S. dollars, using issues underwritten by a U.S. syndicate for delivery in the United States. These bonds are traded in the United States and pay interest semiannually. Over 60 percent of Yankee bonds are issued by Canadian corporations and typically have shorter maturities and longer call protection than U.S. domestic issues. These features increase their appeal.

The Eurodollar bond market is dominated by foreign investors, and the center of trading is in London. Eurodollar bonds pay interest annually. The Eurodollar bond market currently comprises almost 40 percent of the total Eurobond market.

**Japan**
Historically, the Japanese yen international bond market was dominated (over 90 percent) by foreign bonds (Samurai bonds) with the balance in Euroyen bonds. After the issuance requirements for Euroyen bonds were liberalized in the mid-1980s, the ratio of issuance swung heavily in favor of Euroyen bonds.

Samurai bonds are yen-denominated bonds sold by non-Japanese issuers and mainly sold in Japan. The market is fairly small and has limited liquidity. Notably, the market has experienced slow growth in terms of yen but substantial growth in U.S. dollar terms because of changes in the exchange rate.

Euroyen bonds are yen-denominated bonds sold in markets outside Japan by international syndicates. This market has grown substantially because of the liberal issue requirements. Its appeal over time is determined by the strength or weakness of the yen relative to other currencies.

**United Kingdom**
Pound sterling foreign bonds, referred to as bulldog bonds, are sterling-denominated bonds issued by non-English firms and sold in London. Eurosterling bonds are sold in markets outside London by international syndicates. Similar to other countries, the U.K. international bond market has become dominated by the Eurosterling bonds. The procedure for issuing and trading Eurosterling bonds is similar to that of other Eurobonds.

**Eurozone**
The growth of Eurobonds issued by nonresidents has been impressive in recent years. This growth confirmed the popularity of the Euro markets among foreign issuers, including issuers domiciled in the United States that accounted for over 7 percent of the market.

**17.3.5 International Bonds**

Each country’s international bond market has two components. The first, foreign bonds, are issues sold primarily in one country and currency by a borrower of a different nationality. An example would be U.S. dollar-denominated bonds sold in the United States by a Japanese firm. (These are referred to as Yankee bonds.) Second are Eurobonds, which are bonds underwritten by international bond syndicates and sold in several national markets. An example would be Eurodollar bonds, which are securities denominated in U.S. dollars, underwritten by

savings and loans toward mutual funds. This shift occurred during the late 1980s when regulators “encouraged” the insurance companies and S&Ls to reduce or eliminate high-yield bonds from their portfolios.

The purpose of this discussion has been to introduce you to high-yield bonds because of the growth in size and importance of this segment of the market for individual and institutional investors. We revisit this topic in Chapter 19 on bond portfolio management, where we review the historical rates of return and alternative risk factors, including the default experience for these bonds. As discussed by Altman (1990), Fabozzi (1990b), Fridson (1989), and Reilly, Wright, and Gentry (2009), all of this must be considered by potential investors in these securities.

26 For a discussion of the international bond market, see Ramanathan (2012), and for a discussion of emerging market debt, see Brauer and Beker (2012), both of which are in Fabozzi, ed. (2012).
an international syndicate, and sold to non-U.S. investors outside the United States. The relative size of these two markets (foreign bonds versus Eurobonds) varies by country.

**United States** The Eurodollar bond market in the U.S. has become much larger than the Yankee bond market. However, because the Eurodollar bond market is heavily affected by changes in the value of the U.S. dollar, it experiences slower growth during periods when the dollar is weak. Such periods create a desire for diversification by investors.

Yankee bonds are issued by foreign firms who register with the SEC and borrow U.S. dollars, using issues underwritten by a U.S. syndicate for delivery in the United States. These bonds are traded in the United States and pay interest semiannually. Over 60 percent of Yankee bonds are issued by Canadian corporations and typically have shorter maturities and longer call protection than U.S. domestic issues. These features increase their appeal.

The Eurodollar bond market is dominated by foreign investors, and the center of trading is in London. Eurodollar bonds pay interest annually. The Eurodollar bond market currently comprises almost 40 percent of the total Eurobond market.

After the issuance requirements for Euroyen bonds were liberalized in the mid-1980s, the ratio of issuance swung heavily in favor of Euroyen bonds.

Samurai bonds are yen-denominated bonds sold by non-Japanese issuers and mainly sold in Japan. The market is fairly small and has limited liquidity. Notably, the market has experienced slow growth in terms of yen but substantial growth in U.S. dollar terms because of changes in the exchange rate.

Euroyen bonds are yen-denominated bonds sold in markets outside Japan by international syndicates. This market has grown substantially because of the liberal issue requirements. Its appeal over time is determined by the strength or weakness of the yen relative to other currencies.

**United Kingdom** Pound sterling foreign bonds, referred to as bulldog bonds, are sterling-denominated bonds issued by non-English firms and sold in London. Eurosterling bonds are sold in markets outside London by international syndicates.

Similar to other countries, the U.K. international bond market has become dominated by the Eurosterling bonds. The procedure for issuing and trading Eurosterling bonds is similar to that of other Eurobonds.

**Eurozone** The growth of Eurobonds issued by nonresidents has been impressive in recent years. This growth confirmed the popularity of the Euro markets among foreign issuers, including issuers domiciled in the United States that accounted for over 7 percent of the market.

### 17.4 Obtaining Information on Bond Prices

Historically, the price information available to bond investors has been substantially different from price information available to stock investors. Specifically, stock investors can receive up-to-the-minute transaction prices on all NYSE, AMEX, and NASDAQ national stocks as well as daily closing prices for most other NASDAQ stocks. In contrast, most bond trading has been done on the over-the-counter (OTC) market, and there was limited reporting of transactions, with the exception of the very liquid government bond market. Fortunately, this environment in the bond market changed dramatically beginning in 2004. As described by Lucchetti and Soloman (2004) and subsequently by Rappaport (2004b), the National Association of Securities Dealers (NASD), through its Trade Reporting and Compliance Engine (TRACE), began releasing more timely pricing data for a broad group of corporate bonds. Specifically, as of October 2004, NASD expanded the number of corporate bonds for which it reports pricing
information, from 4,500 bonds within 45 minutes of the transaction to 17,000 bonds within 30 minutes of the transaction. The existence of more bond issues than stock issues is possible because companies can have more than one bond issue, but typically only one stock issue. In 2005, the NASD began reporting transactions on all 23,000 corporate bond issues with the goal to reduce the reporting interval to within 15 minutes of the transaction. Clearly, the price transparency in the corporate bond market has changed significantly, and the transaction cost savings for bond investors has been dramatic.

In addition to better pricing data, as discussed by Rappaport (2004a), the overall bond market (and especially the corporate bond market) has benefited from the introduction of electronic bond trading through Thomson Trade Web and Market Axess, the two leading trading platforms. In early 2004, there was electronic trading in government agency and mortgage-backed securities, but it was not until late 2004 that the volume of trading and the size of corporate bond trading brought transparency to this market. Observers contend that the next frontiers will be electronic trading in high-yield bonds, emerging market debt, and interest rate derivatives.

Given this background, the following discussion considers how investors read and interpret bond price information in newspapers and quote sheets.

17.4.1 Interpreting Bond Quotes

Essentially, all bonds are quoted on the basis of either yield or price. Price quotes are always interpreted as a percentage of par. For example, a quote of 98¼ is interpreted not as $98.50 but 98¼ percent of par. The dollar price is derived from the quote, given the par value. If the par value is $5,000 on a municipal bond, then the price of an issue quoted at 98¼ would be $4,925. Actually, the market follows three systems of bond pricing: one system for corporates, another for governments (both Treasury and agency obligations), and a third for municipals.

**Corporate Bond Quotes** Exhibit 17.8 is a listing of corporate bond quotes for the 40 most active fixed-coupon corporate bonds that appeared in Barron’s on May 9, 2011. The data pertain to trading activity for the week ending May 6, 2011. Several quotes have been designated for illustrative purposes.

The first issue designated is a Republic Services (trading symbol RSG) issue that is representative of most corporate prices. This is a 5.700 percent coupon, which means that the annual coupon payment for this $1,000 par value bond is $57.00 or $28.50 every six months. The bond matures on May 15, 2041, which is almost exactly 30 years from May 6, 2011. The last transaction price for a bond trade on May 6 was 100.978 of par or $1,009.78, which implies a yield to maturity (YTM) for this bond (to be explained in detail in Chapter 18) of 5.632 percent. The estimated spread in basis points (100 basis points is one percentage point) indicates how the YTM for this bond compares to the prevailing yield to maturity for a Treasury note or bond of equal maturity. The Treasury issues are limited to the following maturities: 2, 5, 10, and 30 years, and they use the latest issue at the specified maturity (that is referred to as “on the run”) as listed. As shown, the computed spread for the Republic Services bond is 134 basis points (1.34 percent), which implies that at this time the 30-year Treasury bond (a 4.25 coupon bond that matures in November 2040) is yielding about 4.29 percent (5.632 – 1.34). As can be seen from the other bonds in the exhibit, the average spread for all the bonds is fairly small—ranging from 29 to 714 basis points with the vast majority under 200 basis points. These smaller-than-normal spreads are caused by the continuing gradual recovery of the economy that has resulted in a decline in bond defaults along with continued easy money policy by the Federal Reserve.

The second issue designated is the General Electric Capital (GE) bond for the finance subsidiary of this major industrial firm. These bonds, which mature in about 9.5 years, are compared to the 10-year Treasury security that likewise matures in 9.5 years (February 2021). The spread of 126 basis points is relatively small because of the strong AA bond rating that GE
The prevailing 4.466 yield compares to the 10-year Treasury security yield of about 3.20 percent. The third issue is the JPMorgan Chase (JPM) bond that matures in March 1, 2016, which is a little less than 5 years from the date of this exhibit. It has a relatively small spread of 119 basis points relative to the 5-year Treasury note that was currently yielding about 1.86 percent. This spread can be explained mainly by its Aa bond rating, its significant cash flows, and its short maturity. These examples indicate that bond prices are determined by yields to maturity that, in turn, are driven by required spreads to Treasury securities. The estimated volume indicates that there is substantial trading in these very liquid corporate bonds.

All fixed-income obligations, with the exception of preferred stock, are traded on an accrued interest basis. The prices pertain to the value of all future cash flows from the bond and exclude interest that has accrued to the holder since the last interest payment date. The actual price of the bond will exceed the quote listed because accrued interest must be added. Assume a bond with a 6 percent coupon. If two months have elapsed since interest was paid, the current holder of the bond is entitled to two-sixths (one-third) of the bond’s semiannual interest payment that will be paid in four months. More specifically, the 6 percent coupon provides semiannual interest income of $30. The investor who held the obligation for two months beyond the last interest payment date is entitled to one-third of that $30 in the form of accrued interest. Therefore, whatever the current price of the bond, an accrued interest value of $10 will be added. If a bond is trading “flat,” interest is not currently being paid by the issuer and accrued interest would not be added.

## Treasury and Agency Bond Quotes

Exhibit 17.9 illustrates the quote system for Treasury bonds, notes, and bills. These quotes resemble those used for OTC securities because they contain both bid and ask prices. Securities with original maturities over 10 years are Treasury bonds. The security identification is different because it is not necessary to list the issuer. Instead, the usual listing indicates the coupon, the month and year of maturity, and information on a call feature of the obligation. Call features have not been relevant for several years since the Treasury has not issued a bond with a call option since 1985 and all previously outstanding callable issues have matured. The bid-ask figures provided are stated as a percentage of par. The yield figure provided is yield to maturity, or promised yield based on the asking price. This system is used for Treasuries, agencies, and municipals. The data in Exhibit 17.9 under the “US Notes and Bonds” is in two sections, with the first one containing very short-term securities through 2011; the second section begins with bonds due in 2022 to 2041 to show the large number of Treasury bonds available.

Quote 1 is a 5 percent obligation, due in May 2037, that demonstrates the basic difference in the price system of government bonds (i.e., Treasuries and agencies). The bid quote is 112:06, and the ask is 112:08. Governments are traded in 32nds of a point (rather than 8ths), and the figures to the right of the colons indicate the number of 32nds in the fractional bid or ask. In this case, the bid price is actually 112.1875 percent of par. These quotes also are notable in terms of the bid-ask spread, which typically is one or two 32nds, or less than half the size of the spread for most stocks. This small spread reflects the outstanding liquidity and low transaction costs for Treasury securities.

The column that contains quotes for U.S. Treasury zero-coupon securities that have been stripped is divided to show the early and late dates to indicate the large number of zero-coupon bonds available that go out to 2041. Specifically, the typical bond promises a series of coupon payments and its principal at maturity. A stripped security is created by dividing into separate units each coupon payment and principal payment, which are treated like a zero-coupon bond that matures on that date. The security labeled 2 was originally a coupon that was to be paid in August 2012. The asking yield (0.22) is referred to as the spot rate for this maturity (spot rate will be discussed in Chapter 18). The coupon interest payment with no principal is designated 0.22.

Volume represents total volume for each issue; price/yield data are for trades of $1 million and greater. *Denotes a security whose last round lot trade did not take place on the last business day prior to publication. ** Estimated spreads, in basis points (100 basis points is one percentage point), over the 2, 5, 10 or 30-year hot run Treasury note/bond. 2-year: 0.625; 5-year: 0.00; 10-year: 0.00; 20-year: 0.5; 30-year: 0.0. *Comparable U.S. Treasury Issue. Treasury Bonds, Notes and Bills

Explanatory Notes
Representative Over-the-counter quotation based on transactions of $1 million or more. Treasury bond, note and bill quotes are as of mid-afternoon. Colons in bid and asked quotes represent 32nds: 101:01 means 101 1/32. Net changes in 32nds. n-Treasury note, i-indexed issue. Treasury bill quotes in hundreds, quoted on terms of a rate of discount. Days to maturity calculated from settlement date. All yields are to maturity and based on the asked quote. Latest 13-week and 26-week rates are bold-faced. For bonds callable prior to maturity, yields are computed to the earliest call date for issues quoted above par and to the maturity date for issues below par. *When issued.

U.S. Treasury strips as of 3 p.m. Eastern time, also based on transactions of $1 million or more. Colons in bid and asked quotes represent 32nds: 99:01 means 99 1/32. Net changes in 32nds. Yields calculated on the asked quotation, c-stripped coupon interest, b-Treasury bond, stripped principal, op-Treasury note, stripped principal. For bonds callable prior to maturity, yields are computed to the earliest call date for issues quoted above par and to the maturity date for issues below par.

as $ci$ (stripped coupon interest), while the other strips for August 2012 containing only the principal payment are designated $np$ (Treasury note, stripped principal).

The securities listed in the Treasury strip (zero coupon) and Treasury bill section only report dates and days to maturity and no coupons. This is because these are pure discount securities, that is, the return is the difference between the price you pay and the par value at maturity.\footnote{For a discussion of calculating yields, see Fielitz (1983).}

The final section in this part of the exhibit contains Treasury Inflation-Indexed Securities (TIPS), discussed earlier. Notice the accrued principal in the last column that reflects the inflation since the bond was issued. The bond designated 3 has been outstanding the longest time, so it has the highest accrued principal value of 1,371, and its yield to maturity (1.416) is computed using this as the principal amount to be paid at maturity (obviously, this accrued principal will continue to increase until it matures).

The bottom section of the table included above entitled “Other Agency Securities” is included to indicate quotes for some of the available government agency securities discussed earlier.

**Municipal Bond Quotes** Exhibit 17.10 contains municipal bond quotes from The Blue List of Current Municipal Offerings. These are ordered according to states and then alphabetically within states. Each issue gives the amount of bonds being offered (in thousands of dollars), the name of the security, the purpose or description of the issue, the coupon rate, the maturity (which includes month, day, and year), the yield or price, and the dealer offering the bonds. A list in the back of the publication gives the name and phone number of the firm offering the bond.

The first bond is for $115,000 of Indiana State Toll Road bonds with a 9 percent coupon. These bonds have an M/S/F (mandatory sinking fund) that becomes effective in 2011, although the bond matures in 2015. The letters ETM mean that the sinking fund is put into escrow to maturity. The market yield on these bonds is 6.30 percent, which means the bond would be selling at a premium.

The second bond is $1 million of Indiana State Toll Road bonds that are (n/c/s/f11) which means they are noncallable, sinking fund bonds starting in 2011. The coupon is 9 percent, and the bond matures on January 1, 2015, with the sinking fund put into escrow. Finally, the current YTM is 6 percent.

The world bond market is large and is continuing to grow due to government deficits around the world and the need for capital by corporations. It is also very diverse in terms of country alternatives and issuers within countries. This chapter provides the fundamentals that will allow us to consider the valuation of individual bonds in Chapter 18 and the alternative bond portfolio techniques in Chapter 19.

**SUGGESTED READINGS**

Green, Richard, Dan Li, and Norman Schurhoff, "Price Discovery in Illiquid Markets: Do Financial Asset Prices Rise Faster Than They Fall?" *Journal of Finance* 65, no. 4 (December 2010).

**QUESTIONS**

1. Explain the difference between calling a bond and a bond refunding.
2. Identify the three most important determinants of the price of a bond. Describe the effect of each.
3. Given a change in the level of interest rates, discuss how two major factors will influence the relative change in price for individual bonds.
4. Briefly describe two indenture provisions that can affect the maturity of a bond.
5. Explain the differences in taxation of income from municipal bonds, from U.S. Treasury bonds, and from corporate bonds.
6. For several institutional participants in the bond market, explain what type of bond each is likely to purchase and why.
7. Why should investors be aware of the trading volume for bonds in their portfolio?
8. What is the purpose of bond ratings?
9. Based on the data in Exhibit 17.2, discuss the makeup of the Japanese bond market and how and why it differs from the U.S. market.
10. Discuss the positives and negatives of investing in a government agency issue rather than a straight Treasury bond.
11. Discuss the difference between a foreign bond (e.g., a Samurai) and a Eurobond (e.g., a Euroyen issue).

**PROBLEMS**

1. An investor in the 28 percent tax bracket is trying to decide which of two bonds to purchase. One is a corporate bond carrying an 8 percent coupon and selling at par. The other is a municipal bond with a 5½ percent coupon, and it, too, sells at par. Assuming all other relevant factors are equal, which bond should the investor select?
2. What would be the initial offering price for the following bonds (assume semiannual compounding)?
   a. A 15-year zero-coupon bond with a yield to maturity (YTM) of 12 percent
   b. A 20-year zero-coupon bond with a YTM of 10 percent

Bond quote 3 refers to $15,000 of Indianapolis, Indiana, Airport Authority revenue bonds backed by a contract with U.S. Air Corporation. It has a 7.50 percent coupon, matures July 1, 2019, and as of the publication has a yield of 8.25 percent (it is trading at a discount). The broker offering the bonds is Sterling.

It is always necessary to call the dealer to determine the current yield/price because these quotes are at least one day old when they are published.

**SUMMARY**

- We considered the basic features of bonds: interest, principal, and maturity. Certain key relationships affect price behavior. Price is essentially a function of coupon, maturity, and prevailing market interest rates. Bond price volatility depends on coupon and maturity. As will be demonstrated in Chapter 18, bonds with longer maturities and/or lower coupons respond vigorously to a given change in market rates.
- Each bond has unique intrinsic characteristics and can be differentiated by type of issue and indenture provisions. Major benefits to bond investors include high returns for nominal risk, the potential for capital gains, certain tax advantages, and possibly additional returns from active trading of bonds. Active bond investors must consider market liquidity, investment risks, and interest rate behavior. We considered high-yield (junk) bonds because of the growth in size and status of this segment of the bond market.
- The global bond market includes numerous countries. The non-U.S. markets have experienced strong relative growth, whereas the U.S. market has continued to constituted a stable half of the world bond market. The four major bond markets (the United States, Japan, Euroland, and the United Kingdom) have a different makeup in terms of the proportion of governments, agencies, municipals, corporates, and international issues. It is important to recognize that the various market sectors are unique in terms of liquidity, yield spreads, tax implications, and operating features.
- To gauge default risk, most bond investors rely on agency ratings. For additional information on the bond market, prevailing economic conditions, and intrinsic bond features, individual and institutional investors rely on a host of readily available publications. Extensive up-to-date quotes are generally available on Treasury bonds and notes. Although, trading and price information for corporates has been historically difficult to find, this changed dramatically beginning in 2004. Fortunately, the information on munipicals that was previously limited has been improving since 2005 when the Municipal Securities Rulemaking Board (MSRB) required all municipal trades to be reported in 15 minutes, as discussed in Harris and Piwoway (2006).
The world bond market is large and is continuing to grow due to government deficits around the world and the need for capital by corporations. It is also very diverse in terms of country alternatives and issuers within countries. This chapter provides the fundamentals that will allow us to consider the valuation of individual bonds in Chapter 18 and the alternative bond portfolio techniques in Chapter 19.

SUGGESTED READINGS

Green, Richard, Dan Li, and Norman Schurhoff, “Price Discovery in Illiquid Markets: Do Financial Asset Prices Rise Faster Than They Fall?” Journal of Finance 65, no. 4 (December 2010).

QUESTIONS

1. Explain the difference between calling a bond and a bond refunding.
2. Identify the three most important determinants of the price of a bond. Describe the effect of each.
3. Given a change in the level of interest rates, discuss how two major factors will influence the relative change in price for individual bonds.
4. Briefly describe two indenture provisions that can affect the maturity of a bond.
5. Explain the differences in taxation of income from municipal bonds, from U.S. Treasury bonds, and from corporate bonds.
6. For several institutional participants in the bond market, explain what type of bond each is likely to purchase and why.
7. Why should investors be aware of the trading volume for bonds in their portfolio?
8. What is the purpose of bond ratings?
9. Based on the data in Exhibit 17.2, discuss the makeup of the Japanese bond market and how and why it differs from the U.S. market.
10. Discuss the positives and negatives of investing in a government agency issue rather than a straight Treasury bond.
11. Discuss the difference between a foreign bond (e.g., a Samurai) and a Eurobond (e.g., a Euroyen issue).

PROBLEMS

1. An investor in the 28 percent tax bracket is trying to decide which of two bonds to purchase. One is a corporate bond carrying an 8 percent coupon and selling at par. The other is a municipal bond with a 5½ percent coupon, and it, too, sells at par. Assuming all other relevant factors are equal, which bond should the investor select?
2. What would be the initial offering price for the following bonds (assume semiannual compounding)?
   a. A 15-year zero-coupon bond with a yield to maturity (YTM) of 12 percent
   b. A 20-year zero-coupon bond with a YTM of 10 percent
3. An 8.4 percent coupon bond issued by the state of Indiana sells for $1,000. What coupon rate on a corporate bond selling at its $1,000 par value would produce the same after-tax return to the investor as the municipal bond if the investor is in:
   a. the 15 percent marginal tax bracket?
   b. the 25 percent marginal tax bracket?
   c. the 35 percent marginal tax bracket?
4. The Shamrock Corporation has just issued a $1,000 par value zero-coupon bond with an 8 percent yield to maturity, due to mature 15 years from today (assume semiannual compounding).
   a. What is the market price of the bond?
   b. If interest rates remain constant, what will be the price of the bond in three years?
   c. If interest rates rise to 10 percent, what will be the price of the bond in three years?
5. Complete the information requested for each of the following $1,000 face value, zero-coupon bonds, assuming semiannual compounding.

This includes such factors as time to maturity, coupon, callability, and sinking funds.

We return to bond valuation and acknowledge that, when yields change, all bond prices do not change in the same way. An understanding of what factors affect price changes for bonds is important because the price volatility of bonds has increased substantially. Before 1950, bond yields were relatively low and both yields and prices were stable, so bonds were considered very safe investments and most investors held them to maturity. During the last several decades, however, the level of interest rates has increased substantially because of inflation. In addition, interest rates have become more volatile because of changes in the rate of inflation and in monetary policy. As a result, bond prices and rates of return on bonds have become more volatile and the rates of return on bond investments have increased. Although this increase in interest rate volatility has affected all bonds, we discuss why the impact is more significant on bonds with embedded options, such as call features.

18.1 The Fundamentals of Bond Valuation

The value of bonds can be described in terms of dollar values or the rates of return they promise under some set of assumptions. In this section, we describe both the present value model, which computes a specific value for the bond using a single discount value, and the yield model, which computes the promised rate of return based on the bond’s current price and a set of assumptions.

18.1.1 The Present Value Model

In Chapter 11, we saw that the value of a bond (or any asset) equals the present value of its expected cash flows. The cash flows from a bond are the periodic interest payments to the bondholder and the repayment of principal at maturity. Therefore, the value of a bond is the present value of the semiannual interest payments plus the present value of the principal payment. Notably, the traditional valuation technique is to use a single interest rate discount factor, which is the required rate of return on the bond. We can express this in the following present value formula that assumes semiannual compounding:

\[ P_m = \sum_{t=1}^{2n} \frac{C_i}{(1+i/2)^t} + \frac{P_p}{(1+i/2)^2n} \]

where:
- \( P_m \) = the current market price of the bond
- \( n \) = the number of years to maturity
- \( C_i \) = the annual coupon payment for Bond \( i \)
- \( i \) = the prevailing yield to maturity for this bond issue
- \( P_p \) = the par value of the bond

The value computed indicates what an investor would be willing to pay for this bond to realize a rate of return that takes into account expectations regarding the RFR, the expected rate of inflation, and the risk of the bond. The standard valuation technique assumes holding the bond to maturity. Almost all U.S. bonds pay interest semiannually, so it is appropriate to use semiannual compounding wherein you cut the annual coupon rate in half and double the number of periods. To be consistent, you should also use semiannual compounding when discounting the principal payment of a coupon bond or even a zero coupon bond. All our present value calculations assume semiannual compounding.

In this chapter, we apply the valuation principles that were introduced in Chapter 11 to the valuation of bonds. This chapter is concerned with how one goes about finding the value of bonds using the traditional single yield to maturity rate and using multiple spot rates. We will also come to understand the several measures of yields for bonds. It is important to understand why these bond values and yields change over time. To do this, we begin with a review of value estimation for bonds using the present value model introduced in Chapter 11. This background on valuation allows us to understand and compute the expected rates of return on bonds.

After mastering the measurement of bond yields, we consider what factors influence the level of bond yields and what economic forces cause changes in yields over time. Next, we consider the different shapes of the yield curve and the alternative theories that explain changes in its shape. We discuss the effects of various characteristics and indenture provisions that affect the required returns and, therefore, the value of...
specific bond issues. This includes such factors as time to maturity, coupon, callability, and sinking funds.

We return to bond valuation and acknowledge that, when yields change, all bond prices do not change in the same way. An understanding of what factors affect price changes for bonds is important because the price volatility of bonds has increased substantially. Before 1950, bond yields were relatively low and both yields and prices were stable, so bonds were considered very safe investments and most investors held them to maturity. During the last several decades, however, the level of interest rates has increased substantially because of inflation. In addition, interest rates have become more volatile because of changes in the rate of inflation and in monetary policy. As a result, bond prices and rates of return on bonds have become more volatile and the rates of return on bond investments have increased. Although this increase in interest rate volatility has affected all bonds, we discuss why the impact is more significant on bonds with embedded options, such as call features.

### 18.1 The Fundamentals of Bond Valuation

The value of bonds can be described in terms of dollar values or the rates of return they promise under some set of assumptions. In this section, we describe both the present value model, which computes a specific value for the bond using a single discount value, and the yield model, which computes the promised rate of return based on the bond’s current price and a set of assumptions.

#### 18.1.1 The Present Value Model

In Chapter 11, we saw that the value of a bond (or any asset) equals the present value of its expected cash flows. The cash flows from a bond are the periodic interest payments to the bondholder and the repayment of principal at maturity. Therefore, the value of a bond is the present value of the semiannual interest payments plus the present value of the principal payment. Notably, the traditional valuation technique is to use a single interest rate discount factor, which is the required rate of return on the bond. We can express this in the following present value formula that assumes semiannual compounding:

\[
P_m = \sum_{i=1}^{2n} \frac{C_i}{(1 + i/2)^i} + \frac{P_p}{(1 + i/2)^{2n}}
\]

where:

- \(P_m\) = the current market price of the bond
- \(n\) = the number of years to maturity
- \(C_i\) = the annual coupon payment for Bond \(i\)
- \(i\) = the prevailing yield to maturity for this bond issue
- \(P_p\) = the par value of the bond

The value computed indicates what an investor would be willing to pay for this bond to realize a rate of return that takes into account expectations regarding the RFR, the expected rate of inflation, and the risk of the bond. The standard valuation technique assumes holding the

---

1Almost all U.S. bonds pay interest semiannually, so it is appropriate to use semiannual compounding wherein you cut the annual coupon rate in half and double the number of periods. To be consistent, you should also use semiannual compounding when discounting the principal payment of a coupon bond or even a zero coupon bond. All our present value calculations assume semiannual compounding.
A graph of this relationship is shown in Exhibit 18.2. Besides demonstrating that price moves inverse to yield, the graph shows three other important points:

1. When the yield is below the coupon rate, the bond will be priced at a premium to its par value.
2. When the yield is above the coupon rate, the bond will be priced at a discount to its par value.
3. The price-yield relationship is not a straight line; rather, it is convex. As yields decline, the price increases at an increasing rate; and, as yields increase, the price declines at a declining rate. This concept of a convex price-yield curve is referred to as convexity and will be discussed further in a later section.

18.1.2 The Yield Model

Instead of determining the value of a bond in dollar terms, investors often price bonds in terms of yields—the promised rates of return on bonds under certain assumptions. Thus far, we have used cash flows and our required rate of return to compute an estimated value for the bond. To compute an expected yield, we use the current market price \( P_m \) and the expected cash flows to compute the expected yield on the bond. We can express this approach using the same present value model. The difference is that in Equation 18.1, it was assumed that we knew the appropriate discount rate (the required rate of return), and we computed the estimated value (price) of the bond. In this case, we still use Equation 18.1, but it is assumed that we know the price of the bond and we compute the discount rate (yield) that will give us the current market price:

\[
P_m = \sum_{t=1}^{40} \frac{80/2}{(1 + .10/2)^t} + \frac{1,000}{(1 + .10/2)^{40}}
\]

The first term is the present value of an annuity of $40 every 6 months for 40 periods at 5 percent, while the second term is the present value of $1,000 to be received in 40 periods at 5 percent. This can be summarized as follows:

| Present value of interest payments $40 \times 17.1591 | = $686.36 |
| Present value of principal payment $1,000 \times 0.1420 | = $142.00 |
| Total value of bond at 10% | $828.36 |

As expected, the bond will be priced at a discount to its par value because the market’s required rate of return of 10 percent is greater than the bond’s coupon rate—that is, $828.36, or 82.86 percent of par.

Alternatively, if the market’s required rate was 6 percent, the value would be computed as the present value of the annuity at 3 percent for 40 periods and the present value of the principal at 3 percent for 40 periods, as follows:

| Present value of interest payments $40 \times 23.1148 | = $924.59 |
| Present value of principal payment $1,000 \times 0.3066 | = $306.60 |
| Total value of bond at 6% | $1,231.19 |

Because the bond’s discount rate is lower than its coupon, the bond would sell at a premium above par value—that is, $1,231.19 or 123.119 of par.

The Price-Yield Curve When you know the basic characteristics of a bond in terms of its coupon, maturity, and par value, the only factor that determines its value (price) is the market discount rate—its required rate of return. As shown, as we increase the required rate, the price declines. We can demonstrate the specific relationship between the price of a bond and its yield by computing the bond’s price at a range of yields, as shown in Exhibit 18.1.

| Exhibit 18.1 Price-Yield Relationship for a 20-Year, 8 Percent Coupon Bond ($1,000 Par Value) |
|---|---|
| Required Yield | Price of Bond |
| 2 | $1,985.09 |
| 4 | 1,547.12 |
| 6 | 1,231.19 |
| 8 | 1,000.00 |
| 10 | 828.36 |
| 12 | 699.05 |
| 14 | 600.07 |
| 16 | 522.98 |
Approaching the investment decision stating the bond's value as a yield figure rather than a dollar amount, you consider the relationship of the computed bond yield to your required rate of return on this bond. If the computed promised bond yield is equal to or greater than your required rate of return, you should buy the bond; if the computed promised yield is less than your required rate of return, you should not buy the bond and you should sell it if you own it.

These approaches to pricing bonds and making investment decisions are similar to the two alternative approaches by which firms make investment decisions. We referred to one approach, the net present value (NPV) method, in Chapter 14. When you use the NPV approach, you compute the present value of the net cash flows from the proposed investment at your cost of capital and subtract the present value cost of the investment to get the net present value (NPV) of the project. If this NPV is positive, you consider accepting the investment; if it is negative, you reject it. This is basically the way we compared the intrinsic value of an equity investment to its market price.

The second approach is to compute the internal rate of return (IRR) on a proposed investment project. The IRR is the discount rate that equates the present value of cash outflows for an investment with the present value of its cash inflows. You compare this discount rate, or IRR (which is also the estimated rate of return on the project), to your cost of capital, and accept any investment proposal with an IRR equal to or greater than your cost of capital. We do the same thing when we price bonds on the basis of yield. If the estimated (promised) yield on the bond (yield to maturity, yield to call, or horizon yield) is equal to or exceeds your required rate of return on the bond, you should invest in it; if the estimated yield is less than your required rate of return on the bond, you should not invest in it.

18.2 Computing Bond Yields

Bond investors traditionally have used five yield measures for the following purposes:

<table>
<thead>
<tr>
<th>Yield Measure</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td>Nominal yield</td>
<td>Measures the coupon rate.</td>
</tr>
<tr>
<td>Current yield</td>
<td>Measures the current income rate.</td>
</tr>
<tr>
<td>Promised yield to maturity</td>
<td>Measures the estimated rate of return for bond held to maturity.</td>
</tr>
<tr>
<td>Promised yield to call</td>
<td>Measures the estimated rate of return for bond held to first call date.</td>
</tr>
<tr>
<td>Realized (horizon) yield</td>
<td>Measures the estimated rate of return for a bond likely to be sold prior to maturity. It considers specific reinvestment assumptions and an estimated sales price. It also can measure the actual rate of return on a bond during some past period of time.</td>
</tr>
</tbody>
</table>

Nominal and current yields are mainly descriptive and contribute little to investment decision making. The last three yields are derived from the present value model described previously.

To measure an estimated realized yield (also referred to as the horizon yield or total return), a bond investor must estimate a bond's future selling price. Following our presentation of bond yields, we present the procedure for finding these prices. We conclude with a demonstration of valuing bonds using spot rates, which is becoming more prevalent.

18.2.1 Nominal Yield

Nominal yield is the coupon rate of a particular issue. A bond with an 8 percent coupon has an 8 percent nominal yield. This provides a convenient way of describing the coupon characteristics of an issue.

A graph of this relationship is shown in Exhibit 18.2. Besides demonstrating that price moves inverse to yield, the graph shows three other important points:

1. When the yield is below the coupon rate, the bond will be priced at a premium to its par value.
2. When the yield is above the coupon rate, the bond will be priced at a discount to its par value.
3. The price-yield relationship is not a straight line; rather, it is convex. As yields decline, the price increases at an increasing rate; and, as yields increase, the price declines at a declining rate. This concept of a convex price-yield curve is referred to as convexity and will be discussed further in a later section.

18.1.2 The Yield Model

Instead of determining the value of a bond in dollar terms, investors often price bonds in terms of yields—the promised rates of return on bonds under certain assumptions. Thus far, we have used cash flows and our required rate of return to compute an estimated value for the bond. To compute an expected yield, we use the current market price \( P_m \) and the expected cash flows to compute the expected yield on the bond. We can express this approach using the same present value model. The difference is that in Equation 18.1, it was assumed that we knew the appropriate discount rate (the required rate of return), and we computed the estimated value (price) of the bond. In this case, we still use Equation 18.1, but it is assumed that we know the price of the bond and we compute the discount rate (yield) that will give us the current market price \( P_m \):

\[
P_m = \sum_{t=1}^{n} \frac{C_t/2}{(1 + i/2)^t} + \frac{P_f}{(1 + i/2)^n}
\]

where the variables are the same as previously, except:

- \( i \) = the discount rate that will discount the expected cash flows to equal the current market price of the bond

This \( i \) value gives the expected (”promised”) yield of the bond under various assumptions to be noted, assuming you pay the price \( P_m \). In the next section, we will discuss several types of bond yields that arise from the assumptions of the valuation model.
18.2.2 Current Yield

Current yield is to bonds what dividend yield is to stocks. It is computed as:

\[ CY = \frac{C_i}{P_{m}} \]

where:

- \( CY \) = the current yield on a bond
- \( C_i \) = the annual coupon payment of Bond \( i \)
- \( P_{m} \) = the current market price of the bond

Because this yield measures the current income from the bond as a percentage of its price, it is important to income-oriented investors (e.g., retirees) who want current cash flow from their investment portfolios. Current yield has little use for investors who are interested in total return because it excludes the important capital gain or loss component.

18.2.3 Promised Yield to Maturity

Promised yield to maturity is the most widely used bond yield figure because it indicates the fully compounded rate of return promised to an investor who buys the bond at prevailing prices, if two assumptions hold true. Specifically, the promised yield to maturity will be equal to the investor’s realized yield if these assumptions are met. The first assumption is that the investor holds the bond to maturity. This assumption gives this value its shortened name, yield to maturity (YTM). The second assumption is implicit in the present value method of computation. Referring to Equation 18.1, recall that it related the current market price of the bond to the present value of all cash flows as follows:

\[ P_{m} = \sum_{t=1}^{n} \frac{C_i}{(1+i)^t} + \frac{P_p}{(1+i)^n} \]

To compute the YTM for a bond, we solve for the rate \( i \) that will equate the current price \( P_{m} \) to all cash flows from the bond to maturity. As noted, this resembles the computation of the internal rate of return (IRR) on an investment project. Because it is a present value-based computation, it implies a reinvestment rate assumption because it discounts the cash flows. That is, the equation assumes that all interim cash flows (interest payments) are reinvested at the computed YTM rate. This is referred to as a promised YTM because the bond will provide this computed YTM (i.e., you will realize this yield) only if you meet its conditions:

1. You hold the bond to maturity.
2. You reinvest all the interim cash flows at the computed YTM rate.

If a bond promises an 8 percent YTM, you must reinvest coupon income at 8 percent to realize that promised return. If you spend (do not reinvest) the coupon payments or if you cannot find opportunities to reinvest these coupon payments at rates as high as its promised YTM, then the actual realized yield you earn will be less than the promised yield to maturity. As will be demonstrated in the section on realized return, if you can reinvest cash flows at rates above the YTM, your realized (horizon) return will be greater than the promised YTM.

The income earned on this reinvestment of the interim interest payments is referred to as interest-on-interest and is discussed in detail in Homer and Leibowitz (1972, Chapter 1).

The impact of the reinvestment assumption (i.e., the interest-on-interest earnings) on the actual return from a bond varies directly with the bond’s coupon and maturity. A higher coupon and/or a longer term to maturity will increase the loss in value from failure to reinvest the coupon cash flow at the YTM. Put another way, a higher coupon or a longer maturity makes the reinvestment assumption more important—that is, such bonds have greater reinvestment risk.

18.2 Computing Bond Yields

Bond investors traditionally have used five yield measures for the following purposes:

<table>
<thead>
<tr>
<th>Yield Measure</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td>Nominal yield</td>
<td>Measures the coupon rate.</td>
</tr>
<tr>
<td>Current yield</td>
<td>Measures the current income rate.</td>
</tr>
<tr>
<td>Promised yield to maturity</td>
<td>Measures the estimated rate of return for bond held to maturity.</td>
</tr>
<tr>
<td>Promised yield to call</td>
<td>Measures the estimated rate of return for bond held to first call date.</td>
</tr>
<tr>
<td>Realized (horizon) yield</td>
<td>Measures the estimated rate of return for a bond likely to be sold prior to maturity. It considers specific reinvestment assumptions and an estimated sales price. It also can measure the actual rate of return on a bond during some past period of time.</td>
</tr>
</tbody>
</table>

Nominal and current yields are mainly descriptive and contribute little to investment decision making. The last three yields are derived from the present value model described previously.

To measure an estimated realized yield (also referred to as the horizon yield or total return), a bond investor must estimate a bond’s future selling price. Following our presentation of bond yields, we present the procedure for finding these prices. We conclude with a demonstration of valuing bonds using spot rates, which is becoming more prevalent.

18.2.1 Nominal Yield

Nominal yield is the coupon rate of a particular issue. A bond with an 8 percent coupon has an 8 percent nominal yield. This provides a convenient way of describing the coupon characteristics of an issue.
18.2.2 Current Yield

Current yield is to bonds what dividend yield is to stocks. It is computed as:

\[ CY = \frac{C_i}{P_m} \]

where:

- \( CY \) is the current yield on a bond
- \( C_i \) is the annual coupon payment of Bond \( i \)
- \( P_m \) is the current market price of the bond

Because this yield measures the current income from the bond as a percentage of its price, it is important to income-oriented investors (e.g., retirees) who want current cash flow from their investment portfolios. Current yield has little use for investors who are interested in total return because it excludes the important capital gain or loss component.

18.2.3 Promised Yield to Maturity

Promised yield to maturity is the most widely used bond yield figure because it indicates the fully compounded rate of return promised to an investor who buys the bond at prevailing prices, if two assumptions hold true. Specifically, the promised yield to maturity will be equal to the investor’s realized yield if these assumptions are met. The first assumption is that the investor holds the bond to maturity. This assumption gives this value its shortened name, yield to maturity (YTM). The second assumption is implicit in the present value method of computation. Referring to Equation 18.1, recall that it related the current market price of the bond to the present value of all cash flows as follows:

\[ P_m = \sum_{i=1}^{2n} \frac{C_i}{(1 + i/2)^i} + \frac{P_F}{(1 + i/2)^{2n}} \]

To compute the YTM for a bond, we solve for the rate \( i \) that will equate the current price \( (P_m) \) to all cash flows from the bond to maturity. As noted, this resembles the computation of the internal rate of return (IRR) on an investment project. Because it is a present value-based computation, it implies a reinvestment rate assumption because it discounts the cash flows. That is, the equation assumes that all interim cash flows (interest payments) are reinvested at the computed YTM. This is referred to as a promised YTM because the bond will provide this computed YTM (i.e., you will realize this yield) only if you meet its conditions:

1. You hold the bond to maturity.
2. You reinvest all the interim cash flows at the computed YTM rate.

If a bond promises an 8 percent YTM, you must reinvest coupon income at 8 percent to realize that promised return. If you spend (do not reinvest) the coupon payments or if you cannot find opportunities to reinvest these coupon payments at rates as high as its promised YTM, then the actual realized yield you earn will be less than the promised yield to maturity. As will be demonstrated in the section on realized return, if you can reinvest cash flows at rates above the YTM, your realized (horizon) return will be greater than the promised YTM. The income earned on this reinvestment of the interim interest payments is referred to as interest-on-interest and is discussed in detail in Homer and Leibowitz (1972, Chapter 1).

The impact of the reinvestment assumption (i.e., the interest-on-interest earnings) on the actual return from a bond varies directly with the bond’s coupon and maturity. A higher coupon and/or a longer term to maturity will increase the loss in value from failure to reinvest the coupon cash flow at the YTM. Put another way, a higher coupon or a longer maturity makes the reinvestment assumption more important—that is, such bonds have greater reinvestment risk.
Exhibit 18.3 illustrates the impact of interest-on-interest for an 8 percent, 25-year bond bought at par to yield 8 percent. If you invested $1,000 today at 8 percent for 25 years and reinvested all the coupon payments at 8 percent, you would have approximately $7,100 at the end of 25 years. We will refer to this money that you have at the end of your investment horizon as your **ending-wealth value**. To prove that you would have an ending-wealth value of $7,100, look up the compound interest factor for 8 percent for 25 years (6.8493) or 4 percent for 50 periods (which assumes semiannual compounding and it is 7.1073). In the case of U.S. bonds, the semiannual compounding is the appropriate procedure because almost all U.S. bonds pay interest every six months.

Exhibit 18.3 shows that this ending wealth of $7,100 is made up of $1,000 principal return, $2,000 of coupon payments over the 25 years ($80 a year for 25 years), and $4,100 in interest earned on the semiannual coupon payments reinvested at 4 percent semiannually. If you never reinvested any of the coupon payments, you would have an ending-wealth value of only $3,000. This ending-wealth value of $3,000 derived from the beginning investment of $1,000 gives you an actual (realized) yield to maturity of only 4.5 percent. That is, the rate that will discount $3,000 back to $1,000 in 25 years is 4.5 percent. Reinvesting the coupon payments at some rate between 0 and 8 percent would cause your ending-wealth position to be above $3,000 and below $7,100; therefore, your actual realized rate of return would be somewhere between 4.5 percent and 8 percent. Alternatively, if you managed to reinvest the coupon payments at rates consistently above 8 percent, your ending-wealth position would be above $7,100, and your realized (horizon) rate of return would be above 8 percent.

Interestingly, during periods of very high interest rates, you often hear investors talk about “locking in” high yields. These people are subject to **yield illusion** because they do not realize that attaining the high promised yield requires that they reinvest all the coupon payments at the very high promised yields. For example, if you buy a 20-year bond with a promised yield of 8 percent and you reinvest the coupons at a rate of 8 percent, you will have $7,100 at maturity. However, if you reinvest the coupons at a rate of 2 percent, you will have only $3,000 at maturity.
to maturity of 15 percent, you will actually realize the promised 15 percent yield only if you are able to reinvest all the coupon payments at 15 percent over the next 20 years.

**Computing the Promised Yield to Maturity** The promised yield to maturity can be computed by using the present value model with semiannual compounding. The present value model gives the investor an accurate result and is the technique used by investment professionals.

The present value model equation—Equation 18.1—shows the promised yield valuation model:

$$P_m = \sum_{t=1}^{2n} \frac{C_i}{(1 + i/2)^t} + \frac{P_p}{(1 + i/2)^{2n}}$$

All variables are as described previously. This model is somewhat complex because the solution requires iteration. As noted, the present value equation is a variation of the internal rate of return (IRR) calculation where we want to find the discount rate, $i$, that will equate the present value of the cash flows to the market price of the bond ($P_m$). Using the prior example of an 8 percent, 20-year bond, priced at $900, the equation gives us a semiannual promised yield to maturity of 4.545 percent, which implies an annual promised YTM of 9.09 percent.³

$$900 = 40 \sum_{t=1}^{40} \left( \frac{1}{(1.04545)^t} \right) + 1000 \left( \frac{1}{(1.04545)^{40}} \right)$$

= 40(18.2574) + 1000(0.1702)

= 900

The values for $1/(1 + i)$ were taken from the present value interest factor tables in the appendix at the back of the book using interpolation. Fortunately, there are several handheld calculators that will do these calculations for you.

**YTM for a Zero Coupon Bond** In several instances, we have discussed the existence of zero coupon bonds that only have the one cash inflow at maturity. This single cash flow means that the calculation of YTM is substantially easier, as shown by the following example.

Assume a zero coupon bond maturing in 10 years with a maturity value of $1,000 selling for $311.80. Because you are dealing with a zero coupon bond, there is only the one cash flow from the principal payment at maturity. Therefore, you simply need to determine what the discount rate is that will discount $1,000 to equal the current market price of $311.80 in 20 periods (10 years of semiannual payments). The equation is as follows:

$$311.80 = \frac{1,000}{(1 + i/2)^{20}}$$

You will see that $i = 6$ percent, which implies an annual rate of 12 percent. For future reference, this yield also is referred to as the 10-year spot rate, which is the discount rate for a single cash flow to be received in 10 years.

**18.2.4 Promised Yield to Call**

Although investors use promised YTM to value most bonds, they must estimate the return on certain callable bonds with a different measure—the **promised yield to call (YTC)**. Whenever

³You will recall from your corporate finance course that you start with one rate (e.g., 9 percent or 4.5 percent semiannually) and compute the value of the stream. In this example, the value would exceed $900, so you would select a higher rate until you had a present value for the stream of cash flows of less than $900. Given the discount rates above and below the true rate, you would do further calculations or interpolate between the two rates to arrive at the correct discount rate that would give you a value of $900.
a bond with a call feature is selling for a price above par (that is, at a premium) equal to or
greater than its call price, a bond investor should consider valuing the bond in terms of YTC
rather than YTM. This is because the marketplace uses the lowest, most conservative yield
measure in pricing a bond. As discussed in Homer and Leibowitz (1972, chap. 4), when bonds
are trading at or above a specified crossover price, which is approximately the bond’s call
price plus a small premium that increases with time to call, the yield to call will provide the
lowest yield measure. The crossover price is important because at this price the YTM and
the YTC are equal—this is the crossover yield. When the bond rises to this price above
par, the computed YTM becomes low enough that it would be profitable for the issuer to call
the bond and finance the call by selling a new bond at this prevailing market interest rate.3
Therefore, the YTC measures the promised rate of return the investor will receive from holding
this bond until it is retired at the first available call date, that is, at the end of the deferred
call period. Note that if an issue has multiple call dates at different prices (the call price will
decline for later call dates), it will be necessary to compute which of these scenarios provides
the lowest yield—this is referred to as computing yield to worst. Investors must consider com-
puting the YTC for their bonds after a period when numerous high-yielding, high-coupon
bonds have been issued. Following such a period, interest rates will decline, bond prices will
rise, and the high-coupon bonds will subsequently have a high probability of being called—
that is, their market yields will fall below the crossover yield.

**Computing Promised Yield to Call** Again, the present value method assumes that you hold
the bond until the first call date and that you reinvest all coupon payments at the YTC rate.

Yield to call is calculated using a variation of Equation 18.1. To compute the YTC by the
present value method, we would adjust the semiannual present value equation to give:

\[
P_m = \sum_{i=1}^{2n} \frac{C_i/2}{(1+i/2)^t} + \frac{P_c}{(1+i/2)^{2n}}
\]

where:

- \(P_m\) = the current market price of the bond
- \(C_i\) = the annual coupon payment for Bond \(i\)
- \(2n\) = the number of years to first call date
- \(P_c\) = the call price of the bond

Following the present value method, we solve for \(i\), which typically requires several computa-
tions or interpolations to get the exact yield. As before, this is a promised yield that requires
the two assumptions noted earlier except that rather than holding to maturity, it is assumed
that you hold until the first call date.

**18.2.5 Realized (Horizon) Yield**

The final measure of bond yield, realized yield or horizon yield (i.e., the actual return over a
horizon period) measures the expected rate of return of a bond that you anticipate selling
prior to its maturity. In terms of the equation, the investor has a holding period (\(hp\)) or invest-
ment horizon that is less than \(n\). Realized (horizon) yield can be used to estimate rates of re-
turn attainable from various trading strategies. Although it is a very useful measure, it requires
several additional estimates not required by the other yield measures. First, the investor must
estimate the expected future selling price of the bond at the end of the holding period. Second,
this measure also requires a specific estimate of the reinvestment rate for the coupon flows

---

3An extensive literature on the refunding of bond issues includes studies by Boyce and Kalotay (1979), Harris (1980),
Kalotay (1982a), and Finnerty (1983).
prior to selling the bond. This technique also can be used by investors to measure their actual yields after selling bonds.

**Computing Realized (Horizon) Yield** The realized yields over a horizon holding period are variations on the promised yield equations. The substitution of \( P_f \) (future selling price) and \( hp \) into the present value model (Equation 18.1) provides the following realized yield model:

\[
P_m = \sum_{t=1}^{2hp} \frac{C_t/2}{(1 + i/2)^t} + \frac{P_f}{(1 + i/2)^{2hp}}
\]

Again, this present value model requires you to solve for the \( i \) that equates the expected cash flows from coupon payments and the estimated selling price to the current market price.

You will note from the present value realized yield formula in Equation 18.4 that the coupon flows are implicitly discounted at the computed realized (horizon) yield. In many cases, this is an inappropriate assumption because available market rates might be very different from the computed realized (horizon) yield. Therefore, to derive a realistic estimate of the realized yield, you also need to *estimate your expected reinvestment rate during the investment horizon*. We will demonstrate this in a subsequent subsection.

Therefore, to complete your understanding of computing estimated realized yield for alternative investment strategies, the next section considers the calculation of future bond prices. This is followed by a discussion on calculating a realized (horizon) return with different reinvestment rates.

### 18.3 Calculating Future Bond Prices

Dollar bond prices need to be calculated in two instances: (1) when computing realized (horizon) yield, you must determine the future selling price \( P_f \) of a bond if it is to be sold before maturity or first call, and (2) when issues are quoted on a promised yield basis, as with municipals. You can easily convert a yield-based quote to a dollar price by using Equation 18.1, which does not require iteration. (You need only solve for \( P_m \).) The coupon \( C_t \) is given, as is par value \( P_p \) and the promised YTM, which is used as the discount rate.

Consider a 10 percent, 25-year bond with a promised YTM of 12 percent. You would compute the price of this issue as:

\[
P_m = 100/2 \sum_{t=1}^{50} \frac{1}{(1 + 0.120/2)^t} + 1,000 \left( \frac{1}{1 + 0.120/2} \right)^{50}
\]

\[= 50(15.7619) + 1,000(0.0543)\]

\[= 842.40
\]

In this instance, we are determining the prevailing market price of the bond based on the current market YTM. These market yields indicate the prevailing consensus of all investors regarding the value of this bond. An investor with a required rate of return on this bond that differs from the market YTM would estimate a different value for the bond.

In contrast to the current market price, you will need to compute a future price \( P_f \) when estimating the expected realized (horizon) yield performance of alternative bonds. Investors or portfolio managers who consistently trade bonds for capital gains need to compute expected realized (horizon) yield rather than promised yield. They would compute the future price, \( P_f \), through the following variation of the realized yield equation:

\[
P_f = \sum_{t=1}^{2n-2hp} \frac{C_t/2}{(1 + i/2)^t} + \frac{P_p}{(1 + i/2)^{2n-2hp}}
\]
As noted, this calculation assumes that all cash flows are reinvested at the computed \(i\) (27.5 percent). However, it is unlikely that during a period when market rates are going from 14 percent to 10 percent you could reinvest the coupon at 27.5 percent. It is more appropriate and realistic to explicitly estimate the reinvestment rates and calculate the realized yields based on your ending-wealth position. This procedure is more precise and realistic, and it is easier because it does not require iteration.

The basic technique calculates the value of all cash flows at the end of the holding period, which is the investor’s ending-wealth value. We compare this ending-wealth value to our beginning-wealth value to determine the compound rate of return that equalizes these two values.

Adding to our prior example, assume we have the following cash flows:

\[
P_m = \$1,000
\]
\[
P_f = \$1,330.95
\]

The ending value of the four interest payments is determined by our assumptions regarding specific reinvestment rates. Assume each payment is reinvested at a different declining rate that holds for its time period (that is, the first three interest payments are reinvested at progressively lower rates and the fourth interest payment is received at the end of the holding period).

\[
i_1 = 13\% \text{ for } 18 \text{ months} = 70 \times (1 + 0.065)^3 = 84.55
\]
\[
i_2 = 12\% \text{ for } 12 \text{ months} = 70 \times (1 + 0.06)^2 = 78.65
\]
\[
i_3 = 11\% \text{ for } 6 \text{ months} = 70 \times (1 + 0.055) = 73.85
\]
\[
i_4 = \text{not reinvested} = 70 \times (1.0) = 70.00
\]

Future value of interest payments = $307.05

Therefore, our total ending-wealth value is:

\[
\$1,330.95 + 307.05 = \$1,638.00
\]

The compound realized (horizon) rate of return is calculated by comparing our ending-wealth value ($1,638) to our beginning-wealth value ($1,000) and determining what interest rate would equalize these two values over a two-year holding period. To find this, compute the ratio of ending wealth to beginning wealth (1.638). Find this ratio in a compound value table for four periods (assuming semiannual compounding). Table C.3 at the end of the book indicates that the realized rate is somewhere between 12 percent (1.5735) and 14 percent (1.6890). Interpolation gives an estimated semiannual rate of 13.16 percent, which indicates an annual rate of 26.32 percent. Using a calculator or computer, it is equal to \((1.638)^{1/2} - 1\). This compares to an estimate of 27.5 percent when we assume an implicit reinvestment rate of 27.5 percent. The differential is small (26.32 vs. 27.50) because the holding period is so short (2 years).

This realized (horizon) yield computation specifically states the expected reinvestment rates as contrasted to assuming the reinvestment rate is equal to the computed realized yield. The actual assumption regarding the reinvestment rate can be very important.

The steps to calculate an expected realized (horizon) yield can be summarized as follows:

1. Calculate the future value at the horizon date of all coupon payments reinvested at estimated rates.
2. Calculate the expected sales price of the bond at your expected horizon date based on your estimate of the required yield to maturity at the horizon date.
3. Sum the values in Steps 1 and 2 to arrive at the total ending-wealth value.
4. Calculate the ratio of the ending-wealth value to the beginning value (the purchase price of the bond). Given this ratio and the time horizon, compute the compound rate of interest that will grow to this ratio over this time horizon.

\[
P_f = \frac{50}{(1.04)^1} + \frac{1,000}{(1.04)^{10}}
\]

\[
= 50(19.7928) + 1,000(0.2083)
\]

\[
= 989.64 + 208.30
\]

\[
= \$1,197.94
\]

18.3.1 Realized (Horizon) Yield with Differential Reinvestment Rates

The realized yield equation—Equation 18.4—is the standard present value formula with the changes in holding period and ending price. As such, it includes the implicit reinvestment rate assumption that all cash flows are reinvested at the computed \(i\) rate. There may be instances where such an implicit assumption is not appropriate, given your expectations for future interest rates. Assume that current market interest rates are very high and you invest in a long-term bond (e.g., a 20-year, 14 percent coupon) to take advantage of an expected decline in rates from 14 percent to 10 percent over a 2-year period. Computing the future price of a 14 percent 18-year bond yielding 10 percent (equal to $1,330.95) and using the realized yield equation to estimate the realized (horizon) yield, we will get the following fairly high realized rate of return:

\[
P_m = \$1,000
\]
\[
hp = 2 \text{ years}
\]
\[
P_f = \sum_{i=1}^{36} 70/(1 + 0.05)^i + \$1,000/(1.05)^{16}
\]

\[
= $1,158.30 + $172.65
\]

\[
= $1,330.95
\]

\[
$1,000 = \sum_{i=1}^{4} \frac{70}{(1 + 0.025)^i} + \frac{1,330.95}{(1 + 0.025)^4}
\]

\[
i = 27.5\%
\]
As noted, this calculation assumes that all cash flows are reinvested at the computed \( i \) (27.5 percent). However, it is unlikely that during a period when market rates are going from 14 percent to 10 percent you could reinvest the coupon at 27.5 percent. It is more appropriate and realistic to explicitly estimate the reinvestment rates and calculate the realized yields based on your ending-wealth position. This procedure is more precise and realistic, and it is easier because it does not require iteration.

The basic technique calculates the value of all cash flows at the end of the holding period, which is the investor’s ending-wealth value. We compare this ending-wealth value to our beginning-wealth value to determine the compound rate of return that equalizes these two values. Adding to our prior example, assume we have the following cash flows:

\[
\begin{align*}
P_m &= $1,000 \\
i &= \text{interest payments of $70 in 6, 12, 18, and 24 months} \\
P_f &= $1,330.95 \text{ (the ending market value of the bond)}
\end{align*}
\]

The ending value of the four interest payments is determined by our assumptions regarding specific reinvestment rates. Assume each payment is reinvested at a different declining rate that holds for its time period (that is, the first three interest payments are reinvested at progressively lower rates and the fourth interest payment is received at the end of the holding period).

\[
\begin{align*}
i_1 \text{ at } 13\% \text{ for } 18 \text{ months} &= $70 \times (1 + 0.065)^{18} = $ 84.55 \\
i_2 \text{ at } 12\% \text{ for } 12 \text{ months} &= $70 \times (1 + 0.06)^{12} = 78.65 \\
i_3 \text{ at } 11\% \text{ for } 6 \text{ months} &= $70 \times (1 + 0.055)^{6} = 73.85 \\
i_4 \text{ not reinvested} &= $70 \times (1.0) = 70.00
\end{align*}
\]

Future value of interest payments = $307.05

Therefore, our total ending-wealth value is:

\[
$1,330.95 + $307.05 = $1,638.00
\]

The compound realized (horizon) rate of return is calculated by comparing our ending-wealth value ($1,638) to our beginning-wealth value ($1,000) and determining what interest rate would equalize these two values over a two-year holding period. To find this, compute the ratio of ending wealth to beginning wealth (1.638). Find this ratio in a compound value table for four periods (assuming semiannual compounding). Table C.3 at the end of the book indicates that the realized rate is somewhere between 12 percent (1.5735) and 14 percent (1.6890). Interpolation gives an estimated semiannual rate of 13.16 percent, which indicates an annual rate of 26.32 percent. Using a calculator or computer, it is equal to \((1.638)^{1/4} - 1\). This compares to an estimate of 27.5 percent when we assume an implicit reinvestment rate of 27.5 percent. The differential is small (26.32 vs. 27.50) because the holding period is so short (2 years).

This realized (horizon) yield computation specifically states the expected reinvestment rates as contrasted to assuming the reinvestment rate is equal to the computed realized yield. The actual assumption regarding the reinvestment rate can be very important.

The steps to calculate an expected realized (horizon) yield can be summarized as follows:

1. Calculate the future value at the horizon date of all coupon payments reinvested at estimated rates.
2. Calculate the expected sales price of the bond at your expected horizon date based on your estimate of the required yield to maturity at the horizon date.
3. Sum the values in Steps 1 and 2 to arrive at the total ending-wealth value.
4. Calculate the ratio of the ending-wealth value to the beginning value (the purchase price of the bond). Given this ratio and the time horizon, compute the compound rate of interest that will grow to this ratio over this time horizon.
For example, if the promised yield on the tax-exempt bond is 6 percent and the investor’s marginal tax rate is 30 percent, the equivalent taxable yield would be:

\[
ETY = \frac{0.06}{1 - 0.30} = 0.0857 = 8.57\%
\]

The ETY equation has some limitations. It is applicable only to par bonds or current coupon obligations, such as new issues, because the measure considers only interest income and ignores capital gains, which are not tax-exempt. Therefore, we cannot use it for issues trading at a significant variation from par value (premium or discount).

18.3.4 Bond Yield Books

Bond value tables, commonly known as bond books or yield books, can eliminate most of the calculations for bond valuation. A bond yield table is like a present value interest factor table in that it provides a matrix of bond prices for a stated coupon rate, various terms to maturity (on the horizontal axis), and promised yields (on the vertical axis). Such a table allows you to determine either the promised yield or the price of a bond.

As might be expected, access to sophisticated calculators or computers has substantially reduced the need for and use of yield books. In addition, to truly understand alternative yield measures, you must master the present value model and its variations that generate values for promised YTM, promised YTC, realized (horizon) yield, and bond prices.

18.4 Bond Valuation Using Spot Rates

Thus far, we have used the traditional valuation model, which assumes that we discount all cash flows by one common yield, reflecting the overall required rate of return for the bond. Similarly, we compute the yield on the bond (YTM, YTC, horizon yield) as the single interest rate that would discount all the flows from the bond to equal the current market price of the bond. It was noted in the YTM calculations that this was a promised yield that depended on two assumptions: holding the bond to maturity and reinvesting all cash flows at the computed YTM (the IRR assumption). Notably, this second assumption often is very unrealistic because it requires a flat, constant yield curve. We know that it is extremely rare for the yield curve to be flat, much less remain constant for any period of time. The yield curve typically is upward sloping for several reasons, which we discuss in a later section. Investors at any point in time require a different rate of return for flows at different times. For example, if investors are buying alternative zero coupon bonds (promising a single cash flow at maturity), they will almost always require different rates of return if they are offered a bond that matures in 2 years, 5 years, or 10 years.

As mentioned earlier, the rates used to discount a cash flow at a certain point are called spot rates. It is possible to demonstrate the desire for different rates by examining the rates of government discount notes with different maturities (i.e., spot rates) as of June 2011, as shown in Exhibit 18.4. These rates indicate that investors require 0.72 percent for the cash flow in 2 years, 1.75 percent for the cash flow in 5 years, and 3.35 percent for the cash flow in 10 years. These differences in required rates for alternative maturities are similar to historical differentials. The difference in yield between the 1-year bond (0.57 percent) and the 30-year bond (4.63 percent), referred to as the maturity spread, was 406 basis points (4.63 – 0.57) in mid-2011, which is clearly higher than the historical maturity spread. This abnormally high maturity spread was due to the quantitative easing program by the Federal Reserve that was concentrating on the short end of the yield curve.

Because of differences in spot rates across maturities, bond analysts and bond portfolio managers recognize that it is inappropriate to discount all the flows for a bond at one single rate. If all calculations assume semiannual compounding, double the interest rate derived from Step 4.

18.3.2 Price and Yield Determination on Noninterest Dates

So far, we have assumed that the investor buys (or sells) a bond precisely on the date that interest is due, so the measures are accurate only when the issues are traded on coupon payment dates.

However, when the semiannual model is used, and when more accuracy is necessary, another version of the price and yield model must be used for transactions on noninterest payment dates. Fortunately, the basic models need be extended only one more step because the value of an issue that trades X years, Y months, and so many days from maturity is found by extrapolating the bond value (price or yield) for the month before and the month after the day of transaction. Thus, the valuation process involves full months to maturity rather than years or semiannual periods.

Accrued Interest Having computed a value for the bond at a noninterest payment date, it is also necessary to consider the notion of accrued interest. Because the interest payment on a bond, which is paid every six months, is a contractual promise by the issuer, the bond investor has the right to receive a portion of the semiannual interest payment if he or she held the bond for some part of the six-month period. For example, assume an 8 percent, $1,000 par value bond that pays $40 every six months. If you sold the bond two months after the prior interest payment, you would have held it for one-third of the six-month period and would have the right to one-third of the $40 ($13.33). This is referred to as the accrued interest on the bond. Therefore, when you sell the bond, there is a calculation of the bond’s remaining value until maturity, that is, its price. What you receive is this price plus the accrued interest ($13.33).

18.3.3 Yield Adjustments for Tax-Exempt Bonds

Municipal bonds, Treasury issues, and many agency obligations possess one common characteristic: Their interest income is partially or fully tax-exempt. This tax-exempt status affects the valuation of taxable versus nontaxable bonds. Although you could adjust each present value equation for the tax effects, it is not necessary for our purposes. We can envision the approximate impact of such an adjustment, however, by computing the equivalent taxable yield, which is one of the most often cited measures of performance for municipal bonds.

The equivalent taxable yield (ETY) adjusts the promised yield computation for the bond’s tax-exempt status. To compute the ETY, we determine the promised yield on a tax-exempt bond using one of the yield formulas and then adjust the computed yield to reflect the rate of return that must be earned on a fully taxable issue. It is measured as:

\[
ETY = \frac{i}{1 - T}
\]

where:

- \(i\) = the promised yield on the tax-exempt bond
- \(T\) = the amount and type of tax exemption (i.e., the investor’s marginal tax rate)

\[\text{Footnote:} \text{For a detailed discussion of these calculations, see "Bond Pricing and Return Measures" (Fabozzi, 2012, chap. 6).}\]
For example, if the promised yield on the tax-exempt bond is 6 percent and the investor’s marginal tax rate is 30 percent, the equivalent taxable yield would be:

\[
ETY = \frac{0.06}{1 - 0.30} = \frac{0.06}{0.70} = 0.0857 = 8.57\%
\]

The \textit{ETY} equation has some limitations. It is applicable only to par bonds or current coupon obligations, such as new issues, because the measure considers only interest income and ignores capital gains, which are not tax-exempt. Therefore, we cannot use it for issues trading at a significant variation from par value (premium or discount).

### 18.3.4 Bond Yield Books

Bond value tables, commonly known as \textit{bond books} or \textit{yield books}, can eliminate most of the calculations for bond valuation. A bond yield table is like a present value interest factor table in that it provides a matrix of bond prices for a stated coupon rate, various terms to maturity (on the horizontal axis), and promised yields (on the vertical axis). Such a table allows you to determine either the promised yield or the price of a bond.

As might be expected, access to sophisticated calculators or computers has substantially reduced the need for and use of yield books. In addition, to truly understand alternative yield measures, you must master the present value model and its variations that generate values for promised \textit{YTM}, promised \textit{YTC}, realized (horizon) yield, and bond prices.

### 18.4 Bond Valuation Using Spot Rates

Thus far, we have used the traditional valuation model, which assumes that we discount all cash flows by one common yield, reflecting the overall required rate of return for the bond. Similarly, we compute the yield on the bond (\textit{YTM}, \textit{YTC}, horizon yield) as the single interest rate that would discount all the flows from the bond to equal the current market price of the bond. It was noted in the \textit{YTM} calculations that this was a promised yield that depended on two assumptions: holding the bond to maturity and reinvesting all cash flows at the computed \textit{YTM} (the \textit{IRR} assumption). Notably, this second assumption often is very unrealistic because it requires a flat, constant yield curve. We know that it is extremely rare for the yield curve to be flat, much less remain constant for any period of time. The yield curve typically is upward sloping for several reasons, which we discuss in a later section. Investors at any point in time require a different rate of return for flows at different times. For example, if investors are buying alternative zero coupon bonds (promising a single cash flow at maturity), they will almost always require different rates of return if they are offered a bond that matures in 2 years, 5 years, or 10 years.

As mentioned earlier, the rates used to discount a cash flow at a certain point are called \textit{spot rates}. It is possible to demonstrate the desire for different rates by examining the rates of government discount notes with different maturities (i.e., spot rates) as of June 2011, as shown in Exhibit 18.4. These rates indicate that investors require 0.72 percent for the cash flow in 2 years, 1.75 percent for the cash flow in 5 years, and 3.35 percent for the cash flow in 10 years. These differences in required rates for alternative maturities are similar to historical differentials. The difference in yield between the 1-year bond (0.57 percent) and the 30-year bond (4.63 percent), referred to as the \textit{maturity spread}, was 406 basis points (4.63 - 0.57) in mid-2011, which is clearly higher than the historical maturity spread. This abnormally high maturity spread was due to the quantitative easing program by the Federal Reserve that was concentrating on the short end of the yield curve.

Because of differences in spot rates across maturities, bond analysts and bond portfolio managers recognize that it is inappropriate to discount all the flows for a bond at one single
discount rate based on the five-year maturity of all three bonds. If we assume two alternative yields to maturity of 6 percent and 6.5 percent for five-year bonds, the values for the three bonds are:

<table>
<thead>
<tr>
<th>Bond</th>
<th>6%</th>
<th>6.5%</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bond A</td>
<td>$511.81</td>
<td>$505.52</td>
</tr>
<tr>
<td></td>
<td>$744.10</td>
<td>$727.00</td>
</tr>
<tr>
<td>Total</td>
<td>$1,255.91</td>
<td>$1,232.52</td>
</tr>
<tr>
<td>Bond B</td>
<td>$255.90</td>
<td>$252.76</td>
</tr>
<tr>
<td></td>
<td>$744.10</td>
<td>$727.00</td>
</tr>
<tr>
<td>Total</td>
<td>$1,000.00</td>
<td>$979.76</td>
</tr>
<tr>

<td>$744.10</td>
<td>$727.00</td>
</tr>
<tr>
<td>Total</td>
<td>$744.10</td>
<td>$727.00</td>
</tr>
</tbody>
</table>

Because there is a rising spot-yield curve, we know the YTM would be somewhere between these two values. The point is that under these conditions, valuing the bonds with a single high rate tends to generate a value that is lower than that derived from the spot rate curve. This is shown for both Bond A and Bond B using the 6.5 percent discount rate. As shown, Bond A has a spot rate value of $1,238 and a single discount rate value of about $1,233. The Bond B values are likewise different. The value for Bond C is the same because it only has the one flow at maturity. This implies that a single-rate valuation technique would typically mis-value these bonds compared to the more appropriate technique that considers each flow as a single bond discounted by its own spot rate.

18.5 WHAT DETERMINES INTEREST RATES?

Now that we have learned to calculate various yields on bonds and to determine the value of bonds using yields and spot rates, the question arises as to what causes differences and changes in yields over time. Market interest rates cause these effects because the interest rates reported in the media are simply the prevailing YTM's for the bonds being discussed. For example, when you hear that the interest rate on long-term government bonds declined from 5.80 percent to 5.70 percent, this means that the price of this particular bond increased such that the:

</tbody>
</table>

rate where the rate used is often based on the yield to maturity for a government bond with a single maturity. For example, when asked about the value of a particular 20-year bond rated AA, a bond trader typically will respond that the bond should trade a certain number of basis points higher than comparable maturity Treasury bonds (e.g., plus 70 basis points). This means that if 20-year Treasury bonds are currently yielding 4.40 percent, this AA-rated 20-year bond should trade at about a 5.10 percent yield. Notably, this rate would determine the price for the bond with no consideration given to the specific cash flows of this security (i.e., high or low coupon). Therefore, there is a growing awareness that the valuation formula should be specified such that all cash flows should be discounted at spot rates consistent with the timing of the flows, as follows:

18.7

\[ P_m = \sum_{t=1}^{2n} \frac{C_t}{(1 + i_t/2)^t} \]

where:

- \( P_m \) = the market price for the bond
- \( C_t \) = the cash flow at Time \( t \)
- \( n \) = the number of years
- \( i_t \) = the spot rate for Treasury securities at maturity \( t \)

Note that this valuation model requires a different discount rate for each flow so it is not possible to use the annuity concept. Also, the principal payment at the end of the year \( n \) is no different from the interest coupon flow at year \( n \).

To demonstrate the effect of this procedure, consider the following hypothetical spot rate curve for the next five years (in Exhibit 18.5) and the valuation of three example bonds with equal maturities of five years, but with very different cash flows.

Beyond the differences in value because of the differences in cash flows and the rising spot rate curve, a significant comparison is the value that would be derived using a single
computed YTM at the former price was 5.80 percent, but the computed YTM at the new, higher price is 5.70 percent. Yields and interest rates are the same. They are different terms for the same concept.

We have discussed the inverse relationship between bond prices and interest rates. When interest rates decline, the prices of bonds increase; when interest rates rise, there is a decline in bond prices. Alternatively, you could describe an increase in the price of a bond and note that it caused a decline in the bond’s yield. It is natural to ask which of these is the driving force—bond prices or bond interest rates? It is a simultaneous change, and you can envision either factor causing it. Most practitioners probably envision the changes in interest rates as the causes because they constantly use interest rates to describe changes. They use interest rates because they are comparable across bonds, whereas the price of a bond depends not only on the interest rate but also on the bond’s specific characteristics, including its coupon and maturity. The point is, as demonstrated in Exhibit 18.1 and Exhibit 18.2, when you change the interest rate (yield) on a bond, you simultaneously change its price in the opposite direction. Later in the chapter, we will discuss the specific price-yield relationship for individual bonds and demonstrate that this price-yield relationship differs among bonds based on their particular coupon and maturity.

Understanding interest rates and what makes them change is necessary for an investor who hopes to maximize returns from investing in bonds. Therefore, in this section we review our prior discussion of the following topics: what causes overall market interest rates to rise and fall, why alternative bonds have different interest rates, and why the difference in rates (i.e., the yield spread) between alternative bonds changes over time. We begin with a general discussion of what influences interest rates and then consider the term structure of interest rates (shown by yield curves), which relates the interest rates on a set of comparable bonds to their terms to maturity. The term structure is important because it implies a set of spot rates that can be used in the valuation of bonds. In addition, the term structure reflects what investors expect to happen to interest rates in the future, and it dictates their current risk attitude. In this section, we specifically consider the calculation of spot rates and forward rates from the reported yield curve. Finally, we consider yield spreads, which measure the differences in yields between alternative bonds. We describe various yield spreads and explore what causes changes in them over time.

### 18.5.1 Forecasting Interest Rates

As discussed, the ability to forecast interest rates and changes in these rates is critical to successful bond investing. Later, we consider the major determinants of interest rates, but for now you should keep in mind that interest rates are the price for loanable funds. Like any price, interest rates are determined by the supply and demand for these funds. On the one side, investors are willing to provide funds (the supply) at prices based on their required rates of return for a particular borrower. On the other side, borrowers need funds (the demand) to support budget deficits (government), to invest in capital projects (corporations), or to acquire durable goods (cars, appliances) or homes (individuals).

Although lenders and borrowers have some fundamental factors that determine supply and demand curves, the prices for these funds (interest rates) also are affected for short periods by events that shift the curves. Examples include major government bond issues that affect demand for funds, or significant changes in Federal Reserve monetary policy that affect the supply of money.

Our treatment of interest rate forecasting recognizes that you must be aware of the basic determinants of interest rates and monitor these factors. We also recognize that detailed forecasting of interest rates is a very complex task that is best left to professional economists. Therefore, our goal as bond investors and bond portfolio managers is to continuously assess the major factors that affect interest rates but rely on others—such as economic consulting firms, banks, or

<td>$1,000 \times 0.7270 = 727.00</td>
<td></td>
</tr>
</tbody>
</table>

Because there is a rising spot-yield curve, we know the YTM would be somewhere between these two values. The point is that under these conditions, valuing the bonds with a single high rate tends to generate a value that is lower than that derived from the spot rate curve. This is shown for both Bond A and Bond B using the 6.5 percent discount rate. As shown, Bond A has a spot rate value of $1,238 and a single discount rate value of about $1,233. The Bond B values are likewise different. The value for Bond C is the same because it only has the one flow at maturity. This implies that a single-rate valuation technique would typically misvalue these bonds compared to the more appropriate technique that considers each flow as a single bond discounted by its own spot rate.

### 18.5 What Determines Interest Rates?

Now that we have learned to calculate various yields on bonds and to determine the value of bonds using yields and spot rates, the question arises as to what causes differences and changes in yields over time. Market interest rates cause these effects because the interest rates reported in the media are simply the prevailing YTM$s for the bonds being discussed. For example, when you hear that the interest rate on long-term government bonds declined from 5.80 percent to 5.70 percent, this means that the price of this particular bond increased such that the
computed YTM at the former price was 5.80 percent, but the computed YTM at the new, higher price is 5.70 percent. Yields and interest rates are the same. They are different terms for the same concept.

We have discussed the inverse relationship between bond prices and interest rates. When interest rates decline, the prices of bonds increase; when interest rates rise, there is a decline in bond prices. Alternatively, you could describe an increase in the price of a bond and note that it caused a decline in the bond’s yield. It is natural to ask which of these is the driving force—bond prices or bond interest rates? It is a simultaneous change, and you can envision either factor causing it. Most practitioners probably envision the changes in interest rates as the causes because they constantly use interest rates to describe changes. They use interest rates because they are comparable across bonds, whereas the price of a bond depends not only on the interest rate but also on the bond’s specific characteristics, including its coupon and maturity. The point is, as demonstrated in Exhibit 18.1 and Exhibit 18.2, when you change the interest rate (yield) on a bond, you simultaneously change its price in the opposite direction. Later in the chapter, we will discuss the specific price-yield relationship for individual bonds and demonstrate that this price-yield relationship differs among bonds based on their particular coupon and maturity.

Understanding interest rates and what makes them change is necessary for an investor who hopes to maximize returns from investing in bonds. Therefore, in this section we review our prior discussion of the following topics: what causes overall market interest rates to rise and fall, why alternative bonds have different interest rates, and why the difference in rates (i.e., the yield spread) between alternative bonds changes over time. We begin with a general discussion of what influences interest rates and then consider the term structure of interest rates (shown by yield curves), which relates the interest rates on a set of comparable bonds to their terms to maturity. The term structure is important because it implies a set of spot rates that can be used in the valuation of bonds. In addition, the term structure reflects what investors expect to happen to interest rates in the future, and it dictates their current risk attitude. In this section, we specifically consider the calculation of spot rates and forward rates from the reported yield curve. Finally, we consider yield spreads, which measure the differences in yields between alternative bonds. We describe various yield spreads and explore what causes changes in them over time.

18.5.1 Forecasting Interest Rates
As discussed, the ability to forecast interest rates and changes in these rates is critical to successful bond investing. Later, we consider the major determinants of interest rates, but for now you should keep in mind that interest rates are the price for loanable funds. Like any price, interest rates are determined by the supply and demand for these funds. On the one side, investors are willing to provide funds (the supply) at prices based on their required rates of return for a particular borrower. On the other side, borrowers need funds (the demand) to support budget deficits (government), to invest in capital projects (corporations), or to acquire durable goods (cars, appliances) or homes (individuals).

Although lenders and borrowers have some fundamental factors that determine supply and demand curves, the prices for these funds (interest rates) also are affected for short periods by events that shift the curves. Examples include major government bond issues that affect demand for funds, or significant changes in Federal Reserve monetary policy that affect the supply of money.

Our treatment of interest rate forecasting recognizes that you must be aware of the basic determinants of interest rates and monitor these factors. We also recognize that detailed forecasting of interest rates is a very complex task that is best left to professional economists. Therefore, our goal as bond investors and bond portfolio managers is to continuously assess the major factors that affect interest rates but rely on others—such as economic consulting firms, banks, or
investment banking firms—for detailed insights on the real $RFR$ and the expected rate of inflation.\(^5\) This is precisely the way most bond portfolio managers operate.

### 18.5.2 Fundamental Determinants of Interest Rates

As shown in Exhibit 18.6, average interest rates (yields) for long-term (10-year) U.S. government bonds during the period from 2007 to 2010 went from about 5.00 percent to 3.67 percent. These results were similar to those of the United Kingdom and the Euro area, while the rate on Japanese government bonds also declined from about 1.70 percent to 1.05 percent. As a bond investor, you should understand why there are differences in country yields and why interest rates within each country changed.

As you would expect, bond prices increased dramatically during periods when market interest rates dropped, and some bond investors experienced very attractive returns. In contrast, some investors have experienced substantial losses during periods when interest rates increased. This chart, which covers about four years, indicates the need for monitoring interest rates. Essentially, the factors causing interest rates ($i$) to rise or fall are described by the following model:

\[
i = RFR + I + RP
\]

where:

- $RFR =$ the real risk-free rate of interest
- $I =$ the expected rate of inflation
- $RP =$ the risk premium

**Exhibit 18.6 Yields of International Long-Term Government Bonds: Quarterly, 2007–2010**

![Graph showing yields of international long-term government bonds from 2007 to 2010](image)

*Source: International Economic Trends (May 2011), Research Department, Federal Reserve Bank of St. Louis.*

\(^5\)Sources of information on the bond market and interest rate forecasts would include B of A Merrill Lynch’s Fixed Income Weekly and World Bond Market Monitor; Goldman Sachs’s Financial Market Perspectives and The Pocket Chartroom; and the Federal Reserve Bank of St. Louis, Monetary Trends.
This relationship should be familiar based on our presentations in Chapter 1 and Chapter 11. It is a simple but complete statement of interest rate behavior. The more difficult task is estimating the future behavior of some of the variables that impact the RFR, I, and the RP, such as real growth, expected inflation, and economic uncertainty. In this regard, interest rates, like stock prices, are extremely difficult to forecast with any degree of accuracy, as discussed by Fabozzi in “The Structure of Interest Rates” (2012, chap. 8). Alternatively, we can visualize the source of changes in interest rates in terms of the economic conditions and issue characteristics as follows:

\[ i = f (\text{Economic Forces} + \text{Issue Characteristics}) \]
\[ = (\text{RFR} + I) + \text{RP} \]

This rearranged version of the previous equation helps isolate the factors that determine interest rates; as discussed in Van Horne (2001, chaps. 3 and 4).

**Effect of Economic Factors** The real risk-free rate of interest (RFR) is the economic cost of money, that is, the opportunity cost necessary to compensate individuals for forgoing consumption. As discussed previously, it is determined by the real growth rate of the economy with short-run effects due to ease or tightness in the capital market.

The expected rate of inflation is the other economic influence on interest rates. We add the expected level of inflation (I) to the real risk-free rate (RFR) to specify the nominal RFR, which is a market rate like the current rate on government T-bills. Given the stability of the real RFR, it is clear that the wide swings in nominal risk-free interest rates during the years covered by Exhibit 18.6 occurred because of the volatility of expected inflation. Besides the unique country and exchange rate risk that we discuss in the section on risk premiums, differences in the rates of inflation between countries have a major impact on their level of interest rates.

To sum up, one way to estimate the nominal RFR is to begin with the real growth rate of the economy, adjust for short-run ease or tightness in the capital market, and then adjust this real rate of interest for the expected rate of inflation to arrive at the nominal rate.

Another approach to estimating changes in the nominal rate is the macroeconomic view, where the supply and demand for loanable funds are the fundamental economic determinants of i. As the supply of loanable funds increases, the level of interest rates declines, other things being equal. Several factors influence the supply of funds. Federal Reserve monetary policies have a significant impact on the supply of money. The savings patterns of U.S. and non-U.S. investors also affect the supply of funds. Non-U.S. investors have become a stronger influence on the supply of loanable funds available in the United States during recent years, as shown by the significant purchases of U.S. securities by non-U.S. investors. It is widely recognized that this foreign supply of funds to the U.S. bond market has helped reduce our interest rates.

Interest rates increase when the demand for loanable funds increases, all else the same. The demand for loanable funds is affected by the capital and operating needs of the U.S. government, federal agencies, state and local governments, corporations, institutions, and individuals. Federal and state budget deficits increase the demand for loanable funds. Likewise, the level of consumer demand for funds to buy houses, autos, and appliances affects rates, as does corporate demand for funds to pursue investment opportunities. The total of all groups determines the aggregate demand and supply of loanable funds and the level of the nominal RFR.\(^6\)

**The Impact of Bond Characteristics** The interest rate of a specific bond issue is influenced by factors that affect the nominal RFR and also by the unique issue characteristics of the bond that influences the bond’s risk premium (RP). As noted previously, the economic forces that determine the nominal RFR affect all securities, whereas issue characteristics are unique to

\(^6\)For a detailed discussion on the macroeconomic view of interest rates, see Van Horne (2001, chap. 2).
individual securities, market sectors, or countries. Thus, the differences in the yields of corporate and Treasury bonds are generally not caused by economic factors but, rather, by different issue characteristics that affect the risk premiums.

Bond investors separate the risk premium into four components:

1. The quality of the issue as determined by its risk of default relative to other bonds
2. The term to maturity of the issue, which can affect price volatility
3. Indenture provisions, including collateral, call features, and sinking-fund provisions
4. Foreign bond risk, including exchange rate risk and country risk

Of the four factors, quality and maturity have the greatest impact on the risk premium for domestic bonds, while exchange rate risk and country risk are important components of risk for non-U.S. bonds.

The credit quality of a bond reflects the ability of the issuer to service its outstanding debt, which is largely captured in the ratings issued by the bond-rating firms. As a result, bonds with different ratings have different yields. For example, AAA-rated obligations possess lower risk of default than BBB obligations, so they have a lower required yield.

Notably, the risk premium differences between bonds of different quality levels change dramatically over time depending on prevailing economic conditions. When the economy experiences a recession or a period of economic uncertainty, the desire for quality increases (i.e., there is a “flight to quality”), and investors sell lower quality debt and bid up prices of higher-rated bonds, which increases the difference in yield. This difference in yield is referred to as the quality or credit spread. Dialynas and Edington (1992) contend that this yield spread is also influenced by the volatility of interest rates. This variability in the credit risk premium over time was demonstrated and discussed in Chapter 1 and Chapter 11. The U.S. market has experienced dramatic short-run risk premium explosions on several occasions, as follows: in August 1998, in response to defaults on Russian bonds, in 2001, following the terrorist attacks, and especially during the significant credit crisis in 2008–2009.

Term to maturity also influences the risk premium because it affects the price volatility of the bond. In the section on the term structure of interest rates, we will discuss the typical positive relationship between the term to maturity of a bond issue and its interest rate.

As discussed in Chapter 17, indenture provisions indicate the collateral pledged for a bond, its callability, and its sinking-fund provisions. Collateral gives protection to the investor if the issuer defaults on the bond because the investor has a specific claim on some assets in case of liquidation.

Call features indicate when an issuer can buy back the bond prior to its maturity. A bond is called by an issuer when interest rates have declined, so it is not to the advantage of the investor who must reinvest the proceeds at a lower interest rate. Obviously, an investor will charge the issuer for including the call option, and the cost of the option (which is a higher required yield) will increase with the level of interest rates. Therefore, more protection against having the bond called reduces the risk premium. The significance (value) of call protection increases during periods of high interest rates. As noted by Marshall and Yawitz (1980) and Stanhouse and Stock (1999), when you buy a bond with a high coupon, you want protection from having it called away when rates decline.

As discussed by Kalotay (1981, 1982b), a sinking fund reduces the investor’s risk and causes a lower yield for several reasons. First, a sinking fund reduces default risk because it requires the issuer to reduce the outstanding issue systematically. Second, purchases of the bond by the issuer to satisfy sinking-fund requirements provide price support for the bond. These purchases also contribute to a more liquid secondary market for the bond because of the increased trading. Finally, sinking-fund provisions require that the issuer retire a bond before its stated maturity, which reduces the issue’s average maturity. The decline in average maturity tends to reduce the risk premium of the bond.
We know that foreign currency exchange rates change over time and that this increases the risk of global investing. Exchange rates vary among countries because trade balances and rates of inflation differ. Volatile trade balances and inflation rates make exchange rates more volatile, which adds to the uncertainty of future exchange rates and increases the exchange rate risk premium.

In addition, investors also are concerned with the political and economic stability of a country. If investors are unsure about the political or economic environment in a country, they will increase the required risk premium to reflect this country risk.

### 18.5.3 The Term Structure of Interest Rates

The term structure of interest rates (or the *yield curve*, as it is more popularly known) is a static function that relates the term to maturity to the yield to maturity for a sample of bonds at *a given point in time*. Thus, it represents a cross section of yields for a category of bonds that are comparable in all respects but maturity. Specifically, the quality of the issues should be constant, and ideally you should have issues with similar coupons and call features within a single industry category. You can construct different yield curves for Treasuries, government agencies, prime-grade municipals, utilities and corporates with different ratings, and so on. The accuracy of the yield curve will depend on the comparability of the bonds in the sample.

As an example, Exhibit 18.7 shows yield curves for a sample of U.S. Treasury obligations. It is based on the yield to maturity information for a set of comparable Treasury issues contained in publications from the Federal Reserve, the Treasury, or *The Wall Street Journal*. These promised yields were plotted on the graph, and a yield curve was drawn that represents the general configuration of rates. These data represent yield curves at three different points in time to demonstrate the changes in yield levels and in the shape of the yield curve over time.

All yield curves, of course, do not have the same shape as those in Exhibit 18.7. Although individual yield curves are static, their behavior over time is quite fluid. As shown, the yield curve was relatively flat during October 2007. Subsequently, by October 2009, it had a strong positive slope due to significant reductions in short-term rates by the Federal Reserve. In
October 2010, the slope was still very positive but at a lower level. The point is, the shape of the yield curve can undergo dramatic alterations, following one of the four patterns shown in Exhibit 18.8. The rising yield curve is the most common and tends to prevail when interest rates are at low or modest levels. The declining yield curve tends to occur when rates are relatively high. The flat yield curve rarely exists for any period of time. The humped yield curve prevails when extremely high rates are expected to decline to more normal levels. Note that the slope of the yield curve tends to level off after 15 years.

Why does the term structure assume different shapes? Three major theories attempt to explain this: the expectations hypothesis, the liquidity preference hypothesis, and the segmented market hypothesis.

Before we discuss these three alternative hypotheses, we must first discuss two previously noted rates that not only are an integral part of the term structure but also are important in the valuation of bonds. The next two subsections will deal with the specification and computation of spot rates and forward rates. Earlier, we discussed and used spot rates to value bonds with the idea that any coupon bond can be viewed as a collection of zero coupon securities.
The present value of the cash flows discounted at the appropriate spot rates is then:

\[
\begin{align*}
&4.25 \left(1 + z_1\right)^1 + 4.25 \left(1 + z_2\right)^2 + 1.50 \left(1 + z_3\right)^3 \quad \text{where:} \\
&z_1 = \frac{1}{2} \text{the annualized six-month theoretical spot rate} \\
&z_2 = \frac{1}{2} \text{the one-year theoretical spot rate} \\
&z_3 = \frac{1}{2} \text{the 1.5-year theoretical spot rate}
\end{align*}
\]

Because the six-month spot rate and one-year spot rate are 8.0 percent and 8.3 percent, respectively, we know that:

\[
z_1 = 0.04 \\
z_2 = 0.0415
\]

We can compute the present value of the 1.5-year coupon Treasury security as:

\[
\begin{align*}
&4.25 \left(1 + 0.04\right)^1 + 4.25 \left(1 + 0.0415\right)^2 + 1.50 \left(1 + z_3\right)^3 \quad \text{where:} \\
&z_3 = \frac{1}{2} \text{the two-year theoretical spot rate}
\end{align*}
\]

Because the price of the 1.5-year coupon Treasury security (from Exhibit 18.9) is $99.45, the following relationship must hold:

\[
99.45 = 4.25 \left(1 + 0.04\right)^1 + 4.25 \left(1 + 0.0415\right)^2 + 1.50 \left(1 + z_3\right)^3
\]

We can solve for the theoretical 1.5-year spot rate as follows:

\[
99.45 = 4.08654 + 3.91805 + 1.50 \left(1 + z_3\right)^3
\]

Doubling this yield, we obtain the bond-equivalent yield of 0.0893, or 8.93 percent, which is the theoretical 1.5-year spot rate. That rate is the rate that the market would apply to a 1.5-year zero coupon Treasury, if such a security existed.

Given the theoretical 1.5-year spot rate, we can obtain the theoretical 2-year spot rate. The cash flow for the 2-year, 9.0 percent coupon Treasury security in Exhibit 18.9 is:

\[
\begin{align*}
&0.5 \text{ years} \quad 0.090 \times 100 \times 0.5 = \$4.50 \\
&1.0 \text{ years} \quad 0.090 \times 100 \times 0.5 = \$4.50 \\
&1.5 \text{ years} \quad 0.090 \times 100 \times 0.5 + 100 = \$104.50
\end{align*}
\]

The present value of the cash flow is then:

\[
\begin{align*}
&4.50 \left(1 + z_1\right)^1 + 4.50 \left(1 + z_2\right)^2 + 4.50 \left(1 + z_3\right)^3 + 1.50 \left(1 + z_4\right)^4 \quad \text{where:} \\
&z_4 = \frac{1}{2} \text{the two-year theoretical spot rate}
\end{align*}
\]

Because the 6-month, 1-year, and 1.5-year spot rates are 8 percent, 8.3 percent, and 8.93 percent, respectively, then:

\[
\begin{align*}
&z_1 = 0.04 \\
&z_2 = 0.0415 \\
&z_3 = 0.04465
\end{align*}
\]

Therefore, the present value of the two-year coupon Treasury security is:

\[
\begin{align*}
&4.50 \left(1 + 0.04\right)^1 + 4.50 \left(1 + 0.0415\right)^2 + 4.50 \left(1 + 0.04465\right)^3 + 1.50 \left(1 + z_4\right)^4
\end{align*}
\]

\[\text{Exhibit 18.9 Maturity and Yield to Maturity for Hypothetical Treasury Securities}\]

---

\(^8\)This discussion of the theoretical spot rate curve and the subsequent presentation on calculating forward rates draw heavily from “The Structure of Interest Rates,” by Fabozzi (2012, chap. 8).
The present value of the cash flows discounted at the appropriate spot rates is then:

\[
\frac{4.25}{(1 + z_1)^1} + \frac{4.25}{(1 + z_2)^2} + \frac{104.25}{(1 + z_3)^3}
\]

where:

- \( z_1 = \frac{1}{2} \) the annualized six-month theoretical spot rate
- \( z_2 = \frac{1}{2} \) the one-year theoretical spot rate
- \( z_3 = \frac{1}{2} \) the 1.5-year theoretical spot rate

Because the six-month spot rate and one-year spot rate are 8.0 percent and 8.3 percent, respectively, we know that:

\[ z_1 = 0.04 \quad \text{and} \quad z_2 = 0.0415 \]

We can compute the present value of the 1.5-year coupon Treasury security as:

\[
\frac{4.25}{(1.0400)^1} + \frac{4.25}{(1.0415)^2} + \frac{104.25}{(1 + z_3)^3}
\]

Because the price of the 1.5-year coupon Treasury security (from Exhibit 18.9) is $99.45, the following relationship must hold:

\[ 99.45 = \frac{4.25}{(1.0400)^1} + \frac{4.25}{(1.0415)^2} + \frac{104.25}{(1 + z_3)^3} \]

We can solve for the theoretical 1.5-year spot rate as follows:

\[
99.45 = 4.08654 + 3.91805 + \frac{104.25}{(1 + z_3)^3}
\]

\[
91.44541 = \frac{104.25}{(1 + z_3)^3}
\]

\[ 104.25 = 1.140024 = (1 + z_3)^3 \]

\[ (1 + z_3)^3 = 1.140024 \]

\[ z_3 = 0.04465 \]

Doubling this yield, we obtain the bond-equivalent yield of 0.0893, or 8.93 percent, which is the theoretical 1.5-year spot rate. That rate is the rate that the market would apply to a 1.5-year zero coupon Treasury, if such a security existed.

Given the theoretical 1.5-year spot rate, we can obtain the theoretical 2-year spot rate. The cash flow for the 2-year, 9.0 percent coupon Treasury security in Exhibit 18.9 is:

<table>
<thead>
<tr>
<th>Years</th>
<th>Cash Flow</th>
<th>Present Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>0.5</td>
<td>$0.90 \times 100 \times 0.5</td>
<td>$4.50</td>
</tr>
<tr>
<td>1.0</td>
<td>$0.90 \times 100 \times 0.5</td>
<td>$4.50</td>
</tr>
<tr>
<td>1.5</td>
<td>$0.90 \times 100 \times 0.5</td>
<td>$4.50</td>
</tr>
<tr>
<td>2.0</td>
<td>$0.90 \times 100 \times 0.5 + 100</td>
<td>$104.50</td>
</tr>
</tbody>
</table>

The present value of the cash flow is then:

\[
\frac{4.50}{(1 + z_1)^1} + \frac{4.50}{(1 + z_2)^2} + \frac{4.50}{(1 + z_3)^3} + \frac{104.50}{(1 + z_4)^4}
\]

where:

- \( z_4 = \frac{1}{2} \) the two-year theoretical spot rate

Because the 6-month, 1-year, and 1.5-year spot rates are 8 percent, 8.3 percent, and 8.93 percent, respectively, then:

\[ z_1 = 0.04 \quad z_2 = 0.0415 \quad \text{and} \quad z_3 = 0.04465 \]

Therefore, the present value of the two-year coupon Treasury security is:

\[
\frac{4.50}{(1.0400)^1} + \frac{4.50}{(1.0415)^2} + \frac{4.50}{(1.04465)^3} + \frac{104.50}{(1 + z_4)^4}
\]
Because the price of the two-year, 9.0 percent coupon Treasury security is $99.64, the following relationship must hold:

$$99.64 = \frac{4.50}{(1.040)^2} + \frac{4.50}{(1.0415)^2} + \frac{4.50}{(1.04465)^7} + \frac{104.50}{(1 + z_4)^7}$$

We can solve for the theoretical two-year spot rate as follows:

$$99.64 = 4.32962 + 4.14853 + 3.94730 + \frac{104.50}{(1 + z_4)^7}$$

$$87.21725 = \frac{104.50}{(1 + z_4)^7}$$

$$(1 + z_4)^7 = 1.198158$$

$$z_4 = 0.046235$$

Doubling this yield, we obtain the theoretical two-year spot rate bond-equivalent yield of 9.247 percent.

One can follow this approach sequentially to derive the theoretical 2.5-year spot rate from the calculated values of $z_1$, $z_2$, $z_3$, and $z_4$ (the 6-month, 1-year, 1.5-year, and 2-year spot rates) and the price and the coupon of the bond with a maturity of 2.5 years. Subsequently, one could derive the theoretical spot rate for three years. The spot rates thus obtained are shown in Exhibit 18.10. They represent the term structure of spot interest rates for maturities up to three years, based on the prevailing bond price quotations.

As shown, with a rising YTM curve, the theoretical spot rate will increase at a faster rate such that the difference increases with maturity (i.e., the theoretical spot rate curve will be above a positively sloped YTM curve).

**18.6 Calculating Forward Rates from the Spot Rate Curve**

Now that we have derived the theoretical spot rate curve, it is possible to determine what this curve implies regarding the market’s expectation of future short-term rates, which are referred to as forward rates. The following illustrates the process of extrapolating this information about expected future interest rates.

Consider an investor who has a one-year investment horizon and is faced with the following two alternatives:

*Alternative 1: Buy a one-year Treasury bill.*

*Alternative 2: Buy a six-month Treasury bill, and when it matures in six months, buy another six-month Treasury bill.*

The investor will be indifferent between the two alternatives if they produce the same return for the one-year investment horizon. The investor knows the spot rate on the six-month...
Substituting into the formula, we have:

\[ r_0 = 100 \left( 1 + \frac{0.043}{2} \right) = 100 \left( 1 + 0.0215 \right) = 102.15 \]

Therefore, the forward rate six months from now \((t + 0.5)\) on a six-month Treasury security, quoted annually, is 8.6 percent \((0.043 \times 2)\). Let us confirm our results. The price of a one-year Treasury bill with $100 maturity is:

\[ 100 \left( 1 + \frac{0.0415}{2} \right) = 92.19 \]

If $92.19 is invested for six months at the six-month spot rate of 8 percent, the amount at the end of six months would be:

\[ 92.19 (1.0400) = 95.88 \]

If $95.88 is reinvested for another six months in a six-month Treasury bill offering 4.3 percent for six months (8.6 percent annually), the amount at the end of one year would be:

\[ 95.88 (1.043) = 100 \]

Both alternatives will have the same $100 payoff if the six-month Treasury bill yield six months from now is 4.3 percent \((8.6\% \text{ on a bond-equivalent basis})\). This means that, if the investor is guaranteed a 4.3 percent yield on a six-month Treasury bill six months from now, she will be indifferent between the two alternatives.

We used the theoretical spot rates to compute the forward rate. The resulting forward rate is called the \textit{implied forward rate}.

It is possible to use the yield curve to calculate the implied forward rate for any time in the future for any investment horizon. This would include six-month or one-year forward rates for each year in the future. The one-year forward rates would be designated as follows:

\[ r_{t+1} = \text{the 1-year forward rate, 1 year from now} \]
\[ r_{t+2} = \text{the 1-year forward rate, 2 years from now} \]
\[ r_{t+3} = \text{the 1-year forward rate, 3 years from now} \]

Given the calculations, it is clear that with a rising spot rate curve, the forward rate curve would be above the spot rate curve. From Exhibit 18.10, we have the following one-year spot rates, which imply the following one-year forward rates:

\[ r_{t+1} = \left( 1 + \frac{0.09247}{2} \right) \left( 1 + \frac{0.08300}{2} \right) = 1.019349 \]
\[ r_{t+2} = \left( 1 + \frac{0.09787}{3} \right) \left( 1 + \frac{0.09247}{2} \right) = 1.01087 \]

Therefore:

<table>
<thead>
<tr>
<th>Maturity (Years)</th>
<th>Spot Rates</th>
<th>One-Year Forward Rates</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>0.08300</td>
<td>0.1020</td>
</tr>
<tr>
<td>2</td>
<td>0.09247</td>
<td>0.1087</td>
</tr>
<tr>
<td>3</td>
<td>0.09787</td>
<td></td>
</tr>
</tbody>
</table>

Specifically, the one-year forward rate that is expected one year from now \((t + 1)\) is 10.20 percent, while the one-year forward rate that is expected two years from now \((t + 2)\) is 10.87 percent.
18.7.1 Expectations Hypothesis

According to the expectations hypothesis, the shape of the yield curve results from the interest rate expectations of market participants. More specifically, it holds that any long-term interest rate simply represents the geometric mean of current and future one-year interest rates expected to prevail over the maturity of the issue. In essence, the term structure involves a series of intermediate and long-term interest rates, each of which is a reflection of the geometric average of current and expected one-year interest rates (i.e., one year forward rates). Under such conditions, the equilibrium long-term rate is the rate the long-term bond investor would expect to earn through successive investments in short-term bonds over the term to maturity of the long-term bond. Recall that this is what we assumed when computing forward rates.

Generally, this relationship can be formalized as follows:

\[
18.10 \frac{1 + t R_n}{1 + t R_1} = \frac{1 + (t + 1) r_1}{1 + (t + 0.5) r_0.5} = \frac{1 + (t + 1) r_1}{1 + (t + 0.5) r_0.5}
\]

where:

- \( R_n \) = the actual long-term rate
- \( N \) = the term to maturity (in years) of the long issue
- \( t R_1 \) = the current 1-year rate
- \( t + i r_1 \) = the expected 1-year yield during some future period, these expected future 1-year rates are referred to as forward rates.

Given the relationship set forth in this equation, the formula for computing the one-period forward rate beginning at time \( t + n \) and implied in the term structure at time \( t \) is:

\[
18.11 \frac{1 + t + n r_1}{1 + t R_1} = \frac{1 + t + n r_1}{1 + t R_1}
\]

Assume that the five-year spot rate is 10 percent \((t R_5 = 0.10)\) and the four-year spot rate is 9 percent \((t R_4 = 0.09)\). The forward one-year rate four years from now implied by these spot rates can be calculated as follows:

\[
\frac{1 + t + n r_1}{1 + t R_1} = \frac{1 + 0.10}{1 + 0.09} - 1 = 0.1409
\]

Therefore, the forward rate six months from now \((t + 0.5)\) on a six-month Treasury security, quoted annually, is 8.6 percent \((0.043 \times 2)\). Let us confirm our results. The price of a one-year Treasury bill with $100 maturity is:

\[
\frac{100}{1.0415} = 92.19
\]

Therefore, the forward rate six months from now \((t + 0.5)\) on a six-month Treasury security, quoted annually, is 8.6 percent \((0.043 \times 2)\). Let us confirm our results. The price of a one-year Treasury bill with $100 maturity is:

\[
\frac{100}{1.0415} = 92.19
\]

If $92.19 is invested for six months at the six-month spot rate of 8 percent, the amount at the end of six months would be:

\[
92.19(1.0400) = 95.8776
\]

If $95.8776 is reinvested for another six months in a six-month Treasury bill offering 4.3 percent for six months (8.6 percent annually), the amount at the end of one year would be:

\[
95.8776(1.043) = 100
\]

Both alternatives will have the same $100 payoff if the six-month Treasury bill yield six months from now is 4.3 percent (8.6 percent on a bond-equivalent basis). This means that, if the investor is guaranteed a 4.3 percent yield on a six-month Treasury bill six months from now, she will be indifferent between the two alternatives.

We used the theoretical spot rates to compute the forward rate. The resulting forward rate is called the implied forward rate.

It is possible to use the yield curve to calculate the implied forward rate for any time in the future for any investment horizon. This would include six-month or one-year forward rates for each year in the future. The one-year forward rates would be designated as follows:

\[
\begin{align*}
t + 1 r_1 &= \text{the 1-year forward rate, 1 year from now (} t + 1 \text{)} \\
t + 2 r_1 &= \text{the 1-year forward rate, 2 years from now (} t + 2 \text{)} \\
t + 3 r_1 &= \text{the 1-year forward rate, 3 years from now (} t + 3 \text{)}
\end{align*}
\]

Given the calculations, it is clear that with a rising spot rate curve, the forward rate curve would be above the spot rate curve. From Exhibit 18.10, we have the following one-year spot rates, which imply the following one-year forward rates:

\[
\begin{align*}
t + 1 r_1 &= \frac{(1.09247)^2}{(1.08300)} - 1 = \frac{1.19349}{1.08300} - 1 = 0.1020 \\
t + 2 r_1 &= \frac{(1.09787)^3}{(1.09247)^2} - 1 = \frac{1.32328}{1.19349} - 1 = 0.1087
\end{align*}
\]

Therefore:

<table>
<thead>
<tr>
<th>Maturity (Years)</th>
<th>Spot Rates</th>
<th>One-Year Forward Rates</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>0.08300</td>
<td>0.1020</td>
</tr>
<tr>

<td>0.09247</td>
<td>0.1087</td>
</tr>
<tr>
<td>3</td>
<td>0.09787</td>
<td></td>
</tr>
</tbody>
</table>

Specifically, the one-year forward rate that is expected one year from now \((t + 1 r_1)\) is 10.20 percent, while the one-year forward rate that is expected two years from now \((t + 2 r_1)\) is 10.87 percent.
18.7 Term Structure Theories

18.7.1 Expectations Structure Hypothesis

According to the expectations hypothesis, the shape of the yield curve results from the interest rate expectations of market participants. More specifically, it holds that any long-term interest rate simply represents the geometric mean of current and future one-year interest rates expected to prevail over the maturity of the issue. In essence, the term structure involves a series of intermediate and long-term interest rates, each of which is a reflection of the geometric average of current and expected one-year interest rates (i.e., one year forward rates). Under such conditions, the equilibrium long-term rate is the rate the long-term bond investor would expect to earn through successive investments in short-term bonds over the term to maturity of the long-term bond. Recall that this is what we assumed when computing forward rates.

Generally, this relationship can be formalized as follows:

\[ (1 + tR_n) = \left[ (1 + tR_1)(1 + t + 1R_1) \cdots (1 + t + nR_1) \right]^{1/N} \]

where:

- \( R_n \) = the actual long-term rate
- \( N \) = the term to maturity (in years) of the long issue
- \( tR_1 \) = the current 1-year rate
- \( t + 1R_1 \) = the expected 1-year yield during some future period, \( t + i \) (these expected future 1-year rates are referred to as forward rates)

Given the relationship set forth in this equation, the formula for computing the one-period forward rate beginning at time \( t + n \) and implied in the term structure at time \( t \) is:

\[ 1 + t + nR_{tt} = \frac{(1 + tR_{tt})(1 + t + 1R_{tt})(1 + t + 2R_{tt}) \cdots (1 + t + nR_{tt})}{(1 + tR_{tt})(1 + t + 1R_{tt}) \cdots (1 + t + nR_{tt})} \]

\[ = \frac{(1 + tR_{tt})^{n+1}}{(1 + tR_{tt})^n} \]

\[ t + nR_{tt} = \frac{(1 + tR_{tt})^{n+1}}{(1 + tR_{tt})^n} - 1 \]

where \( t + nR_{tt} \) is the one-year forward rate prevailing at \( t + n \), using the term structure at time \( t \).

Assume that the five-year spot rate is 10 percent (\( R_5 = 0.10 \)) and the four-year spot rate is 9 percent (\( R_4 = 0.09 \)). The forward one-year rate four years from now implied by these spot rates can be calculated as follows:

\[ t + nR_{tt} = \frac{(1 + tR_{tt})^{n+1}}{(1 + tR_{tt})^n} - 1 \]

\[ = \frac{(1 + 0.10)^5}{(1 + 0.09)^4} - 1 \]

\[ = \frac{1.6105}{1.4116} - 1 \]

\[ = 1.1409 - 1 = 0.1409 = 14.09\% \]

The term structure at time \( t \) implies that the one-year spot rate four years from now (during Year 5) will be 14.09 percent. This concept and formula can be used to derive future rates for multiple years. Thus, the two-year spot rate that will prevail three years from now (which is a
forward rate) could be calculated using the three-year spot rate and the five-year spot rate. The general formula for computing the \( j \)-period forward rate beginning at time \( t + n \) as of time \( t \) is:

\[
R_{t+n} = \frac{\left(1 + R_{t+n+1}\right)^n}{\left(1 + R_n\right)^n} - 1
\]

As a practical approximation of Equation 18.10, it is possible to use the arithmetic average of one-year rates to generate long-term yields.

The expectations theory can explain any shape of yield curve. Expectations for rising short-term rates in the future cause a rising yield curve; expectations for falling short-term rates in the future will cause long-term rates to lie below current short-term rates, and the yield curve will decline. Similar explanations account for flat and humped yield curves.

Consider the following explanation by the expectations hypothesis of the shape of the term structure of interest rates using arithmetic averages of:

\[ R_1 = \text{5.5 percent the 1-year rate of interest prevailing now (Period t)} \]
\[ R_{t+1} = \text{6 percent the 1-year rate of interest expected to prevail next year (Period } t+1) \]
\[ R_{t+2} = \text{7.5 percent the 1-year rate of interest expected to prevail 2 years from now (Period } t+2) \]
\[ R_{t+3} = \text{8.5 percent the 1-year rate of interest expected to prevail 3 years from now (Period } t+3) \]

Using these hypothetical forward rates and the known rate on a one-year bond, we compute rates on two-, three-, or four-year bonds (designated \( R_2, R_3, \text{ and } R_4 \)) as follows:

\[ R_1 = \text{5.5 percent} \]
\[ R_2 = \frac{(0.055 + 0.06)}{2} = 5.75 \text{ percent} \]
\[ R_3 = \frac{(0.055 + 0.06 + 0.075)}{3} = 6.33 \text{ percent} \]
\[ R_4 = \frac{(0.055 + 0.06 + 0.075 + 0.085)}{4} = 6.88 \text{ percent} \]

In this illustration (which uses the arithmetic average as an approximation of the geometric mean), the yield curve is upward sloping because, at present, investors expect future short-term rates to be above current short-term rates. This is not the formal method for constructing the yield curve. Rather, the yield curve is constructed on the basis of the prevailing promised yields for bonds with different maturities.

The expectations hypothesis attempts to explain why the yield curve is upward sloping, downward sloping, humped, or flat by explaining the expectations implicit in yield curves with different shapes. The evidence is fairly substantial and convincing that the expectations hypothesis is a workable explanation of the term structure. Because of the supporting evidence, its relative simplicity, and the intuitive appeal of the theory, the expectations hypothesis of the term structure of interest rates is rather widely accepted.

**Consistent Investor Actions** Besides the theory and empirical support, it is also possible to present a scenario wherein investor actions will cause the yield curve postulated by the theory. The expectations hypothesis predicts a declining yield curve when interest rates are expected to fall in the future rather than rise. Assuming investors expect falling rates, long-term bonds would be considered attractive investments because investors would want to buy them to lock in prevailing higher yields (which are not expected to be as high in the future) or they would buy them to capture the increase in bond prices (as capital gains) that will accompany a decline in rates. By the same reasoning, investors will sell short-term bonds and reinvest the funds in long-term bonds that will experience larger price increases if rates decline. The point is, investor transactions will reinforce the declining shape of the yield curve as they bid up the
18.7.2 Liquidity Preference (Term Premium) Hypothesis
The theory of liquidity preference holds that long-term securities should provide higher returns than short-term obligations because investors are willing to accept lower yields for short-maturity obligations to avoid the higher price volatility of long-maturity bonds. Another way to interpret the liquidity preference hypothesis is to say that lenders prefer short-term loans, and to induce them to invest in volatile long-term bonds, it is necessary to offer higher yields.

The liquidity preference (also called term premium) theory contends that uncertainty and volatility cause investors to favor short-term issues over bonds with longer maturities because short-term bonds are less volatile and can easily be converted into predictable amounts of cash (i.e., they are more liquid) should unforeseen events occur. This theory in isolation argues that the yield curve should generally slope upward and that any other shape should be viewed as a temporary aberration.

This theory is generally considered to be an extension of the expectations hypothesis because the formal liquidity preference position contends that the liquidity (term) premium inherent in the yields for longer maturity bonds should be added to the expected future rate in arriving at long-term yields. Specifically, the liquidity (or term) premium \( L \) compensates the investor in long-term bonds for the added volatility inherent in long-term bonds compared to short-maturity securities. Because the liquidity premium \( L \) is provided to compensate the long-term investor, it is simply a variation of Equation 18.10, as follows:

\[
(1 + r_N) = [(1 + r_1)(1 + r_2 + L_2) \cdot \cdot \cdot (1 + r_{N-1} + L_{N-1} + L_N)]^{1/N}
\]

In this specification, the \( Ls \) are not the same but would be expected to increase with maturity because the price volatility increases with maturity. The liquidity preference theory has been found to possess some strong empirical support by Kessel (1965), Cagan (1969), and McCulloch (1975).

To see how the liquidity preference theory predicts future yields and how it compares with the pure expectations hypothesis, let us predict future long-term rates from a single set of one-year rates: 6 percent, 7.5 percent, and 8.5 percent. The liquidity preference theory suggests that investors add increasing liquidity premiums to successive rates to derive actual market rates. As an example, given the pure expectation rates above they might arrive at rates of 6.3 percent, 7.9 percent, and 9.0 percent.

As a matter of historical fact, the yield curve shows an upward bias, which implies that some combination of the expectations theory and the liquidity preference (term premium) theory will more accurately explain the shape of the yield curve than either of them alone. Specifically, actual long-term rates consistently tend to be above what is envisioned from the pure price expectations hypothesis. This tendency implies the existence of a liquidity (term) premium.

18.7.3 Segmented Market Hypothesis
Despite meager empirical support, a third theory for the shape of the yield curve is the segmented market hypothesis, which enjoys wide acceptance among market practitioners. Also known as
Chapter 18: The Analysis and Valuation of Bonds

The differences among these bonds cause yield spreads that may be either positive or negative. More important, the magnitude or the direction of a spread can change over time. These changes in size or direction of yield spreads offer profit opportunities. We say that the spread narrows whenever the differences in yield become smaller; it widens as the differences increase. Exhibit 18.11 contains data on a variety of past yield spreads that have changed over time.

As a bond investor, you should evaluate yield spread changes because these changes influence bond price behavior and comparative return performance. You should attempt to identify (1) any normal yield spread that is expected to become abnormally wide or narrow in response to an anticipated swing in market interest rates, or (2) an abnormally wide or narrow yield spread that is expected to become normal.

Economic and market analyses will help you develop expectations regarding the potential for yield spreads to change. Taking advantage of these changes requires a knowledge of historical spreads, an ability to predict future total market changes, and an understanding of why and when specific spreads will change.

In this chapter, we have learned about alternative bond yields, how to calculate them, what determines bond yields (interest rates), and what causes them to change. Now that we understand why yields change, we can logically ask: What is the effect of these yield changes on the prices and rates of return for different bonds? We have discussed the inverse relationship between changes in yields and the price of bonds, so we can now discuss the specific factors that affect the amount of price change for a yield change in different bonds. This can also be referred to as the interest rate sensitivity of a bond. This section lists the specific factors that affect bond price changes for a given change in interest rates (i.e., the interest rate sensitivity of a bond) and demonstrates the effect for different bonds.

A given change in interest rates can cause vastly different percentage price changes for alternative bonds, which implies different interest rate sensitivity. This section will help you understand what causes these differences in interest rate sensitivity. To maximize your rate of return from an expected decline in interest rates, for example, you need to know which bonds will benefit the most from the yield change. This section helps you understand how to make this bond selection decision.

18.7.4 Trading Implications of the Term Structure

Information on maturity yields can help you formulate yield expectations by simply observing the shape of the yield curve. If the yield curve is declining sharply, historical evidence suggests that interest rates will probably decline. Strong expectation theorists would suggest that you need to examine only the prevailing yield curve to predict the future direction of interest rates.

Based on these theories, bond investors use the prevailing yield curve to predict the shapes of future yield curves. Using this prediction and knowledge of current interest rates, investors can determine expected yield volatility by maturity sector. As suggested by Hourdouvelis (1988), the maturity segments that are expected to experience the greatest yield changes give the investor the largest potential price change opportunities.

18.7.5 Yield Spreads

Another technique that helps bond investors make profitable trades is the analysis of yield spreads—the differences in promised yields between bond issues or segments of the market at any point in time. Such differences are specific to the particular issues or segments of the bond market. Thus, yield spreads further shape the rates determined by the basic economic forces \((RFR + I)\). There are four major yield spreads:

1. Different segments of the bond market may have different yields. For example, pure government bonds will have lower yields than government agency bonds, and government bonds have much lower yields than corporate bonds.
2. Bonds in different sectors of the same market segment may have different yields. For example, prime-grade municipal bonds will have lower yields than good-grade municipal bonds, and you will find spreads between AA utilities and BBB utilities, or between AAA industrial bonds and AAA public utility bonds.
3. Different coupons or seasoning within a given market segment or sector may cause yield spreads. Examples include current coupon government bonds versus deep-discount governments or recently issued AA industrials versus seasoned AA industrials.
4. Different maturities within a given market segment or sector also cause differences in yields. An example is the top line in Exhibit 18.11, which shows the maturity spreads between long-term and short-term government bonds.
Throughout this section, we talk about bond price changes or bond price volatility interchangeably. Bond price volatility is measured as the percentage change in the price of the bond, computed as follows:

\[
\text{EPB} - \text{BPB} = \frac{\text{EPB} - \text{BPB}}{\text{BPB}}
\]

where:
- EPB = the ending price of the bond
- BPB = the beginning price of the bond

A bond with high price volatility or high interest rate sensitivity is one that experiences a relatively large percentage price change for a given change in yields.

Bond price volatility is influenced by more than yield behavior alone. Malkiel (1962) used the bond valuation model to demonstrate that the market price of a bond is a function of four factors: (1) its par value, (2) its coupon, (3) the number of years to its maturity, and (4) the prevailing market interest rate. Malkiel's mathematical proofs showed the following relationships between yield (interest rate) changes and bond price behavior:

1. Bond prices move inversely to bond yields (interest rates).
2. For a given change in yields (interest rates), longer maturity bonds experience larger price changes; thus, bond price volatility is directly related to term to maturity.
3. Bond price volatility increases at a diminishing rate as term to maturity increases.
4. Bond price movements resulting from equal absolute increases or decreases in yield are not symmetrical. A decrease in yield raises bond prices by more than an increase in yield of the same amount lowers prices.
5. Higher coupon issues show smaller percentage price fluctuation for a given change in yield; thus, bond price volatility is inversely related to coupon.

Homer and Leibowitz (1972) showed that the absolute level of market yields also affects bond price volatility. As the level of prevailing yields rises, the price volatility of bonds increases, assuming a constant percentage change in market yields. Note that if you assume a constant percentage change in yield, the basis-point change will be greater when rates are high. For example, a 25 percent change in interest rates when rates are at 4 percent will be 100 basis points; the same 25 percent change when rates are at 8 percent will be a 200 basis-point change. In the discussion of bond duration, we will see that this difference in basis point change is important.

Exhibits 18.12, 18.13, and 18.14 demonstrate these relationships assuming semiannual compounding. Exhibit 18.12 demonstrates the effect of maturity on price volatility. In all four maturity classes, we assume a bond with an 8 percent coupon and assume that the discount rate (YTM) changes from 7 percent to 10 percent. The only difference among the four cases is the

<table>
<thead>

The differences among these bonds cause yield spreads that may be either positive or negative. More important, the magnitude or the direction of a spread can change over time. These changes in size or direction of yield spreads offer profit opportunities. We say that the spread narrows whenever the differences in yield become smaller; it widens as the differences increase. Exhibit 18.11 contains data on a variety of past yield spreads that have changed over time.

As a bond investor, you should evaluate yield spread changes because these changes influence bond price behavior and comparative return performance. You should attempt to identify (1) any normal yield spread that is expected to become abnormally wide or narrow in response to an anticipated swing in market interest rates, or (2) an abnormally wide or narrow yield spread that is expected to become normal.

Economic and market analyses will help you develop expectations regarding the potential for yield spreads to change. Taking advantage of these changes requires a knowledge of historical spreads, an ability to predict future total market changes, and an understanding of why and when specific spreads will change.9

### 18.8 What Determines the Price Volatility for Bonds?

In this chapter, we have learned about alternative bond yields, how to calculate them, what determines bond yields (interest rates), and what causes them to change. Now that we understand why yields change, we can logically ask: What is the effect of these yield changes on the prices and rates of return for different bonds? We have discussed the inverse relationship between changes in yields and the price of bonds, so we can now discuss the specific factors that affect the amount of price change for a yield change in different bonds. This can also be referred to as the interest rate sensitivity of a bond. This section lists the specific factors that affect bond price changes for a given change in interest rates (i.e., the interest rate sensitivity of a bond) and demonstrates the effect for different bonds.

A given change in interest rates can cause vastly different percentage price changes for alternative bonds, which implies different interest rate sensitivity. This section will help you understand what causes these differences in interest rate sensitivity. To maximize your rate of return from an expected decline in interest rates, for example, you need to know which bonds will benefit the most from the yield change. This section helps you understand how to make this bond selection decision.

---

9An article that identifies four determinants of relative market spreads and suggests scenarios when they will change is Dialynas and Edlington (1992).
Throughout this section, we talk about bond price changes or bond price volatility interchangeably. **Bond price volatility** is measured as the percentage change in the price of the bond, computed as follows:

\[
\frac{EPB - 1}{BPB}
\]

where:

- \( EPB \) = the ending price of the bond
- \( BPB \) = the beginning price of the bond

A bond with high price volatility or high interest rate sensitivity is one that experiences a relatively large percentage price change for a given change in yields.

Bond price volatility is influenced by more than yield behavior alone. Malkiel (1962) used the bond valuation model to demonstrate that the market price of a bond is a function of four factors: (1) its par value, (2) its coupon, (3) the number of years to its maturity, and (4) the prevailing market interest rate. Malkiel’s mathematical proofs showed the following relationships between yield (interest rate) changes and bond price behavior:

1. Bond prices move inversely to bond yields (interest rates).
2. For a given change in yields (interest rates), longer maturity bonds experience larger price changes; thus, bond price volatility is directly related to term to maturity.
3. Bond price volatility increases at a diminishing rate as term to maturity increases.
4. Bond price movements resulting from equal absolute increases or decreases in yield are not symmetrical. A decrease in yield raises bond prices by more than an increase in yield of the same amount lowers prices.
5. Higher coupon issues show smaller percentage price fluctuation for a given change in yield; thus, bond price volatility is inversely related to coupon.

Homer and Leibowitz (1972) showed that the absolute level of market yields also affects bond price volatility. As the level of prevailing yields rises, the price volatility of bonds increases, assuming a constant percentage change in market yields. Note that if you assume a constant percentage change in yield, the basis-point change will be greater when rates are high. For example, a 25 percent change in interest rates when rates are at 4 percent will be 100 basis points; the same 25 percent change when rates are at 8 percent will be a 200 basis-point change. In the discussion of bond duration, we will see that this difference in basis point change is important.

Exhibits 18.12, 18.13, and 18.14 demonstrate these relationships assuming semiannual compounding. Exhibit 18.12 demonstrates the effect of maturity on price volatility. In all four maturity classes, we assume a bond with an 8 percent coupon and assume that the discount rate (YTM) changes from 7 percent to 10 percent. The only difference among the four cases is the

Exhibit 18.14 demonstrates the yield level effect. In these examples, all the bonds have the same 20-year maturity and the same 4 percent coupon. In the first three cases, the YTM changed by a constant 33.3 percent (i.e., from 3 percent to 4 percent, from 6 percent to 8 percent, and from 9 percent to 12 percent). Note that the first change is 100 basis points, the second is 200 basis points, and the third is 300 basis points. The results in the first three columns confirm the statement that when rates change by a constant percentage, the change in the bond price is larger when the rates are at a higher level.

The fourth column shows that if you assume a constant basis-point change in yields, you get the opposite results. Specifically, a 100 basis-point change in yields from 3 percent to 4 percent provides a price change of 14.1 percent, while the same 100 basis-point change from 9 percent to 10 percent results in a price change of only 11 percent. Therefore, the yield level effect can differ, depending on whether the yield change is specified as a constant percentage change or a constant basis-point change.

Thus, the price volatility of a bond for a given change in yield (i.e., its interest rate sensitivity) is affected by the bond’s coupon, its term to maturity, the level of yields (depending on what kind of change in yield), and the direction of the yield change. However, although both the level and the direction of change in yields affect price volatility, they cannot be used for trading strategies because the portfolio manager cannot control these variables. When yields change, the two variables that have a dramatic effect on a bond’s interest rate sensitivity are coupon and maturity.

18.8.1 Trading Strategies
Knowing that coupon and maturity are the major variables that influence a bond’s interest rate sensitivity, we can develop some strategies for maximizing rates of return when interest rates change. Specifically, if you expect a major decline in interest rates, you know that bond prices will increase, so you want a portfolio of bonds with the maximum interest rate sensitivity so that you will enjoy maximum price changes (capital gains) from the change in interest rates. In this situation, the previous discussion regarding the effect of maturity and coupon indicates that you should attempt to build a portfolio of long-maturity bonds with low coupons (ideally, a long-term zero coupon bond). A portfolio of such bonds should experience the maximum price appreciation for a given decline in market interest rates.

In contrast, if you expect an increase in market interest rates, you know that bond prices will decline, and you want a portfolio with minimum interest rate sensitivity to minimize the capital losses caused by the increase in rates. Therefore, you would want to change your portfolio to short-maturity bonds with high coupons. This combination should experience minimal price volatility for a change in market interest rates.

18.8.2 Duration Measures
Because the price volatility (interest rate sensitivity) of a bond varies inversely with its coupon and positively with its term to maturity, it is necessary to determine the best combination of these two variables to achieve your objective. This effort would benefit from a composite measure that considered both coupon and maturity.

A composite measure of the interest rate sensitivity of a bond is referred to as duration. This concept and its development as a tool in bond analysis and portfolio management have existed for over 75 years. Notably, several specifications of duration have been derived over the past 25 years. First, Macaulay duration, developed over 75 years ago by Frederick Macaulay (1938), is a measure of the time flow of cash from a bond. A modified version of Macaulay duration can be used under certain conditions to indicate the price volatility of a bond in response to interest rate changes. Second, modified duration is derived by making a small adjustment (modification) to the Macaulay duration value. As will be discussed, under certain conditions, modified duration is a better measure of price volatility than Macaulay duration.

maturities of the bonds. The demonstration involves computing the value of each bond at a 7 percent yield and at a 10 percent yield and noting the percentage change in price. As shown, this constant change in yield caused the price of the one-year bond to decline by only 2.9 percent, while the 30-year bond declined by almost 29 percent. Clearly, the longer maturity bond experienced the greater price volatility.

Also, price volatility increased at a decreasing rate with maturity. When maturity doubled from 10 years to 20 years, the percent change in price increased by less than 50 percent (from 18.5 percent to 25.7 percent). A much smaller change occurred when going from 20 years to 30 years. Therefore, Exhibit 18.12 demonstrates the first three of our price-yield relationships: (1) bond price is inversely related to yields, (2) bond price volatility is positively related to term to maturity, and (3) bond price volatility increases at a decreasing rate with maturity.

It also is possible to demonstrate the fourth relationship with this exhibit. Using the 20-year bond for demonstration purposes, if you computed the percentage change in price related to an increase in rates (e.g., from 7 percent to 10 percent), you would get the answer reported—a 25.7 percent decrease. In contrast, if you computed the effect on price of a decrease in yields from 10 percent to 7 percent, you would get a 34.7 percent increase in price (from $828 to $1,115). This demonstrates that prices change more in response to a decrease in rates (from 10 percent to 7 percent) than to a comparable increase in rates (from 7 percent to 10 percent).

Exhibit 18.13 demonstrates the coupon effect. In this set of examples, all the bonds have equal maturity (20 years) and experience the same change in YTM (from 7 percent to 10 percent). The exhibit shows the inverse relationship between coupon rate and price volatility: The smallest coupon bond (the zero) experienced the largest percentage price change (almost 45 percent) versus a 24 percent change for the 12 percent coupon bond.
Restrictive conditions (most important, there are no embedded options), modified duration can provide an approximation to the interest rate sensitivity of a bond (or any financial asset). Third, effective duration is a direct measure of the interest rate sensitivity of a bond (or any financial instrument) in cases where it is possible to estimate price changes following an interest rate change using a valuation model. Finally, empirical duration measures directly the percentage price change of an asset for an actual change in interest rates. This measure can be used to estimate the duration for an asset when there is no exact valuation model available. Because of the development of many new financial instruments that have very unique cash flows that change with interest rates, effective duration and empirical duration have become widely used because of their flexibility and ability to provide a useful measure of interest rate sensitivity—the primary goal of duration. Therefore, in this section, we discuss and demonstrate these four duration measures, including their limitations.

### Macaulay Duration

Macaulay showed that the duration of a bond was a more appropriate measure of time characteristics than the term to maturity of the bond because duration considers both the repayment of capital at maturity and the size and timing of coupon payments prior to final maturity. Using annual compounding, duration \((D)\) is:

\[
D = \frac{\sum_{t=1}^{n} C_t \left(1 + i\right)^{-t}}{\sum_{t=1}^{n} C_t \left(1 + i\right)^{-t}}
\]

where:

- \(t\) = the time period in which the coupon or principal payment occurs
- \(C_t\) = the interest or principal payment that occurs in period \(t\)
- \(i\) = the yield to maturity on the bond

The denominator in this equation is the price of a bond as determined by the present value model. The numerator is the present value of all cash flows weighted according to the time to cash receipt. The following example, which demonstrates the specific computations for two bonds, shows the procedure and highlights some of the properties of Macaulay duration. Consider the following two sample bonds:

<table>
<thead>
<tr>
<th>Bond</th>
<th>Face value</th>
<th>Maturity</th>
<th>Coupon</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bond A</td>
<td>$1,000</td>
<td>10 years</td>
<td>4%</td>
</tr>
<tr>
<td>Bond B</td>
<td>$1,000</td>
<td>10 years</td>
<td>8%</td>
</tr>
</tbody>
</table>

Assuming annual interest payments and an 8 percent yield to maturity on the bonds, duration is computed as shown in Exhibit 18.15.

If duration is computed by discounting flows using the yield to maturity of the bond, it is called Macaulay duration.

#### Characteristics of Macaulay Duration

This example illustrates several characteristics of Macaulay duration. First, the Macaulay duration of a bond with coupon payments always will be less than its term to maturity because duration gives weight to these interim interest payments. Second, there is an inverse relationship between coupon and duration. A bond with a larger coupon will have a shorter duration because more of the total cash flows come earlier in the form of interest payments. As shown in Exhibit 18.15, the 8 percent coupon bond has a shorter duration than the 4 percent coupon bond.

We assume annual interest payments to reduce the space requirements and computations. In practice, you would assume semiannual payments that would cause a slightly shorter duration since you receive half the payments earlier.

### 18.8.1 Trading Strategies

Knowing that coupon and maturity are the major variables that influence a bond’s interest rate sensitivity, we can develop some strategies for maximizing rates of return when interest rates change. Specifically, if you expect a major decline in interest rates, you know that bond prices will increase, so you want a portfolio of bonds with the maximum interest rate sensitivity so that you will enjoy maximum price changes (capital gains) from the change in interest rates. In this situation, the previous discussion regarding the effect of maturity and coupon indicates that you should attempt to build a portfolio of long-maturity bonds with low coupons (ideally, a long-term zero coupon bond). A portfolio of such bonds should experience the maximum price appreciation for a given decline in market interest rates.

In contrast, if you expect an increase in market interest rates, you know that bond prices will decline, and you want a portfolio with minimum interest rate sensitivity to minimize the capital losses caused by the increase in rates. Therefore, you would want to change your portfolio to short-maturity bonds with high coupons. This combination should experience minimal price volatility for a change in market interest rates.

### 18.8.2 Duration Measures

Because the price volatility (interest rate sensitivity) of a bond varies inversely with its coupon and positively with its term to maturity, it is necessary to determine the best combination of these two variables to achieve your objective. This effort would benefit from a composite measure that considered both coupon and maturity.

A composite measure of the interest rate sensitivity of a bond is referred to as duration. This concept and its development as a tool in bond analysis and portfolio management have existed for over 75 years. Notably, several specifications of duration have been derived over the past 25 years. First, Macaulay duration, developed over 75 years ago by Frederick Macaulay (1938), is a measure of the time flow of cash from a bond. A modified version of Macaulay duration can be used under certain conditions to indicate the price volatility of a bond in response to interest rate changes. Second, modified duration is derived by making a small adjustment (modification) to the Macaulay duration value. As will be discussed, under certain
A zero coupon bond or a pure discount bond, such as a Treasury bill, will have duration equal to its term to maturity. In Exhibit 18.15, if you assume a single payment at maturity, duration will equal term to maturity because the only cash flow comes in the final (maturity) year—that is, you receive 100 percent of cash flows in year n.

Third, generally a positive relationship between term to maturity and Macaulay duration, but duration increases at a decreasing rate with maturity. Therefore, a bond with longer term to maturity almost always will have a higher duration. The relationship is not direct because as maturity increases the present value of the principal declines in value.

As shown in Exhibit 18.16, the shape of the duration-maturity curve depends on the coupon and the yield to maturity. The duration-maturity curve for a zero coupon bond is a straight line, indicating that duration equals term to maturity. In contrast, the curve for a low-coupon bond selling at a deep discount (due to a high YTM) will turn down at long maturities, which means that under these conditions, the longer maturity bond will have lower duration because the discounted value of the principal payment becomes insignificant, which shifts the weight to the early interest payments, causing a decline in Macaulay duration.

Fourth, all else the same, there is an inverse relationship between YTM and duration. A higher yield to maturity of a bond reduces its duration. As an example, in Exhibit 18.15, if the yield to maturity had been 12 percent rather than 8 percent, the duration for the 4 percent bond would have gone from 8.12 to 7.75, and the duration of the 8 percent bond would have gone from 7.24 to 6.75.

**Macaulay Duration** Macaulay showed that the duration of a bond was a more appropriate measure of time characteristics than the term to maturity of the bond because duration considers both the repayment of capital at maturity and the size and timing of coupon payments prior to final maturity. Using annual compounding, duration (D) is:

\[
D = \frac{\sum_{t=1}^{n} C_t (1 + i)^{-t}}{\sum_{t=1}^{n} C_t (1 + i)^{-t}}
\]

where:

- \( t \) = the time period in which the coupon or principal payment occurs
- \( C_t \) = the interest or principal payment that occurs in period \( t \)
- \( i \) = the yield to maturity on the bond

The denominator in this equation is the price of a bond as determined by the present value model. The numerator is the present value of all cash flows weighted according to the time to cash receipt. The following example, which demonstrates the specific computations for two bonds, shows the procedure and highlights some of the properties of Macaulay duration. Consider the following two sample bonds:

<table>
<thead>
<tr>
<th>Bond</th>
<th>Face value</th>
<th>Maturity</th>
<th>Coupon</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bond A</td>
<td>$1,000</td>
<td>10 years</td>
<td>4%</td>
</tr>
<tr>
<td>Bond B</td>
<td>$1,000</td>
<td>10 years</td>
<td>8%</td>
</tr>
</tbody>
</table>

Assuming annual interest payments and an 8 percent yield to maturity on the bonds, duration is computed as shown in Exhibit 18.15. If duration is computed by discounting flows using the yield to maturity of the bond, it is called Macaulay duration.

**Characteristics of Macaulay Duration** This example illustrates several characteristics of Macaulay duration. First, the Macaulay duration of a bond with coupon payments always will be less than its term to maturity because duration gives weight to these interim interest payments.

Second, there is an inverse relationship between coupon and duration. A bond with a larger coupon will have a shorter duration because more of the total cash flows come earlier in the form of interest payments. As shown in Exhibit 18.15, the 8 percent coupon bond has a shorter duration than the 4 percent coupon bond.

---

10We assume annual interest payments to reduce the space requirements and computations. In practice, you would assume semiannual payments that would cause a slightly shorter duration since you receive half the payments earlier.
The combined effect of the inverse relationships between duration and both coupon and yield can be seen with the curve for the bond with a 15 percent coupon and yield where the duration tops out at about six years. The real-world example of such a bond would be a high-yield bond.

Finally, sinking funds and call provisions can have a dramatic effect on a bond’s duration. They can change the total cash flows for a bond and, therefore, significantly change its duration. Between these two factors, the characteristic that causes the greatest uncertainty is the call feature—it is difficult to estimate when the call option will be exercised since it is a function of changes in interest rates. We consider this further when we discuss the effect of embedded options on the duration and convexity of a bond.

A summary of Macaulay duration characteristics is as follows:

- The duration of a zero coupon bond will equal its term to maturity.
- The duration of a coupon bond always will be less than its term to maturity.
- There is an inverse relationship between coupon and duration.
- There is generally a positive relationship between term to maturity and duration. Note that the duration of a coupon bond increases at a decreasing rate with maturity and the shape of the duration/maturity curve will depend on the coupon and YTM of the bond. Also, the duration of a deep discount bond will decline at very long maturities (over 20 years).
- There is an inverse relationship between yield to maturity and duration.
- Sinking funds and call provisions can cause a dramatic change in the duration of a bond. The effect of embedded options is discussed in a subsequent section.

</table>

A zero coupon bond or a pure discount bond, such as a Treasury bill, will have duration equal to its term to maturity. In Exhibit 18.15, if you assume a single payment at maturity, duration will equal term to maturity because the only cash flow comes in the final (maturity) year—that is, you receive 100 percent of cash flows in year n.

Third, there is generally a positive relationship between term to maturity and Macaulay duration, but duration increases at a decreasing rate with maturity. Therefore, a bond with longer term to maturity almost always will have a higher duration. The relationship is not direct because as maturity increases the present value of the principal declines in value.

As shown in Exhibit 18.16, the shape of the duration-maturity curve depends on the coupon and the yield to maturity. The duration-maturity curve for a zero coupon bond is a straight line, indicating that duration equals term to maturity. In contrast, the curve for a low-coupon bond selling at a deep discount (due to a high YTM) will turn down at long maturities, which means that under these conditions, the longer maturity bond will have lower duration because the discounted value of the principal payment becomes insignificant, which shifts the weight to the early interest payments, causing a decline in Macaulay duration.

Fourth, all else the same, there is an inverse relationship between YTM and duration. A higher yield to maturity of a bond reduces its duration. As an example, in Exhibit 18.15, if the yield to maturity had been 12 percent rather than 8 percent, the duration for the 4 percent bond would have gone from 8.12 to 7.75, and the duration of the 8 percent bond would have
18.8.3 Modified Duration and Bond Price Volatility

An adjusted measure of duration called modified duration can be used to approximate the interest rate sensitivity of an option-free (straight) bond. Modified duration equals Macaulay duration (computed in Exhibit 18.15) divided by 1 plus the current yield to maturity divided by the number of payments in a year. As an example, a bond with a Macaulay duration of 10 years, a yield to maturity \((i)\) of 8 percent, and semiannual payments would have a modified duration of:

\[
D_{\text{mod}} = \frac{10}{1 + \frac{0.08}{2}} = \frac{10}{1 + 0.04} = 9.62
\]

It has been shown, both theoretically and empirically by Hopewell and Kaufman (1973), that price movements of option-free bonds will vary proportionally with modified duration for small changes in yields. Specifically, as shown in the following equation, an estimate of the percentage change in bond price equals the change in yield times modified duration:

\[
\frac{\Delta P}{P} \times 100 = -D_{\text{mod}} \times \Delta i
\]

where:

- \(\Delta P\) = the change in price for the bond
- \(P\) = the beginning price for the bond
- \(D_{\text{mod}}\) = the modified duration of the bond
- The minus sign is because of the inverse relationship between yield changes and price changes.
- \(\Delta i\) = the yield change in basis points divided by 100.

For example, if interest rates go from 8.00 to 8.50 percent, \(\Delta i = \frac{50}{100} = 0.50\).

Consider a bond with Macaulay \(D = 8\) years and \(i = 0.10\). Assume that you expect the bond’s YTM to decline by 75 basis points (e.g., from 10 percent to 9.25 percent). The first step is to compute the bond’s modified duration, as follows:

\[
D_{\text{mod}} = \frac{8}{1 + \frac{0.10}{2}} = \frac{8}{1 + 0.05} = 7.62
\]

The estimated percentage change in the price of the bond using Equation 18.14 is:

\[
\frac{\Delta P}{P} \times 100 = -\left(7.62\right) \times \left(-0.75\right) = 5.72
\]

This indicates that the bond price should increase by approximately 5.72 percent in response to the 75-basis-point decline in YTM. If the price of the bond before the decline in interest rates was $900, the price after the decline in interest rates should be approximately $900 \times 1.0572 = $951.48.

The modified duration is always a negative value for a noncallable bond because of the inverse relationship between yield changes and bond price changes. Also, remember that this specification "for small changes in yields" will become clear when we discuss convexity in the next section. Because modified duration is an approximate measure of interest rate sensitivity, the "years" label is not appropriate.

Exhibit 18.16 Duration versus Maturity

Exhibit 18.16 shows the relationship between duration and maturity for various types of bonds. The graph illustrates that the duration of a bond increases as the time to maturity increases. This is because the cash flows of a bond are spread out over a longer period, and the effect of an interest rate change on the bond price is more pronounced.

The graph also shows that the duration of a bond is negatively correlated with its coupon rate. Bonds with higher coupon rates have shorter durations because their cash flows are more concentrated in the early years of the bond’s life.

Finally, sinking funds and call provisions can have a dramatic effect on a bond’s duration. They can change the total cash flows for a bond and, therefore, significantly change its duration. Between these two factors, the characteristic that causes the greatest uncertainty is the call feature—it is difficult to estimate when the call option will be exercised since it is a function of changes in interest rates. We consider this further when we discuss the effect of embedded options on the duration and convexity of a bond.

A summary of Macaulay duration characteristics is as follows:

- The duration of a zero coupon bond will equal its term to maturity.
- The duration of a coupon bond always will be less than its term to maturity.
- There is an inverse relationship between coupon and duration.
- There is generally a positive relationship between term to maturity and duration. Note that the duration of a coupon bond increases at a decreasing rate with maturity and the shape of the duration/maturity curve will depend on the coupon and YTM of the bond. Also, the duration of a deep discount bond will decline at very long maturities (over 20 years).
- There is an inverse relationship between yield to maturity and duration.
- Sinking funds and call provisions can cause a dramatic change in the duration of a bond. The effect of embedded options is discussed in a subsequent section.

---

11 These properties are discussed and demonstrated in Reilly and Sidhu (1980) and Fabozzi, Buetow, and Johnson (2012).
18.8.3 Modified Duration and Bond Price Volatility

An adjusted measure of duration called modified duration can be used to approximate the interest rate sensitivity of an option-free (straight) bond. Modified duration equals Macaulay duration (computed in Exhibit 18.15) divided by 1 plus the current yield to maturity divided by the number of payments in a year. As an example, a bond with a Macaulay duration of 10 years, a yield to maturity \( i \) of 8 percent, and semiannual payments would have a modified duration of:

\[
D_{\text{mod}} = \frac{10}{1 + \frac{0.08}{2}}
\]

\[
= \frac{10}{1.04} = 9.62
\]

It has been shown, both theoretically and empirically by Hopewell and Kaufman (1973), that price movements of option-free bonds will vary proportionally with modified duration for small changes in yields.\(^{13} \) Specifically, as shown in the following equation, an estimate of the percentage change in bond price equals the change in yield times modified duration:

\[
\frac{\Delta P}{P} \times 100 = -D_{\text{mod}} \times \Delta i
\]

where:

\( \Delta P \) = the change in price for the bond

\( P \) = the beginning price for the bond

\(-D_{\text{mod}}\) = the modified duration of the bond. The minus sign is because of the inverse relationship between yield changes and price changes.

\( \Delta i \) = the yield change in basis points divided by 100. For example, if interest rates go from 8.00 to 8.50 percent, \( \Delta i = 50/100 = 0.50 \).

Consider a bond with Macaulay \( D = 8 \) years and \( i = 0.10 \). Assume that you expect the bond’s YTM to decline by 75 basis points (e.g., from 10 percent to 9.25 percent). The first step is to compute the bond’s modified duration, as follows:

\[
D_{\text{mod}} = \frac{8}{1 + \frac{0.10}{2}}
\]

\[
= \frac{8}{1.05} = 7.62
\]

The estimated percentage change in the price of the bond using Equation 18.14 is:

\[
\%\Delta P = -(7.62) \times \frac{-75}{100}
\]

\[
= (7.62) \times (0.75)
\]

\[
= 5.72
\]

This indicates that the bond price should increase by approximately 5.72 percent in response to the 75-basis-point decline in YTM. If the price of the bond before the decline in interest rates was $900, the price after the decline in interest rates should be approximately $900 \times 1.0572 = $951.48.

The modified duration is always a negative value for a noncallable bond because of the inverse relationship between yield changes and bond price changes. Also, remember that this

\(^{13}\)The importance of the specification “for small changes in yields” will become clear when we discuss convexity in the next section. Because modified duration is an approximate measure of interest rate sensitivity, the “years” label is not appropriate.
discount the flows from this bond at a yield of 1 percent, you would get a price of $2,989.47; discounting these same flows at 10 percent gives a price of $1,171.59. The graph of these prices relative to the yields that produced them (Exhibit 18.19) indicates that the price-yield relationship for this bond is not a straight line but a curvilinear relationship. That is, it is convex.

Two points are important about the price-yield relationship:

1. This relationship can be applied to a single bond, a portfolio of bonds, or any stream of future cash flows.

formulation provides an *estimate* or *approximation* of the percent change in the price of the bond. The following section on convexity shows that this formula, which uses only modified duration, provides an exact estimate of the percentage price change only for very small changes in yields of option-free securities.

**Trading Strategies Using Modified Duration** We know that the longest duration security provides the maximum price variation. Exhibit 18.17 demonstrates that numerous ways exist to achieve a given level of duration. The following discussion indicates that an active bond investor who wants to adjust his or her portfolio for anticipated interest rate changes can use this measure of interest rate sensitivity to structure a portfolio to take advantage of changes in market yields.

If you expect a *decline* in interest rates, you should *increase* the average modified duration of your bond portfolio to experience maximum price volatility. If you expect an *increase* in interest rates, you should *reduce* the average modified duration of your portfolio to minimize your price decline. Note that the modified duration of your portfolio is the *market-value-weighted average of the modified durations of the individual bonds in the portfolio*.

**18.8.4 Bond Convexity**

Modified duration allows us to estimate bond price changes for a change in interest rates. However, the equation we used to make this calculation (Equation 18.14) is accurate only for *very small changes* in market yields. We will see that the accuracy of the estimate of the price change deteriorates with larger changes in yields because the modified duration calculation is a *linear* approximation of a bond price change. Recall that earlier we discussed price-yield curves and noted that these followed a *curvilinear* (convex) function. Because of the importance of understanding the effect of this *convexity*, we consider the price-yield relationship for alternative bonds in detail in the following section.13

**The Price-Yield Relationship for Bonds** Because the price of a bond is the present value of its cash flows at a particular discount rate, if you are given the coupon, maturity, and a yield for a bond, you can calculate its price at a point in time. The price-yield curve provides a set of prices for a specific maturity/coupon bond at a point in time using a range of yields to maturity (discount rates). As an example, Exhibit 18.18 lists the computed prices for a 12 percent, 20-year bond, assuming yields from 1 percent to 12 percent. The exhibit shows that if you

13For a further discussion of this topic, see Dunetz and Mahoney (1988) and Fabozzi, Buetow, and Johnson (2012).
The convex price-yield relationship will differ among bonds or other cash flow streams, depending on the nature of the cash flow stream, that is, its coupon and maturity. For example, the price-yield relationship for a high-coupon, short-term security will be almost a straight line because the price does not change as much for a change in yields (e.g., the 12 percent, three-year bond in Exhibit 18.18 and shown in Exhibit 18.20). In contrast, the price-yield relationship for a low-coupon, long-term bond will have a significant curve (i.e., be very convex), as shown by the zero coupon, 30-year bond in Exhibit 18.18. These differences in convexity are shown graphically in Exhibit 18.20. The curved nature of the price-yield relationship is referred to as the bond’s convexity.

The Desirability of Convexity

As shown by the graph in Exhibit 18.20, because of the convexity of the price-yield relationship (especially the long-term, zero coupon bond) as yield increases, the rate at which the price of the bond declines becomes slower. Similarly, when yields decline, the rate at which the price of the bond increases becomes faster. Therefore, convexity is considered a desirable trait. Specifically, if you have two bonds with equal duration but one has greater convexity, you would want the bond with greater convexity because it would have better price performance whether yields rise (the bond price declines less) or yields fall (the bond price increases more).

Given this price-yield curve, modified duration is the percentage change in price for a nominal change in yield as follows:

\[ D_{mod} = \frac{dP}{di} \]

Notice that the \( \frac{dP}{di} \) line is tangent to the price-yield curve at a given yield as shown in Exhibit 18.21. For small changes in yields (i.e., from \( y^* \) to either \( y_1 \) or \( y_2 \)), this tangent straight line gives a good estimate of the actual price changes. In contrast, for larger changes in yields Exhibit 18.20 Price-Yield Relationships for Alternative Bonds

discount the flows from this bond at a yield of 1 percent, you would get a price of $2,989.47; discounting these same flows at 10 percent gives a price of $1,171.59. The graph of these prices relative to the yields that produced them (Exhibit 18.19) indicates that the price-yield relationship for this bond is not a straight line but a curvilinear relationship. That is, it is convex.

Two points are important about the price-yield relationship:

1. This relationship can be applied to a single bond, a portfolio of bonds, or any stream of future cash flows.

Exhibit 18.19 Price-Yield Relationship and Modified Duration at 4 Percent Yield

12% Coupon, 20-Year Bond

[Graph showing price-yield relationship and modified duration at 4 percent yield]
2. The convex price-yield relationship will differ among bonds or other cash flow streams, depending on the nature of the cash flow stream, that is, its coupon and maturity. For example, the price-yield relationship for a high-coupon, short-term security will be almost a straight line because the price does not change as much for a change in yields (e.g., the 12 percent, three-year bond in Exhibit 18.18 and shown in Exhibit 18.20). In contrast, the price-yield relationship for a low-coupon, long-term bond will have a significant curve (i.e., be very convex), as shown by the zero coupon, 30-year bond in Exhibit 18.18. These differences in convexity are shown graphically in Exhibit 18.20. The curved nature of the price-yield relationship is referred to as the bond’s convexity.

The Desirability of Convexity As shown by the graph in Exhibit 18.20, because of the convexity of the price-yield relationship (especially the long-term, zero coupon bond) as yield increases, the rate at which the price of the bond declines becomes slower. Similarly, when yields decline, the rate at which the price of the bond increases becomes faster. Therefore, convexity is considered a desirable trait. Specifically, if you have two bonds with equal duration but one has greater convexity, you would want the bond with greater convexity because it would have better price performance whether yields rise (the bond price declines less) or yields fall (the bond price increases more).

Given this price-yield curve, modified duration is the percentage change in price for a nominal change in yield as follows:\(^{14}\)

\[
D_{\text{mod}} = \frac{dP}{dt}
\]

Notice that the \(dP/dt\) line is tangent to the price-yield curve at a given yield as shown in Exhibit 18.21. For small changes in yields (i.e., from \(y^*\) to either \(y_1\) or \(y_2\)), this tangent straight line gives a good estimate of the actual price changes. In contrast, for larger changes in yields

---

\(^{14}\)In mathematical terms, modified duration is the first differential of this price-yield relationship with respect to yield.
These graphs demonstrate the following relationship between these factors and the convexity of a bond:

1. There is an inverse relationship between coupon and convexity (yield and maturity constant) — that is, lower coupon, higher convexity.
2. There is a direct relationship between maturity and convexity (yield and coupon constant) — that is, longer maturity, higher convexity.
3. There is an inverse relationship between yield and the convexity along the price-yield curve (coupon and maturity constant). This means that the price-yield curve is more convex at lower yields (upper left segment) and less convex at higher yields.

Therefore, a short-term, high-coupon bond, such as the 12 percent coupon, three-year bond in Exhibit 18.20, has very low convexity — it is almost a straight line. In contrast, the zero-coupon, 30-year bond has high convexity.

Notably, the determinants of duration and convexity for option-free bonds are very similar. Specifically, the three factors are the same — maturity, coupon, and yield — and the direction of impact is the same — that is, maturity is positively related to both duration and convexity and both coupon and yield are inverse. Therefore, high-duration, option-free bonds have high convexity.

The Modified-Duration-Convexity Effects

In summary, the change in a bond’s price resulting from a change in yield can be attributed to two sources: the bond’s modified duration and its convexity. The relative effect of these two factors on the price change will depend on the characteristics of the bond (i.e., its convexity) and the size of the yield change. For example, if you are estimating the price change for a 300-basis-point change in yield for a zero-coupon, 30-year bond, the convexity effect would be fairly large because this bond would have high convexity, and a 300-basis-point change in yield is relatively large. In contrast, if you are dealing with only a 10-basis-point change in yields, the convexity effect would be minimal because it is a small change in yield. Similarly, the convexity effect would likewise be small even if you assume a larger yield change if you are dealing with a bond with small convexity (i.e., a high-coupon, short-maturity bond) because the price-yield curve for such a bond is almost a straight line.

In conclusion, modified duration can help you derive an approximate percentage bond price change for a given change in interest rates, but you must remember that it is only a good estimate when you are considering small yield changes. The point is, you must also consider the convexity effect on price change when you are dealing with large yield changes and/or when the securities or cash flows have high convexity.

Computation of Convexity

Again, the formula for computing the convexity of a stream of cash flows looks fairly complex, but it can be broken down into manageable steps. You will recall from our convexity equation (18.16) that:

\[
\text{Convexity} = \frac{d^2P}{dt^2} \div \frac{dP}{dt}
\]

Exhibit 18.21 Price Approximation Using Modified Duration

(i.e., from \( y^* \) to either \( y_3 \) or \( y_4 \)), the straight line will estimate the new price of the bond at less than the actual price shown by the price-yield curve. This misestimate arises because the modified-duration line is a linear estimate of a curvilinear relationship. Specifically, the estimate using only modified duration will underestimate the actual price increase caused by a yield decline and overestimate the actual price decline caused by an increase in yields. This graph, which demonstrates the convexity effect, also shows that price changes are not symmetric when yields increase or decrease. As shown, when rates decline, there is a larger price error than when rates increase because, due to convexity, when yields decline prices rise at an increasing rate, while prices decline at a decreasing rate when yields rise.

Determinants of Convexity Convexity is a measure of the curvature of the price-yield relationship. In turn, because modified duration is the slope of the curve at a given yield, convexity indicates changes in duration. Mathematically, convexity is the second derivative of price with respect to yield \((d^2P/dt^2)\) divided by price. Specifically, convexity is the percentage change in \( dP/dt \) for a given change in yield:

\[
\text{Convexity} = \frac{d^2P}{dt^2} \div \frac{dP}{dt}
\]

Convexity is a measure of how much a bond’s price-yield curve deviates from the linear approximation of that curve. As indicated by Exhibit 18.19 and Exhibit 18.21, for noncallable bonds convexity always is a positive number, implying that the price-yield curve lies above the modified-duration (tangent) line. Exhibit 18.20 illustrates the price-yield relationship for two bonds with very different coupons and maturities. (The yields and prices are contained in Exhibit 18.18.)
These graphs demonstrate the following relationship between these factors and the convexity of a bond:

- There is an inverse relationship between coupon and convexity (yield and maturity constant)—that is, lower coupon, higher convexity.
- There is a direct relationship between maturity and convexity (yield and coupon constant)—that is, longer maturity, higher convexity.
- There is an inverse relationship between yield and the convexity along the price-yield curve (coupon and maturity constant). This means that the price-yield curve is more convex at lower yields (upper left segment) and less convex at higher yields.

Therefore, a short-term, high-coupon bond, such as the 12 percent coupon, three-year bond in Exhibit 18.20, has very low convexity—it is almost a straight line. In contrast, the zero-coupon, 30-year bond has high convexity.

Notably, the determinants of duration and convexity for option-free bonds are very similar. Specifically, the three factors are the same—maturity, coupon, and yield—and the direction of impact is the same—that is, maturity is positively related to both duration and convexity and both coupon and yield are inverse. Therefore, high-duration, option-free bonds have high convexity.

The Modified-Duration-Convexity Effects In summary, the change in a bond’s price resulting from a change in yield can be attributed to two sources: the bond’s modified duration and its convexity. The relative effect of these two factors on the price change will depend on the characteristics of the bond (i.e., its convexity) and the size of the yield change. For example, if you are estimating the price change for a 300-basis-point change in yield for a zero coupon, 30-year bond, the convexity effect would be fairly large because this bond would have high convexity, and a 300-basis-point change in yield is relatively large. In contrast, if you are dealing with only a 10-basis-point change in yields, the convexity effect would be minimal because it is a small change in yield. Similarly, the convexity effect would likewise be small even if you assume a larger yield change if you are dealing with a bond with small convexity (i.e., a high-coupon, short-maturity bond) because the price-yield curve for such a bond is almost a straight line.

In conclusion, modified duration can help you derive an approximate percentage bond price change for a given change in interest rates, but you must remember that it is only a good estimate when you are considering small yield changes. The point is, you must also consider the convexity effect on price change when you are dealing with large yield changes and/or when the securities or cash flows have high convexity.

Computation of Convexity Again, the formula for computing the convexity of a stream of cash flows looks fairly complex, but it can be broken down into manageable steps. You will recall from our convexity equation (18.16) that:

\[
\text{Convexity} = \frac{d^2P/dt^2}{P}
\]

In turn:

\[
\frac{d^2P/dt^2}{P} = \frac{1}{(1+i)^t} \left[ \sum_{t=1}^{n} \frac{CF_t}{(1+i)^t} \right]
\]

Exhibit 18.22 contains the computations related to this calculation for a three-year bond with a 12 percent coupon and 9 percent YTM, assuming annual flows.

The convexity for this bond is very low because it has a short maturity, high coupon, and high yield. Note that the convexity of a security will vary along the price-yield curve. You will get a different convexity at a 3 percent yield than at a 12 percent yield. In terms of the
Funds from a new issue sold at a lower yield. Observers refer to this as a bond with an embedded option. We noted earlier that the duration of a bond can be seriously affected by an embedded call option if interest rates decline substantially below a bond’s coupon rate. In such a case, the issuer will likely call the bond, which will dramatically change the maturity and the duration of the bond. For example, assume a firm issues a 30-year bond with a 9 percent coupon with a deferred call provision whereby the bond can be called in six years at 109 percent of par. If the bond is issued at par, its original duration to maturity will be about 11 years. A year later, if rates decline to about 7 percent, its duration to maturity will still be over 10 years because duration is inversely related to yield and yields have declined. Notably, at a yield of 7 percent, this bond will probably trade at yield to call because at a 7 percent yield the firm will likely exercise its option and call the bond in five years. Notably, the bond’s duration to first

### Exhibit 18.22 Computation of Convexity

Convexity = \( \frac{d^2 P}{dY^2} \) = \( \frac{d^2 P}{dY^2} \) \[ \text{Price} \]

\[ \frac{d^2 P}{dY^2} = \frac{1}{(1+i)^2} \sum_{t=1}^{n} [t^2 + t] \frac{CF_t}{(1+i)^t} \]

Convexity = \( \frac{d^2 P}{dY^2} \) \[ \text{Price} \]

</table>

\( \frac{1}{(1+i)^2} = \frac{1}{(1.09)^2} = \frac{1}{1.19} = 0.84 \)

\$11,204.50 \times 0.84 = \$9,411.78

Convexity = \( \frac{9,411.78}{1,075.95} = 8.75 \)

Computation, the maturity and coupon will be the same, but you will use a different discount rate that reflects where you are on the curve. This is similar to the earlier observation that you will get a different modified duration and convexity at different points on the price-yield curve because the slope varies along the curve (the duration) and the rate of change in the slope (the convexity) also varies. You also can see this mathematically because, depending on where you are on the curve, you will be using a different market yield, and the Macaulay and modified durations are inverse to the discount rate.\(^1\)

To compute the price change attributable to the convexity effect after you know the bond’s convexity, use this equation:

\[ \text{Price change due to convexity} = \frac{1}{2} \times \text{price} \times \text{convexity} \times (\Delta \text{in yield})^2 \]

Exhibit 18.23 shows the change in bond price considering the duration effect and the convexity effect for an 18-year bond with a 12 percent coupon and 9 percent YTM. For demonstration purposes, we assumed a decline of 100 and 300 basis points (BP) in rates (i.e., 9 percent to 8 percent and 9 percent to 6 percent).

With the 300-basis-point change, if you considered only the modified-duration effect, you would have estimated that the bond went from 126.50 to 158.30 (a 25.14 percent increase), when, in fact, the actual price is closer to 164.41, which is about a 30 percent increase.

### 18.8.5 Duration and Convexity for Callable Bonds

The discussion and presentation thus far regarding Macaulay and modified durations and convexity have been concerned with option-free bonds. A callable bond is different because it provides the issuer with an option to call the bond under certain conditions and pay it off with

\(^1\) Exhibit 18.31 in the appendix to this chapter is a table that combines the computation of Macaulay and modified duration and convexity using semiannual cash flows.
Clearly, there is a significant difference between duration to maturity (over 10 years) and duration to first call (about 4 years). To understand the impact of the call feature on the duration and convexity of a bond, it is important to consider what determines the price of a callable bond. A callable bond is a combination of a noncallable bond plus a call option that was sold to the issuer, which allows the issuer to call the bond under the conditions discussed earlier. Because the call option is owned by the issuer, it has negative value for the investor in the bond. Thus, the bondholder’s position is:

\[
\text{Long a callable bond} = \text{Long a noncallable bond} + \text{A short position in a call option}
\]

Therefore, the value (price) of a callable bond is equal to:

\[
\text{Callable bond price} = \text{Noncallable bond price} - \text{call option price}
\]

Given this valuation, anything that increases the value of the call option will reduce the value of the callable bond.

The point is, when interest rates decline, the right-hand side of this equation experiences a conflict between the value of the noncallable bond that increases in value, and the value of the call option that also increases but this option value has a negative effect on the bond price. Notably, if the value of the call option increases faster than the value of the noncallable bond, the overall value of the callable bond will decline when interest rates decline and this is referred to as negative duration—that is, in contrast to the usual inverse relationship between yield changes and bond price changes, in this case yield changes and price changes both decline.

Option-Adjusted Duration

Given these two extreme values of (1) duration to maturity and (2) duration to first call, the investment community derives a duration estimate that is referred to as an option-adjusted or call-adjusted duration based on the probability that the issuing firm will exercise its call option for the bond when the bond becomes freely callable. This option-adjusted duration will be somewhere between these two extreme values. Specifically, when interest rates are substantially above the coupon rate, the probability of the bond being called is very small (i.e., the call option has very little value) and the option-adjusted duration will approach the duration to maturity. In contrast, if interest rates decline to levels substantially below the coupon rate, the probability of the bond being called at the first opportunity is very high (i.e., the call option is very valuable and will probably be exercised) and the option-adjusted duration will approach the duration to first call. In summary, the bond’s option-adjusted duration will be somewhere between these two extremes with the exact option-adjusted duration depending on the level of interest rates relative to the bond’s coupon rate.

The option-adjusted duration can also be envisioned or computed based on the duration of the two components, as follows:

\[
\text{Option-adjusted duration} = \text{Duration of the noncallable bond} - \text{duration of the call option}
\]

If one conceives of duration as interest rate sensitivity, we know that at high interest rates a change in yield will have little if any impact on the value of the option. Thus, the duration (i.e., interest rate sensitivity) of the option would be close to zero and the option-adjusted duration would equal that of a noncallable bond. In contrast, when yields decline below the coupon yield, the call option will be very interest rate sensitive since the option will experience a large increase in value at low yields. Thus, the duration (i.e., the interest rate sensitivity) of the option will be fairly high and have a large impact on the callable bond’s option-adjusted duration.

For a further discussion of the effect of these embedded options, see Fabozzi, Buetow, and Johnson (2012) and Fabozzi, Kalotay, and Dorigan (2012). Also see Winkelmann (1989).

The discussion in this subsection will consider the option-adjusted duration on a conceptual and intuitive basis. For a detailed mathematical treatment, see Dunetz and Mahoney (1988).
it will drive the duration of the callable bond toward the duration to first call. In fact, it is possible to conceive of an option that is very leveraged such that it is extremely interest rate sensitive (i.e., has a very large duration that exceeds the duration of the noncallable bond), resulting in a negative option-adjusted duration. An example is a mortgage-backed security that might decline in price when there is a decline in interest rates.

**Convexity of Callable Bonds**

Exhibit 18.24 shows what happens to the price of a callable bond versus the value of a noncallable bond when interest rates increase or decline. Starting from yield \( y^* \) (which is close to the par value yield), if interest rates increase, the value of the call option declines because at market interest rates are substantially above the coupon rate, it is unlikely the issuer will want to call the issue. Therefore, the call option has very little value, and the price of the callable bond will be similar to the price of a noncallable bond. In contrast, when interest rates decline below \( y^* \), there is an increase in the probability that the issuer will want to use the call option—that is, the value of the call option increases. As a result, the value of the callable bond will deviate from the value of the noncallable bond— that is, the price of the callable bond will initially not increase as fast as the noncallable bond price and eventually will not increase at all. This is what is shown in curve \( a-b \).

In the case of the noncallable bond, we indicated that it had positive convexity because as yields declined, the price of the bond increased at a faster rate. With the callable bond, when rates decline, the price increases at a slower rate and eventually does not change at all. This pattern of price-yield change for a callable bond when yields decline is referred to as negative convexity. Needless to say, this price pattern (negative convexity) is one of the risks of a callable bond versus a noncallable bond when interest rates decline.

18.8.6 Limitations of Macaulay and Modified Duration

It is important to understand Macaulay and modified duration because of the perspective they provide regarding factors that affect the volatility and interest rate sensitivity of bonds. However, it also is important for bond analysts and portfolio managers to recognize the serious limitations of these measures in the real world. The major limitations are as follows.

Exhibit 18.24 Noncallable and Callable Bond Price-Yield Relationship

\[
\begin{align*}
\text{Callable Bond} & \quad a-b \\
\text{Noncallable Bond} & \quad a-a' \\
\end{align*}
\]

**Option-Adjusted Duration**

Given these two extreme values of (1) duration to maturity and (2) duration to first call, the investment community derives a duration estimate that is referred to as an option-adjusted or call-adjusted duration based on the probability that the issuing firm will exercise its call option for the bond when the bond becomes freely callable. This option-adjusted duration will be somewhere between these two extreme values. Specifically, when interest rates are substantially above the coupon rate, the probability of the bond being called is very small (i.e., the call option has very little value) and the option-adjusted duration will approach the duration to maturity. In contrast, if interest rates decline to levels substantially below the coupon rate, the probability of the bond being called at the first opportunity is very high (i.e., the call option is very valuable and will probably be exercised) and the option-adjusted duration will approach the duration to first call. In summary, the bond’s option-adjusted duration will be somewhere between these two extremes with the exact option-adjusted duration depending on the level of interest rates relative to the bond’s coupon rate.

The option-adjusted duration can also be envisioned or computed based on the duration of the two components, as follows:

\[ \text{Option-adjusted duration} = \text{Duration of the noncallable bond} - \text{duration of the call option} \]

If one conceives of duration as interest rate sensitivity, we know that at high interest rates a change in yield will have little if any impact on the value of the option. Thus, the duration (i.e., interest rate sensitivity) of the option would be close to zero and the option-adjusted duration would equal that of a noncallable bond. In contrast, when yields decline below the coupon yield, the call option will be very interest rate sensitive since the option will experience a large increase in value at low yields. Thus, the duration (i.e., the interest rate sensitivity) of the option will be fairly high and have a large impact on the callable bond’s option-adjusted

---

16 For a further discussion of the effect of these embedded options, see Fabozzi, Buetow, and Johnson (2012) and Fabozzi, Kalotay, and Dorigan (2012). Also see Winkelmann (1989).

17 The discussion in this subsection will consider the option-adjusted duration on a conceptual and intuitive basis. For a detailed mathematical treatment, see Dufetz and Mahoney (1988).
First, as noted in the discussion on convexity, the percent change estimates using modified duration are good only for small-yield changes. This was demonstrated in Exhibit 18.21. As a result, two bonds with equal duration may experience different price changes for large-yield changes depending on differences in the convexity of the bonds.

Second, it is difficult to determine the interest rate sensitivity of a portfolio of bonds when there is a change in interest rates and the yield curve experiences a nonparallel shift. It was noted earlier that the duration of a portfolio is the weighted average of the durations of the bonds in the portfolio. Everything works well as long as all yields change by the same amount—that is, there is a parallel shift of the yield curve. However, when yields change, the yield curve seldom experiences a parallel shift. Assuming a nonparallel shift, which yield do you use to describe the change— the short-, intermediate-, or long-maturity yield? Two portfolios that begin the period with the same duration can have different ending durations and perform very differently, depending on how the yield curve changed (i.e., did it steepen or flatten?) and the composition of the portfolio (i.e., relative to its duration, was it a bullet or a barbell?). Consider the following simple example for two portfolios that have a duration of 4.50 years:

<table>
<thead>
<tr>
<th>Bond</th>
<th>Coupon</th>
<th>Maturity (Years)</th>
<th>Yield</th>
<th>Modified Duration</th>
<th>Weights</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>7.00</td>
<td>4</td>
<td>7.00</td>
<td>2.70</td>
<td>0.555</td>
</tr>
<tr>
<td>B</td>
<td>9.00</td>
<td>20</td>
<td>9.00</td>
<td>6.75</td>
<td>0.445</td>
</tr>
<tr>
<td>C</td>
<td>8.00</td>
<td>10</td>
<td>8.00</td>
<td>4.50</td>
<td>1.000</td>
</tr>
</tbody>
</table>

As shown, the modified durations are equal at the initiation of the portfolio. Assume a nonparallel change in yields where the yield curve steepens. Specifically, 4-year yields decline to 6 percent, 10-year yields do not change, and 20-year yields rise to 10 percent. Portfolio B would experience a very small change in value because of stability in yield for 10-year bonds. In contrast, the price for 4-year bonds will experience a small increase (because of small duration), and the value of 20-year bonds will experience a large decline. Overall, the value of Portfolio A will decline because of the weight of Bond B in the portfolio and its large decline in value due to its large modified duration. Obviously, if the yield curve had flattened or inverted, the barbell portfolio would have benefited from the change. This differential performance because of the change in the shape of the yield curve (i.e., it did not experience a parallel shift) is referred to as yield curve risk, which cannot be captured by the traditional duration-convexity presentation.

The third limitation of Macaulay and modified durations involves our initial calculation. We assumed that cash flows from the bond were not affected by yield changes—that is, we assumed option-free bonds. Later, we saw the effect on the computed duration and convexity when we considered the effect of an embedded call option in Exhibit 18.24. Specifically, we saw that the option-adjusted duration would be some value between the duration to maturity and duration to first call and the specific value would depend on the current market yield relative to the bond’s coupon. Further, we saw that when interest rates declined with an embedded call option, the convexity of the bond went from some positive value to negative convexity because the price of the callable bond increased at a slower rate or it did not change when the yields declined (i.e., there is price compression).

Because of these limitations, practitioners have developed a way to approximate the duration of a bond or any security that can be impacted by a change in interest rates. This is referred to as effective duration, which is discussed in the following section.

**Effective Duration**

As noted previously, the purpose of duration is to indicate the price change of an asset to a change in yield—that is, it is a measure of the interest rate sensitivity of an asset. Because modified duration is based on Macaulay duration, it can provide a 18 This section benefited substantially from the thorough presentation in Fabozzi, Buetow, and Johnson (2012).

**Convexity of Callable Bonds** Exhibit 18.24 shows what happens to the price of a callable bond versus the value of a noncallable bond when interest rates increase or decline. Starting from yield \( y^* \) (which is close to the par value yield), if interest rates increase, the value of the call option declines because at market interest rates that are substantially above the coupon rate, it is unlikely the issuer will want to call the issue. Therefore, the call option has very little value, and the price of the callable bond will be similar to the price of a noncallable bond. In contrast, when interest rates decline below \( y^* \), there is an increase in the probability that the issuer will want to use the call option—that is, the value of the call option increases. As a result, the value of the callable bond will deviate from the value of the noncallable bond—that is, the price of the callable bond will initially not increase as fast as the noncallable bond price and eventually will not increase at all. This is what is shown in curve a-b.

In the case of the noncallable bond, we indicated that it had positive convexity because as yields declined, the price of the bond increased at a faster rate. With the callable bond, when rates decline, the price increases at a slower rate and eventually does not change at all. This pattern of price-yield change for a callable bond when yields decline is referred to as negative convexity.

Needless to say, this price pattern (negative convexity) is one of the risks of a callable bond versus a noncallable bond when interest rates decline.

**18.8.6 Limitations of Macaulay and Modified Duration**

It is important to understand Macaulay and modified duration because of the perspective they provide regarding factors that affect the volatility and interest rate sensitivity of bonds. However, it also is important for bond analysts and portfolio managers to recognize the serious limitations of these measures in the real world. The major limitations are as follows.

---

**Exhibit 18.24 Noncallable and Callable Bond Price-Yield Relationship**

![Graph showing price-yield relationship for noncallable and callable bonds.]

First, as noted in the discussion on convexity, the percent change estimates using modified duration are good only for small-yield changes. This was demonstrated in Exhibit 18.21. As a result, two bonds with equal duration may experience different price changes for large-yield changes—depending on differences in the convexity of the bonds.

Second, it is difficult to determine the interest rate sensitivity of a portfolio of bonds when there is a change in interest rates and the yield curve experiences a nonparallel shift. It was noted earlier that the duration of a portfolio is the weighted average of the durations of the bonds in the portfolio. Everything works well as long as all yields change by the same amount—that is, there is a parallel shift of the yield curve. However, when yields change, the yield curve seldom experiences a parallel shift. Assuming a nonparallel shift, which yield do you use to describe the change—the short-, intermediate-, or long-maturity yield? Two portfolios that begin the period with the same duration can have different ending durations and perform very differently, depending on how the yield curve changed (i.e., did it steepen or flatten?) and the composition of the portfolio (i.e., relative to its duration, was it a bullet or a barbell?). Consider the following simple example for two portfolios that have a duration of 4.50 years:

<table>
<thead>
<tr>
<th>Bond</th>
<th>Coupon</th>
<th>Maturity (Years)</th>
<th>Yield</th>
<th>Modified Duration</th>
<th>Weights</th>
</tr>
</thead>
<tbody>
<tr>
<td>Portfolio A</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>A</td>
<td>7.00</td>
<td>4</td>
<td>7.00</td>
<td>2.70</td>
<td>0.555</td>
</tr>
<tr>
<td>B</td>
<td>9.00</td>
<td>20</td>
<td>9.00</td>
<td>6.75</td>
<td>0.445</td>
</tr>
<tr>
<td>Portfolio B</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>C</td>
<td>8.00</td>
<td>10</td>
<td>8.00</td>
<td>4.50</td>
<td>1.000</td>
</tr>
</tbody>
</table>

As shown, the modified durations are equal at the initiation of the portfolio. Assume a nonparallel change in yields where the yield curve steepens. Specifically, 4-year yields decline to 6 percent, 10-year yields do not change, and 20-year yields rise to 10 percent. Portfolio B would experience a very small change in value because of stability in yield for 10-year bonds. In contrast, the price for 4-year bonds will experience a small increase (because of small duration), and the value of 20-year bonds will experience a large decline. Overall, the value of Portfolio A will decline because of the weight of Bond B in the portfolio and its large decline in value due to its large modified duration. Obviously, if the yield curve had flattened or inverted, the barbell portfolio would have benefited from the change. This differential performance because of the change in the shape of the yield curve (i.e., it did not experience a parallel shift) is referred to as yield curve risk, which cannot be captured by the traditional duration-convexity presentation.

The third limitation of Macaulay and modified durations involves our initial calculation. We assumed that cash flows from the bond were not affected by yield changes—that is, we assumed option-free bonds. Later, we saw the effect on the computed duration and convexity when we considered the effect of an embedded call option in Exhibit 18.24. Specifically, we saw that the option-adjusted duration would be some value between the duration to maturity and duration to first call and the specific value would depend on the current market yield relative to the bond’s coupon. Further, we saw that when interest rates declined with an embedded call option, the convexity of the bond went from some positive value to negative convexity because the price of the callable bond increased at a slower rate or it did not change when the yields declined (i.e., there is price compression).

Because of these limitations, practitioners have developed a way to approximate the duration of a bond or any security that can be impacted by a change in interest rates. This is referred to as effective duration, which is discussed in the following section.

**Effective Duration**

As noted previously, the purpose of duration is to indicate the price change of an asset to a change in yield—that is, it is a measure of the interest rate sensitivity of an asset. Because modified duration is based on Macaulay duration, it can provide a...

---

18This section benefited substantially from the thorough presentation in Fabozzi, Buetow, and Johnson (2012).
reasonable approximation of the interest rate sensitivity of a bond that experiences a small-
yield change and one that is option-free—if yield changes do not change the cash flows for
the bond. Unfortunately, the Macaulay and modified-duration measures cannot be used for:
(1) large-yield changes, (2) assets with embedded options, or (3) assets that are affected by
variables other than interest rates, such as common stocks or real estate.

To overcome these limitations, practitioners use effective duration, a direct measure of the
interest rate sensitivity of a bond or any asset assuming that there is a pricing model available to
estimate the market prices given a change in interest rates. As we will demonstrate, using this
measure it is possible to derive negative durations (which is not mathematically possible with
Macaulay) or durations that are longer than the maturity of the asset (likewise not possible
with Macaulay). Specifically, effective duration measures the interest rate sensitivity of a bond
taking into consideration that the cash flows of the bond can change when yields change due
to the existence of embedded options (e.g., call or put options). It is also possible to calculate
the effective duration for an option-free bond, in which case the computed duration value will
be equal to what would be derived for small-yield changes using modified duration. Put another
way, for an option-free bond the effective duration would equal the modified duration.

Notably, to implement the effective duration formula, it is necessary to use an interest rate
model and a corresponding pricing model that will provide price estimates for the asset when
interest rates and cash flows change. The formulas for calculating effective duration and effective
convexity are:

\[
\text{Effective Duration } (D_{eff}) = \frac{(P_+) - (P_-)}{2PS}
\]

\[
\text{Effective Convexity } (C_{eff}) = \frac{(P_+) - (P_-) - 2P}{PS^2}
\]

where:

\(P_\) = the estimated price of the asset after a downward shift in interest rates
\(P_+\) = the estimated price of the asset after an upward shift in interest rates
\(P\) = the current price of the asset (before any interest rate shifts)
\(S\) = the assumed shift in the term structure

The formulas are implemented by assuming small changes in yield (e.g., 10 basis points) both
down and up and using a pricing model to estimate the expected market prices (both \(P_-\) and
\(P_+\)) at the new yields. Everything else in the formulas is given. Consider the following bond
that we will initially assume is option free:

<table>
<thead>
<tr>
<th>Description</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Par value</td>
<td>$1,000</td>
</tr>
<tr>
<td>Coupon</td>
<td>6%</td>
</tr>
<tr>
<td>Maturity</td>
<td>8 years</td>
</tr>
<tr>
<td>Initial YTM</td>
<td>6%</td>
</tr>
<tr>
<td>Initial price (P)</td>
<td>100</td>
</tr>
</tbody>
</table>

Given this initial scenario, we assume a change in yields of 10 basis points. The prices for the
bond at yields to maturity of 5.90 percent (\(P_-\)) and 6.10 percent (\(P_+\)) are:

\[0.0590(P_-) = 100.42760054\]
\[0.0610(P_+) = 99.57457612\]

\[(P_-) - (P_+) = 0.85302442\]
\[2PS = (2)(100)(0.001) = 0.20\]
\[D_{eff} = \frac{0.85302442}{0.20} = 4.265122\]
In this instance, the investor owns the option that allows him or her to sell the bond back to the issuer at a stated price. This option has a positive impact on the value of the bond, and this option increases in value when interest rates increase. Therefore, when rates increase, the price of the bond does not decline as much as an option-free bond, but when rates decline, its price pattern is similar to that of an option-free bond because the value of the put option approaches zero.

A visual presentation of the effect of the call option on the price-yield curve was contained in Exhibit 18.24. Alternatively, Exhibit 18.25 and Exhibit 18.26 contain the effective duration-yield curves and the effective convexity-yield curves, which show the significant impact of embedded options on the effective duration and effective convexity of fixed-income securities.

Effective Duration Greater than Maturity

Because effective duration is simply interest rate sensitivity, it is possible to have an asset that is highly levered such that its interest rate sensitivity exceeds its maturity. For example, there are five-year, collateralized mortgage obligations (CMOs) that are highly levered, and their prices will change by 15 percent to 20 percent when interest rates change by 100 basis points. Using the formula discussed (Equation 18.22), you would compute an effective duration of 15 or 20 for this five-year maturity security.

Negative Effective Duration

We know from the formula for Macaulay duration that it is not possible to compute a negative duration. Further, in the calculation for price volatility where we use $-D_{mod}$ to reflect the negative relationship between price changes and interest rate changes for option-free bonds. At the same time, we know that when we leave the world of option-free bonds and consider bonds with embedded options, it is possible to envision cases where bond prices move in the same direction as yields, which implies negative duration. A prime example would be mortgage-backed securities where a significant decline in interest rates will cause a substantial increase in refinancing prepayments by homeowners, which will reduce the value of these bonds to holders. Therefore, you would see a decline in interest rates and ad e -cline in the price of these mortgage-backed bonds, which implies negative duration. Another way to explain a price decline with lower interest rates is the value formula (Equation 18.20)—that is, with lower interest rates, the value of the call option increases in value by more than the increase in value of the noncallable bond, which causes a decline in the value of the callable bond.

Empirical Duration

In the preceding discussion of effective duration, the point was made that these computations required the use of an interest rate model and a bond pricing model that considered cash flow changes when yields changed and generated market price estimates that were inputs into the effective duration and effective convexity formulas. The question arises regarding what happens when you want to estimate interest rate sensitivity for an asset class where it is not possible to generate well-specified market price estimates in response to yield changes. The classic example would be common stocks where there is an impact on price when interest rates change, but the interest rate effect can be overpowered by the growth rate effect that is likewise unknown. The other obvious example would be bonds with exotic embedded options (including mortgage-backed bonds) where prices can change based upon the value of the exotic option that is difficult to price. In order to derive some estimate of interest rate sensitivity under such circumstances, analysts and portfolio managers employ empirical duration, which is the actual percentage price change for an asset in response to a change in yield during a specified historical time period. The concept is best described by recalling the formula in Equation 18.14 used to determine the percentage price change for a bond using modified duration as follows:

$$\% \Delta Price = -D_{mod} \times \frac{\Delta i}{100}$$

where:

- $D_{mod}$ = the modified Macaulay duration
- $\Delta i$ = the change in interest rates in basis points divided by 100

As expected, because of the embedded call option that would have increased in value with a decline in yields, this duration value (2.92) would be lower than the duration for the option-free bond discussed earlier (4.34). In contrast, the effective durations for callable bonds at higher yields (e.g., 8 percent) would be equal to the durations for option-free bonds because the value of the option approaches zero.

The effective convexity of this callable bond at 4 percent would be:

$$C_{eff} = \frac{108.55626094 + 107.92318176 - [2(108.24082177)]}{(108.24082177)(0.001)^2}$$

$$= -20.33$$

As discussed, this is an example of negative convexity because the price increase is limited due to the increasing value of the call option. For comparison purposes, the convexity of the option-free bond at 4 percent is 23.76, which is, as expected, slightly higher than its convexity of 21.77 at 6 percent (recall that both duration and convexity are inversely related to yield).

**Putable Bonds** Although it is not feasible to discuss in detail the properties of bonds with put options (putable bonds), it is possible to envision the effects if one considers the basic value of a putable bond as follows:

**18.24 Value of putable bond = Value of nonputable bond + value of the put option**
In this instance, the investor owns the option that allows him or her to sell the bond back to the issuer at a stated price. This option has a positive impact on the value of the bond, and this option increases in value when interest rates increase. Therefore, when rates increase, the price of the bond does not decline as much as an option-free bond, but when rates decline, its price pattern is similar to that of an option-free bond because the value of the put option approaches zero.

A visual presentation of the effect of the call option on the price-yield curve was contained in Exhibit 18.24. Alternatively, Exhibit 18.25 and Exhibit 18.26 contain the effective duration-yield curves and the effective convexity-yield curves, which show the significant impact of embedded options on the effective duration and effective convexity of fixed-income securities.

**Effective Duration Greater than Maturity** Because effective duration is simply interest rate sensitivity, it is possible to have an asset that is highly levered such that its interest rate sensitivity exceeds its maturity. For example, there are five-year, collateralized mortgage obligations (CMOs) that are highly levered, and their prices will change by 15 percent to 20 percent when interest rates change by 100 basis points. Using the formula discussed (Equation 18.22), you would compute an effective duration of 15 or 20 for this five-year maturity security.

**Negative Effective Duration** We know from the formula for Macaulay duration that it is not possible to compute a negative duration. Further, in the calculation for price volatility where we use modified duration, we use $-D^*$ to reflect the negative relationship between price changes and interest rate changes for option-free bonds. At the same time, we know that when we leave the world of option-free bonds and consider bonds with embedded options, it is possible to envision cases where bond prices move in the same direction as yields, which implies negative duration. A prime example would be mortgage-backed securities where a significant decline in interest rates will cause a substantial increase in refinancing prepayments by homeowners, which will reduce the value of these bonds to holders. Therefore, you would see a decline in interest rates and a decline in the price of these mortgage-backed bonds, which implies negative duration. Another way to explain a price decline with lower interest rates is the value formula (Equation 18.20)—that is, with lower interest rates, the value of the call option increases in value by more than the increase in value of the noncallable bond, which causes a decline in the value of the callable bond.

**Empirical Duration** In the preceding discussion of effective duration, the point was made that these computations required the use of an interest rate model and a bond pricing model that considered cash flow changes when yields changed and generated market price estimates that were inputs into the effective duration and effective convexity formulas. The question arises regarding what happens when you want to estimate interest rate sensitivity for an asset class where it is not possible to generate well-specified market price estimates in response to yield changes. The classic example would be common stocks where there is an impact on price when interest rates change, but the interest rate effect can be overpowered by the growth rate effect that is likewise unknown. The other obvious example would be bonds with exotic embedded options (including mortgage-backed bonds) where prices can change based upon the value of the exotic option that is difficult to price. In order to derive some estimate of interest rate sensitivity under such circumstances, analysts and portfolio managers employ empirical duration, which is the actual percentage price change for an asset in response to a change in yield during a specified historical time period. The concept is best described by recalling the formula in Equation 18.14 used to determine the percentage price change for a bond using modified duration as follows:

$$\% \Delta \text{Price} = -D_{mod} \times (\Delta i)$$

where:

$D_{mod}$ = the modified Macaulay duration

$\Delta i$ = the change in interest rates in basis points divided by 100

---

19The discussion in this section considered the analysis in Hayre and Chang (1997).
Exhibit 18.25 Effective Duration-Yield Curves

A. Effective Duration-Yield Curve for 8-Year, 6% Option-Free Bond

B. Effective Duration-Yield Curve for 8-Year, 6% Callable Bond after 3 Years

C. Effective Duration-Yield Curve for 8-Year, 6% Putable Bond after 3 Years
The typical assumption is that we know $D_{\text{mod}}$ and $\Delta_i$ and can solve for the approximate percentage price change. Alternatively, given this relationship, we can solve for $D_{\text{mod}}$ as follows:

$$18.25 - D_{\text{mod}} = \% \Delta \text{Price} \Delta_i$$

When we solve for it this way, it is no longer $D_{\text{mod}}$ (modified duration), but $D_{\text{emp}}$ — empirical duration. Given this formulation, if you observe a change in interest rates ($\Delta_i$) and the change in the price of an asset during the same time period, you can solve for the empirical duration of the asset. Consider the following simple example:

1. Interest rates decline by 200 BP.
2. The price of a bond increases by 10 percent.

$$D_{\text{emp}} = \frac{-10 - 200}{2} = 5$$

Therefore, the change in price coincident with a change in interest rates indicates that this bond has an empirical duration ($D_{\text{emp}}$) of 5. This is a direct measure of the bond’s interest rate sensitivity. You should think of it as the approximate percentage change in price for a 100-basis-point change in interest rates.

While this simple example indicates the concept of empirical duration, the technique that is generally suggested for estimating empirical duration is to employ the following regression model:

$$18.26 \Delta P = \alpha + D_{\text{**}} \Delta Y + u$$

where:

$\Delta P$ = percentage change in price

$\alpha$ = constant term

$D_{\text{**}}$ = an estimate of $D_{\text{emp}}$ (empirical duration)

$\Delta Y$ = change in yield in basis points

$u$ = random error term

The time interval for the data and the time period considered can vary based upon the asset and purpose of the analysis. When working with bonds, some analysts employ daily data for short time periods (months), while investigators using the concept for stocks or real estate (to be discussed) have employed weekly and monthly data for longer time periods (quarters or years).

Empirical Duration for Common Stock

If one considers the Macaulay duration of common stock, it is possible to envision a fairly high number because you are dealing with a perpetuity, and some growth stocks pay low dividends for many years. The values derived by Reilly and Sidhu (1980), using various assumptions of price and growth, ranged from 10 years to 20 years. In contrast, using empirical duration, one gets very different results. Because we are dealing with the interest rate sensitivity of an asset, it is possible to compute an empirical duration for common stock that is much lower than what is implied by Macaulay duration and it is more variable. Observing a change in interest rates and the accompanying percentage change in stock prices would indicate the interest rate sensitivity of stocks. Leibowitz (1987) conducted such an analysis and derived a rolling, one-year effective duration for the S&P 500 that ranged from about zero to almost seven. When measuring the interest rate sensitivity of aggregate common stocks over time, you would expect changes because, as demonstrated by Reilly, Wright, and Chan (2000), the correlation between stock and bond returns...
The typical assumption is that we know $D_{mod}$ and $\Delta i$ and can solve for the approximate percentage price change. Alternatively, given this relationship, we can solve for $D_{mod}$ as follows:

$$D_{mod} = \frac{\%\Delta \text{ Price}}{\Delta i}$$

When we solve for it this way, it is no longer $D_{mod}$ (modified duration), but $D_{emp}$—empirical duration. Given this formulation, if you observe a change in interest rates ($\Delta i$) and the change in the price of an asset during the same time period, you can solve for the empirical duration of the asset. Consider the following simple example:

- Interest rates decline by 200 BP.
- The price of a bond increases by 10 percent.

$$D_{emp} = -\frac{10}{-200/100} = -\frac{10}{-2} = 5$$

Therefore, the change in price coincident with a change in interest rates indicates that this bond has an empirical duration ($D_{emp}$) of 5. This is a direct measure of the bond’s interest rate sensitivity. You should think of it as the approximate percentage change in price for a 100-basis-point change in interest rates.

While this simple example indicates the concept of empirical duration, the technique that is generally suggested for estimating empirical duration is to employ the following regression model:

$$\frac{\Delta P}{P} = \alpha + D^{**} \Delta Y + u$$

where:

- $\frac{\Delta P}{P}$ = percentage change in price
- $\alpha$ = constant term
- $D^{**}$ = an estimate of $D_{emp}$ (empirical duration)
- $\Delta Y$ = change in yield in basis points
- $u$ = random error term

The time interval for the data and the time period considered can vary based upon the asset and purpose of the analysis. When working with bonds, some analysts employ daily data for short time periods (months), while investigators using the concept for stocks or real estate (to be discussed) have employed weekly and monthly data for longer time periods (quarters or years).

**Empirical Duration for Common Stock** If one considers the Macaulay duration of common stock, it is possible to envision a fairly high number because you are dealing with a perpetuity, and some growth stocks pay low dividends for many years. The values derived by Reilly and Sidhu (1980), using various assumptions of price and growth, ranged from 10 years to 20 years. In contrast, using empirical duration, one gets very different results.

Because we are dealing with the interest rate sensitivity of an asset, it is possible to compute an empirical duration for common stock that is much lower than what is implied by Macaulay duration and it is more variable. Observing a change in interest rates and the accompanying percentage change in stock prices would indicate the interest rate sensitivity of stocks. Leibowitz (1987) conducted such an analysis and derived a rolling, one-year effective duration for the S&P 500 that ranged from about zero to almost seven. When measuring the interest rate sensitivity of aggregate common stocks over time, you would expect changes because, as demonstrated by Reilly, Wright, and Chan (2000), the correlation between stock and bond returns...
varies substantially over time. In addition, you might anticipate significant differences in the effective duration for alternative stocks. For example, you would expect a large difference in the interest rate sensitivity (empirical duration) of a banking or utility stock (which is very interest rate sensitive) compared to the empirical duration of a small-cap or technology stock, where its value is based more on changes in its specific growth expectations than interest rates. These differences in the interest rate sensitivity of common stocks are documented in Reilly, Wright, and Johnson (2007).

### 18.9 Yield Spreads with Embedded Options

Earlier in the chapter, we discussed the analysis of yield spread as a technique to enhance bond investments or bond trades. At this point, it is necessary to revisit the concept of yield spreads, keeping in mind the term structure of interest rates but, more important, with an awareness of the significant impact that interest rate volatility has on the value of embedded options in bonds. In this revisitation, we will consider two spreads: (1) **static yield spreads** that consider the total term structure, and (2) **option-adjusted spreads (OAS)** that consider changes in the term structure and alternative estimates of the volatility of interest rates.

#### 18.9.1 Static Yield Spreads

You will recall that the traditional yield spread compares the yields between two bonds with similar coupons and equal maturities as follows:

<table>
<thead>
<tr>
<th>8%—20-Year AA Corporate Bond</th>
<th>8.20%</th>
</tr>
</thead>
<tbody>
<tr>
<td>8%—20-Year Treasury Bond</td>
<td>7.10%</td>
</tr>
<tr>
<td>Yield Spread</td>
<td>110 bp</td>
</tr>
</tbody>
</table>

There are three problems with this “traditional” yield spread:

- The two yields do not consider the prevailing term structures of interest rates but only consider the yield spread at the one point on the curve (at 20 years).
- The analysis does not consider the fact that the corporate bond could have an embedded option (put or call), whereby expected interest rate volatility may alter the cash flow for this bond.
- While not true in this example, it is possible that investors would compare two bonds with equal maturities but different coupon cash flow (e.g., a zero coupon bond versus a coupon bond or a 12 percent coupon versus a 4 percent coupon).

The first concern (neglect of the term structure) suggests the consideration of the **static yield spread**. It is contended that the proper way to compare non-Treasury bonds of the same maturity but with different coupon rates is to compare them to a portfolio of Treasury securities that have the same cash flow. The way to do this, if there is not an existing Treasury bond with the specified flows, is to discount the corporate bond’s cash flow as if the flows were risk free. Specifically, discount them using the prevailing Treasury spot rates for the life of the corporate bond. Consider the following example:

**Corporate bond—8%, 5-year bond**

If we discount this bond’s flows using the hypothetical Treasury spot rate curve contained in Exhibit 18.27, the price would be $1,040.56, which is what this bond would sell at if it were a Treasury bond. In fact, the bond is priced at $1,006.70. The question is, what is the spread that must be added to all maturities of the Treasury spot rate curve that will reduce the value of the bond from $1,040.56 to $1,006.70? Therefore, the **static spread** (also called the **zero volatility**
The goal of the OAS is similar to the static spread, except that the technique allows for a change in the term structure over time based on alternative estimates of interest rate volatility. The concept of OAS is best understood by a presentation of the steps involved in estimating the OAS for a specific bond, as follows:

1. Based upon the prevailing Treasury yield curve, estimate the term structure of interest rates (i.e., the prevailing Treasury spot rate curve) and the implied short-term forward rates derived from the spot rates.

2. Select a probability distribution for short-term Treasury spot rates. This should be based on the current term structure and the historical behavior of interest rates. The significant estimate is the volatility of interest rates (i.e., the standard deviation of yields)—that is, how much will the forward rates change each period?

3. Using the probability distribution specified in Step 2 and Monte Carlo simulation, it is possible to randomly generate a large number of interest rate paths (e.g., 1,000).

4. For bonds with embedded options (such as callable bonds), develop rules for determining when the option will be exercised. For example, given the coupon, maturity, and call option, at what interest rate will the issue be called?

5. For each interest rate path generated in Step 3, determine the cash flows from the bond, given (a) the information about the bond (i.e., its call provision), and (b) the rules established in Step 4 for calling the bond.

6. For an assumed spread relative to the Treasury term structure of spot rates along a path, calculate a present value for all paths created in Step 3.

7. Calculate the average present value for all the interest rate paths.

8. Compare the average present value calculated in Step 7 to the market price of the bond. If they are equal, the assumed spread used in Step 6 is the option-adjusted spread. If they are not, try another spread and repeat Steps 6, 7, and 8.

The computed option-adjusted spread (OAS) is the average spread over the Treasury spot rate curve based on the potential paths that can be realized in the future for interest rates. The reason it is referred to as “option adjusted” is because the potential paths of cash flow are adjusted to reflect the effect of the options embedded in the bonds. Therefore, this option-adjusted spread (OAS) is the spread after taking account of the spread required by the embedded option, and, therefore, this OAS can be compared to a spread for an option-free bond. For example, the nominal spread for a callable corporate bond may be 300 basis points (3.00 percent) and look desirable relative to a noncallable corporate with a spread of only 125 basis points (1.25 percent). The fact is, the OAS for this callable bond might be only 140 basis points (which implies that the required extra yield for the embedded call option is 160 basis points). It is this 140 BP (1.40 percent) that needs to be compared to the 125 BP for the noncallable corporate bond.

The following are some technical issues that an analyst should be aware of when attempting to estimate the OAS and also factors that can cause differences in an estimate of the OAS for a bond by alternative dealers:

- It is necessary to have a large number of paths for the simulation.
- The estimate of the probability distribution, which includes your expected interest rate volatility, is crucial. Notably, if alternative firms differ in this estimate of expected interest rate volatility, it can cause differences in the OAS estimate.
- It is necessary to determine the relationship between short-term rates and refinancing rates. Specifically, how much more does the firm have to pay above the short-term forward rate (i.e., the refinancing rate is a long-term rate)? Empirically, what is this relationship?
- A call rule must be specified. This depends upon the coupon rate for the bond and other costs. It has been assumed to be almost 300 BP below the coupon rate (e.g., 5.0 percent with at least three years to maturity).

18.9.2 Option-Adjusted Spread

As noted, the traditional spread was a problem because it did not consider the full-term structure or the impact of interest rate volatility. The term structure problem was addressed by estimating the static (zero volatility) spread.

The interest rate volatility factor is considered by the option-adjusted spread (OAS) analysis. Why is interest rate volatility a problem? The point is, as discussed earlier in the chapter, if a bond has an embedded call option, this option can affect the bond’s expected cash flow. The likelihood of the call being exercised will depend on future interest rates, the remaining maturity of the bond, the call price, and other costs of a call and new issue.

Present Value $1,006.70
The goal of the OAS is similar to the static spread, except that the technique allows for a change in the term structure over time based on alternative estimates of interest rate volatility.

The concept of OAS is best understood by a presentation of the steps involved in estimating the OAS for a specific bond, as follows:

1. Based upon the prevailing Treasury yield curve, estimate the term structure of interest rates (i.e., the prevailing Treasury spot rate curve) and the implied short-term forward rates derived from the spot rates.
2. Select a probability distribution for short-term Treasury spot rates. This should be based on the current term structure and the historical behavior of interest rates. The significant estimate is the volatility of interest rates (i.e., the standard deviation of yields)—that is, how much will the forward rates change each period?
3. Using the probability distribution specified in Step 2 and Monte Carlo simulation, it is possible to randomly generate a large number of interest rate paths (e.g., 1,000).
4. For bonds with embedded options (such as callable bonds), develop rules for determining when the option will be exercised. For example, given the coupon, maturity, and call option, at what interest rate will the issue be called?
5. For each interest rate path generated in Step 3, determine the cash flows from the bond, given (a) the information about the bond (i.e., its call provision), and (b) the rules established in Step 4 for calling the bond.
6. For an assumed spread relative to the Treasury term structure of spot rates along a path, calculate a present value for all paths created in Step 3.
7. Calculate the average present value for all the interest rate paths.
8. Compare the average present value calculated in Step 7 to the market price of the bond. If they are equal, the assumed spread used in Step 6 is the option-adjusted spread. If they are not, try another spread and repeat Steps 6, 7, and 8.

The computed option-adjusted spread (OAS) is the average spread over the Treasury spot rate curve based on the potential paths that can be realized in the future for interest rates. The reason it is referred to as “option adjusted” is because the potential paths of cash flow are adjusted to reflect the effect of the options embedded in the bonds. Therefore, this option-adjusted spread (OAS) is the spread after taking account of the spread required by the embedded option and, therefore, this OAS can be compared to a spread for an option-free bond. For example, the nominal spread for a callable corporate bond may be 300 basis points (3.00 percent) and look desirable relative to a noncallable corporate with a spread of only 125 basis points (1.25 percent). The fact is, the OAS for this callable bond might be only 140 basis points (which implies that the required extra yield for the embedded call option is 160 basis points). It is this 140 BP (1.40 percent) that needs to be compared to the 125 BP for the noncallable corporate bond.

The following are some technical issues that an analyst should be aware of when attempting to estimate the OAS and also factors that can cause differences in an estimate of the OAS for a bond by alternative dealers:

• It is necessary to have a large number of paths for the simulation.
• The estimate of the probability distribution, which includes your expected interest rate volatility, is crucial. Notably, if alternative firms differ in this estimate of expected interest rate volatility, it can cause differences in the OAS estimate.
• It is necessary to determine the relationship between short-term rates and refinancing rates. Specifically, how much more does the firm have to pay above the short-term forward rate (i.e., the refinancing rate is a long-term rate)? Empirically, what is this relationship?
• A call rule must be specified. This depends upon the coupon rate for the bond and other costs. It has been assumed to be almost 300 BP below the coupon rate (e.g., 5.0 percent with at least three years to maturity).
As noted, different assumptions regarding these technical issues can cause different estimates of the OAS by alternative dealers. The critical estimate is the expected interest rate volatility, and this can vary between dealers; also, individual dealers can change their estimates over time.

**SUMMARY**

- The value of a bond equals the present value of all future cash flows accruing to the investor. Cash flows for the conservative buy-and-hold bond investor include periodic interest payments and principal return; cash flows for the aggressive investor include periodic interest payments and the capital gain or loss when the bond is sold prior to its maturity. Bond investors can maximize their portfolio rates of return by accurately estimating the level of interest rates and, more importantly, by estimating changes in interest rates, yield spreads, and credit quality. Similarly, they must compare coupon rates, maturities, and call features of alternative bonds.

- There are five bond yield measures: nominal yield, current yield, promised yield to maturity, promised yield to call, and realized (horizon) yield. The promised YTM and promised YTC equations include the interest-on-interest (or coupon reinvestment) assumption. For the realized (horizon) yield computation, the investor must estimate the reinvestment rate and the future selling price for the bond. The fundamental determinants of interest rates are a real risk-free rate, the expected rate of inflation, and a risk premium.

- The yield curve (or the term structure of interest rates) shows the relationship between the yields on a set of comparable bonds and the term to maturity. Based upon this yield curve, it is possible to derive a theoretical spot rate curve. In turn, these spot rates can be used to value bonds using an individual spot rate for each cash flow. This valuation approach is becoming more useful in a world where bonds have very different cash flows. In addition, these spot rates imply investor expectations about future rates, referred to as forward rates. Yield curves exhibit four basic patterns. Three theories attempt to explain the shape of the yield curve: the expectations hypothesis, the liquidity preference (term premium) hypothesis, and the segmented market (preferred habitat) hypothesis.

- It is important to understand what causes changes in interest rates and how these changes in rates affect the prices of bonds. Differences in bond price volatility are mainly a function of differences in yield, coupon, and term to maturity. There are four duration measures that have been used as measures of bond price volatility or interest rate sensitivity. The Macaulay duration measure incorporates coupon, maturity, and yield to maturity. In turn, modified duration (which is directly related to Macaulay duration) provides an estimate of the response of bond prices to changes in interest rates under certain assumptions. Because modified duration provides a straight-line estimate of the curvilinear price-yield function, you must consider modified duration together with the convexity of a bond for large changes in yields and/or when dealing with securities that have high convexity. Notably, an embedded call option feature on a bond can have a significant impact on its duration (the call feature can shorten it dramatically) and on its convexity (the call feature can change the convexity from a positive value to a negative value). Following a discussion of some of the limitations of Macaulay and modified durations as measures of interest rate sensitivity, effective duration is introduced as a direct measure of interest rate sensitivity—that is, it is the estimated percentage change in price for a 100-basis-point change in interest rates and allows for the repricing of bonds due to changes in cash flow caused by changes in interest rates. Notably, with effective duration, it is necessary to have a valid bond pricing model and it is possible to have effective durations longer than maturity as well as negative duration.

- Finally, there are instances when it is very difficult to estimate the price of some bonds or other assets when there is a change in interest rates as required for effective duration (e.g., some mortgage-backed securities, common stock, and real estate). In these instances, analysts consider estimating empirical duration, which is based on the analysis of historical data on price changes that accompany interest rate changes. While it is possible to derive such estimates for a range of assets, it is important to remember that the empirical duration values derived can vary dramatically and are notoriously unstable.

- We concluded the chapter by revisiting yield spreads for bonds with embedded options. To take
account of the spread across the total term structure of interest rates, we described and demonstrated the static spread. In order to consider the impact of interest rate volatility on the embedded options, we discussed and described the steps to estimate the option-adjusted spread (OAS) for these bonds.

- Given the background in bond valuation and the factors that influence bond value and bond return volatility, we are ready to consider how to build a bond portfolio that is consistent with our goals and objectives. Bond portfolio analysis is the topic of Chapter 19.

**SUGGESTED READINGS**

**QUESTIONS**

1. Why does the present value equation appear to be more useful for the bond investor than for the common stock investor?
2. What are the important assumptions made when you calculate the promised yield to maturity? What are the assumptions when calculating promised YTC?
3. a. Define the variables included in the following model:
   \[ i = (RFR, I, RP) \]
   b. Assume that the firm whose bonds you are considering is not expected to break even this year. Discuss which factor in the model will be affected by this information.
4. We discussed three alternative hypotheses to explain the term structure of interest rates. Briefly discuss the three hypotheses, and indicate which one you think best explains the alternative shapes of a yield curve.
5. a. Explain what is meant by the term structure of interest rates. Explain the theoretical basis of an upward-sloping yield curve.
   b. Explain the economic circumstances under which you would expect to see an inverted yield curve.
   c. Define “real” rate of interest.
   d. Over the past several years, fairly wide yield spreads between AAA corporates and Treasuries have occasionally prevailed. Discuss the possible reasons for this.
6. As the portfolio manager for a large pension fund, you are offered the following bonds:

<table>
<thead>
<tr>
<th>Coupon</th>
<th>Maturity</th>
<th>Price</th>
<th>Call Price</th>
<th>Yield to Maturity</th>
</tr>
</thead>
<tbody>
<tr>
<td>Edgar Corp. (new issue) 14.00%</td>
<td>2012</td>
<td>$101.3/4</td>
<td>$114</td>
<td>13.75%</td>
</tr>
<tr>
<td>Edgar Corp. (new issue) 6.00%</td>
<td>2012</td>
<td>48.1/8</td>
<td>103</td>
<td>13.60</td>
</tr>
<tr>
<td>Edgar Corp. (2000 issue) 6.00%</td>
<td>2012</td>
<td>48.7/8</td>
<td>103</td>
<td>13.40</td>
</tr>
</tbody>
</table>

Assuming that you expect a decline in interest rates over the next three years, identify and justify which of these bonds you would select.
7. You expect interest rates to decline over the next six months.
   a. Given your interest rate outlook, state what kinds of bonds you want in your portfolio
      in terms of duration, and explain your reasoning for this choice.
   b. You must make a choice between the following three sets of noncallable bonds. For
      each set, select the bond that would be best for your portfolio, given your interest
      rate outlook and the consequent strategy set forth in Part a. In each case, briefly dis-
      cuss why you selected the bond.

<table>
<thead>
<tr>
<th>Maturity</th>
<th>Coupon</th>

<td>Noncallable</td>
</tr>
<tr>
<td></td>
<td>Deferred call features that</td>
</tr>
<tr>
<td></td>
<td>range from 1 to 3 years</td>
</tr>
</tbody>
</table>

Select one of the portfolios and discuss three factors that would justify your selection.

9. The Francesca Finance Corporation has issued a bond with the following characteristics:
   Maturity—25 years
   Coupon—9%
   Yield to maturity—9%
   Callable—after 3 years @ 109
   Duration to maturity—8.2 years
   Duration to first call—2.1 years

   a. Discuss the concept of call-adjusted duration, and indicate the approximate value
      (range) for it at the present time.
   b. Assuming interest rates increase substantially (i.e., to 13 percent), discuss what will
      happen to the call-adjusted duration and the reason for the change.
   c. Assuming interest rates decline substantially (i.e., they decline to 4 percent), discuss
      what will happen to the bond’s call-adjusted duration and the reason for the change.
   d. Discuss the concept of negative convexity as it relates to this bond.

10. *Option-adjusted duration and effective duration* are alternative measures used by analysts
    to evaluate fixed-income securities with embedded options. Briefly describe each
    measure, and how to apply each to the evaluation of fixed-income securities with embedded
    options.

11. A portfolio manager at Madison Trust Company is structuring a fixed-income portfolio
    to meet the objectives of a client. This client plans on retiring in 15 years and wants a
    substantial lump sum at that time. The client has specified the use of AAA-rated
    securities.
The portfolio manager compares coupon U.S. Treasuries with zero coupon stripped U.S. Treasuries and observes a significant yield advantage for the stripped bonds.

<table>
<thead>
<tr>
<th>Maturity</th>

</tbody>
</table>

Briefly discuss two reasons why zero coupon stripped U.S. Treasuries could yield more than coupon U.S. Treasuries with the same final maturity.

12. a. In terms of option theory, explain the impact on the offering yield of adding a call feature to a proposed bond issue.
   b. Explain the impact on both bond duration and convexity of adding a call feature to a proposed bond issue.
      Assume that a portfolio of corporate bonds is managed to maintain targets for modified duration and convexity.
   c. Explain how the portfolio could include both callable and noncallable bonds while maintaining the targets.
   d. Describe one advantage and one disadvantage of including callable bonds in this portfolio.

13. David Young, CFA, has decided to add some asset-backed securities (ABS) to his fixed-income portfolio. He has narrowed the choice to an automobile ABS and a fixed-rate home equity loan (second mortgage) ABS.
   Automobile ABS are available at a pricing spread of 75 basis points over comparable-maturity Treasuries, with a zero volatility spread of 67 basis points. Home equity loan ABS are available at a pricing spread of 85 basis points over comparable-maturity Treasuries, with an option-adjusted spread of 60 basis points.
   a. Explain why the traditional yield spread is not an appropriate measure of yield advantage for ABS.
   b. Describe the concepts of:
      (1) Zero volatility spread
      (2) Option-adjusted spread
   c. Explain why option-adjusted spread is the appropriate measure of yield for a second mortgage ABS.

14. The asset-backed securities (ABS) market has grown in the past few years partly as a result of credit enhancements to ABS.
   a. Describe a “letter of credit” and the risk to the investor associated with relying exclusively on this type of credit enhancement.
   b. Describe “early amortization” and the risk to the investor associated with relying exclusively on this type of credit enhancement.

15. Cara Kiley owns a newly issued U.S. government agency fixed-rate pass-through mortgage backed security (MBS) and wants to evaluate the sensitivity of its principal cash flow to the following interest rate scenario:
    - Interest rates instantaneously decline by 250 basis points for all maturities, remain there for one year, and then,
    - Interest rates instantaneously increase 350 basis points for all maturities and remain there for the next year.
Currently, the MBS is priced close to par and the yield curve is “flat.” Cara does not expect the shape of the yield curve to change during her interest rate scenario.

a. (1) State whether, in the interest rate scenario described, the MBS principal cash flows:
   • Increase or decrease in the first year
   • Increase or decrease in the second year
   (2) Discuss the reason why principal cash flows change.

Cara also wants to evaluate the price sensitivity of her MBS to changes in interest rates. She knows that modified duration and effective duration are two possible measures she could use to evaluate price sensitivity.

b. Select and justify with one reason which duration measure Cara should use to evaluate the price sensitivity of her MBS.

c. State whether the IO security price increases or decreases in the first year of the interest rate scenario described. Justify your response.

16. On May 30, 2011, Alessandra Burke is considering purchasing one of the newly issued 10-year AAA corporate bonds shown in the following exhibit. Alessandra notes that the yield curve is currently flat and assumes that the yield curve shifts in an instantaneous and parallel manner.

### BOND CHARACTERISTICS

<table>

</tbody>
</table>

a. Contrast the effect on the price of both bonds if yields decline more than 100 basis points. (No calculation is required).

b. State and explain under which two interest rate forecasts Alessandra would prefer the Celeste bond over the Sophie bond.

c. State the directional price change, if any, assuming interest rate volatility increases, for each of the following:
   (1) The Sophie bond
   (2) The Celeste bond

### PROBLEMS

1. Four years ago, your firm issued $1,000 par, 25-year bonds, with a 7 percent coupon rate and a 10 percent call premium.

a. If these bonds are now called, what is the approximate yield to call for the investors who originally purchased them?

b. If these bonds are now called, what is the actual yield to call for the investors who originally purchased them at par?

c. If the current interest rate on the bond is 5 percent and the bonds were not callable, at what price would each bond sell?

2. Assume that you purchased an 8 percent, 20-year, $1,000 par, semiannual payment bond priced at $1,012.50 when it has 12 years remaining until maturity. Compute:

   a. Its promised yield to maturity
   b. Its yield to call if the bond is callable in three years with an 8 percent premium

3. Calculate the Macaulay duration of an 8 percent, $1,000 par bond that matures in three years if the bond’s YTM is 10 percent and interest is paid semiannually.

   a. Calculate this bond’s modified duration.

   b. Assuming the bond’s YTM goes from 10 percent to 9.5 percent, calculate an estimate of the price change.
4. Two years ago, you acquired a 10-year zero coupon, $1,000 par value bond at a 12 percent YTM. Recently, you sold this bond at an 8 percent YTM. Using semiannual compounding, compute the annualized horizon return for this investment.

5. A bond for the Chelle Corporation has the following characteristics:
   Maturity—12 years
   Coupon—10%
   Yield to maturity—9.50%
   Macaulay duration—5.7 years
   Convexity—48
   Noncallable

   a. Calculate the approximate price change for this bond using only its duration, assuming its yield to maturity increased by 150 basis points. Discuss (without calculations) the impact when you include the convexity effect.
   b. Calculate the approximate price change for this bond (using only its duration) if its yield to maturity declined by 300 basis points. Discuss (without calculations) what would happen to your estimate of the price change if this was a callable bond.

6. The Clarence Corporation has issued bonds that pay semiannually with the following characteristics:

<table>
<thead>
<tr>
<th>Coupon</th>
<th>Yield to Maturity</th>
<th>Maturity</th>
<th>Macaulay Duration</th>
</tr>
</thead>
<tbody>
<tr>
<td>8%</td>
<td>8%</td>
<td>15 years</td>
<td>10 years</td>
</tr>
</tbody>
</table>

   a. Calculate modified duration using the information provided.
   b. Explain why modified duration is a better measure than maturity when calculating the bond’s sensitivity to changes in interest rates.
   c. Identify the direction of change in modified duration if:
      1. the coupon of the bond were 4 percent, not 8 percent.
      2. the maturity of the bond were 7 years, not 15 years
   d. Define convexity and explain how modified duration and convexity are used to approximate the bond’s percentage change in price, given a large change in interest rates.

7. a. Using the information in the following table, calculate the projected price change for Bond B if the yield to maturity for this bond falls by 75 basis points.
   b. Describe the shortcoming of analyzing Bond A strictly to call or to maturity. Explain an approach to remedy this shortcoming.

   **LAUREN CORPORATION BOND INFORMATION (AS OF 2012)**

8. U.S. Treasuries represent a significant holding in Lauren’s pension portfolio. You decide to analyze the yield curve for U.S. Treasury Notes.
10. Bonds of Francesca Corporation with a par value of $1,000 sell for $960, mature in five years, and have a 7 percent annual coupon rate paid semiannually. 

(a) Calculate the:

(1) current yield
(2) yield to maturity (to the nearest whole percent — that is, 3 percent, 4 percent, 5 percent, etc.)
(3) horizon yield (also called realized or total return) for an investor with a three-year holding period and a reinvestment rate of 6 percent over the period. At the end of three years, the 7 percent coupon bonds with two years remaining will sell to yield 7 percent. 

(b) Cite one major shortcoming for each of the following fixed-income yield measures:

(1) current yield
(2) yield to maturity
(3) horizon yield (also called realized or total return)

11. Exhibit 18.29 shows the characteristics of two annual pay bonds from the same issuer with the same priority in the event of default, and Exhibit 18.30 displays spot interest rates. Neither bond’s price is consistent with the spot rates. Using the information in Exhibits 18.29 and 18.30, recommend either Bond A or Bond B for purchase. Justify your choice.

12. You ran a regression of the yield of TBR Company’s 10-year bond on the 10-year U.S. Treasury benchmark’s yield using month-end data for the past year. You found the following result:

\[
\text{Yield}_{\text{TBR}} = 0.54 + 1.22 \times \text{Yield}_{\text{Treasury}}
\]

where \( \text{Yield}_{\text{TBR}} \) is the yield on the TBR bond and \( \text{Yield}_{\text{Treasury}} \) is the yield on the U.S. Treasury bond. The modified duration on the 10-year U.S. Treasury is 7.0 years, and modified duration on the TBR bond is 6.93 years.

(a) Calculate the percentage change in the price of the 10-year U.S. Treasury, assuming a 50-basis-point change in the yield on the 10-year U.S. Treasury.

(b) Calculate the percentage change in the price of the TBR bond, using the regression equation, assuming a 50-basis-point change in the yield on the 10-year U.S. Treasury.

a. Using the data in the following table, calculate the five-year spot and forward rates, assuming annual compounding. Show calculations.

<table>
<thead>
<tr>
<th>Years to Maturity</th>
<th>Par Coupon Yield to Maturity</th>
<th>Calculated Spot Rates</th>
<th>Calculated Forward Rates</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>5.00</td>

<td>5.20</td>
<td>5.21</td>
<td>5.42</td>
</tr>
<tr>
<td>3</td>
<td>6.00</td>
<td>6.05</td>
<td>7.75</td>
</tr>
<tr>
<td>4</td>
<td>7.00</td>
<td>7.16</td>
<td>10.56</td>
</tr>
<tr>
<td>5</td>
<td>7.00</td>
<td>—</td>
<td>—</td>
</tr>
</tbody>
</table>

b. Define and describe each of the following three concepts:

- Yield to maturity
- Spot rate
- Forward rate

Explain how these three concepts are related.

You are considering the purchase of a zero coupon U.S. Treasury Note with four years to maturity.

c. Based on the preceding yield curve analysis, calculate both the expected yield to maturity and the price for the security. Show calculations.

9. The following table shows yields to maturity on U.S. Treasury securities as of January 1, 2011:

<table>
<thead>
<tr>
<th>Term to Maturity</th>
<th>Yield to Maturity</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 year</td>
<td>3.50%</td>
</tr>
<tr>
<td>2 years</td>
<td>4.50%</td>
</tr>
<tr>
<td>3 years</td>
<td>5.00%</td>
</tr>
<tr>
<td>4 years</td>
<td>5.50%</td>
</tr>
<tr>
<td>5 years</td>
<td>6.00%</td>
</tr>
<tr>
<td>10 years</td>
<td>6.60%</td>
</tr>
</tbody>
</table>

a. Based on the data in the table, calculate the implied forward one-year rate of interest at January 1, 2014.

b. Describe the conditions under which the calculated forward rate would be an unbiased estimate of the one-year spot rate of interest at January 1, 2014.

Assume that one year earlier, at January 1, 2010, the prevailing term structure for U.S. Treasury securities was such that the implied forward one-year rate of interest at January 1, 2014, was significantly higher than the corresponding rate implied by the term structure at January 1, 2011.

c. On the basis of the pure expectations theory of the term structure, briefly discuss two factors that could account for such a decline in the implied forward rate.

Multiple-scenario forecasting frequently makes use of information from the term structure of interest rates.

d. Briefly describe how the information conveyed by this observed decrease in the implied forward rate for 2014 could be used in making a multiple-scenario forecast.
10. Bonds of Francesca Corporation with a par value of $1,000 sell for $960, mature in five years, and have a 7 percent annual coupon rate paid semiannually.
   a. Calculate the:
      (1) current yield
      (2) yield to maturity (to the nearest whole percent—that is, 3 percent, 4 percent, 5 percent, etc.)
      (3) horizon yield (also called realized or total return) for an investor with a three-year holding period and a reinvestment rate of 6 percent over the period. At the end of three years, the 7 percent coupon bonds with two years remaining will sell to yield 7 percent.
      Show your work.
   b. Cite one major shortcoming for each of the following fixed-income yield measures:
      (1) current yield
      (2) yield to maturity
      (3) horizon yield (also called realized or total return)

11. Exhibit 18.29 shows the characteristics of two annual pay bonds from the same issuer with the same priority in the event of default, and Exhibit 18.30 displays spot interest rates. Neither bond’s price is consistent with the spot rates. Using the information in Exhibits 18.29 and 18.30, recommend either Bond A or Bond B for purchase. Justify your choice.

12. You ran a regression of the yield of TBR Company’s 10-year bond on the 10-year U.S. Treasury benchmark’s yield using month-end data for the past year. You found the following result:

   \[ \text{Yield}_{\text{TBR}} = 0.54 + 1.22 \text{Yield}_{\text{Treasury}} \]

   where Yieldd_{TBR} is the yield on the TBR bond and Yieldd_{Treasury} is the yield on the U.S. Treasury bond. The modified duration on the 10-year U.S. Treasury is 7.0 years, and modified duration on the TBR bond is 6.93 years.
   a. Calculate the percentage change in the price of the 10-year U.S. Treasury, assuming a 50-basis-point change in the yield on the 10-year U.S. Treasury.
   b. Calculate the percentage change in the price of the TBR bond, using the regression equation, assuming a 50-basis-point change in the yield on the 10-year U.S. Treasury.

b. Compute, under the pure expectations theory, the two-year implied forward rate three years from now, given the information provided in the preceding table. State the assumption underlying the calculation of the implied forward rate.
CHAPTER 19
Bond Portfolio Management

Strategies

After you read this chapter, you should be able to answer the following questions:

1. What are the five major classes of bond portfolio management strategies?
2. How is the investment style box defined for fixed-income portfolios?
3. What are the two main types of passive bond portfolio management strategies?
4. What are the main active bond portfolio management strategies?
5. How do active bond portfolio strategies differ from one another in terms of scope, scalability, and risk-adjusted return potential?
6. What is meant by core-plus bond portfolio management?
7. What are the primary "plus" strategies in a core-plus approach to management?
8. How does a matched-funding approach to bond portfolio management differ from an active or passive approach?
9. How does bond immunization work and how does that strategy differ from a cash-matching approach to managing a bond portfolio?
10. What other dedicated management strategies are available to bond managers?
11. What is meant by a contingent immunization approach to bond portfolio management?

In this chapter, we shift attention from bond valuation and analysis to an examination of the most widely used bond portfolio management strategies. After a brief discussion of how bonds have performed as an asset class in recent years and how fixed-income investment styles are typically classified, we will see that these strategies can be classified into one of five broad approaches: passive management, active management, core-plus management, matched-funding management, and contingent and structured active management. In the following sections, we describe these approaches in more detail and give examples of how each is used in practice.

### Exhibit 18.31 Calculation of Duration and Convexity for an 8 Percent, 5-Year Bond Selling to Yield 6 Percent

Macaulay Duration = \( \frac{9,234.50}{2 \times 1,085.30} = 4.25 \)

Modified Duration = \( \frac{4.25}{1.03} = 4.13 \)

Convexity = \( \frac{95,874.32}{(1.03)^2 \times 2^2 \times 1,085.30} = 20.82 \)
CHAPTER 19
Bond Portfolio Management Strategies

After you read this chapter, you should be able to answer the following questions:

- What are the five major classes of bond portfolio management strategies?
- How is the investment style box defined for fixed-income portfolios?
- What are the two main types of passive bond portfolio management strategies?
- What are the main active bond portfolio management strategies?
- How do active bond portfolio strategies differ from one another in terms of scope, scalability, and risk-adjusted return potential?
- What is meant by core-plus bond portfolio management?
- What are the primary “plus” strategies in a core-plus approach to management?
- How does a matched-funding approach to bond portfolio management differ from an active or passive approach?
- How does bond immunization work and how does that strategy differ from a cash-matching approach to managing a bond portfolio?
- What other dedicated management strategies are available to bond managers?
- What is meant by a contingent immunization approach to bond portfolio management?

In this chapter, we shift attention from bond valuation and analysis to an examination of the most widely used bond portfolio management strategies. After a brief discussion of how bonds have performed as an asset class in recent years and how fixed-income investment styles are typically classified, we will see that these strategies can be classified into one of five broad approaches: passive management, active management, core-plus management, matched-funding management, and contingent and structured active management. In the following sections, we describe these approaches in more detail and give examples of how each is used in practice.

19.1 Bond Portfolio Performance, Style, and Strategy

The volatile pattern of interest rates prevailing during recent decades has provided increasingly attractive returns to bond investors of all types. Active bond portfolio managers have found the frequent opportunities to realize capital gains that resulted from those rate shifts to be especially attractive. However, despite the favorable economic climate that has prevailed for most of the last quarter century, it remains the case that fixed-income portfolios generally produce both less return and less volatility than other asset classes (e.g., domestic equity, foreign equity, real estate). Exhibit 19.1 summarizes the average annual returns and standard deviations for several performance indexes over the 20-year period ending in 2010, a time horizon that saw two major downturns in equity markets. Bond portfolios—as represented by the Citigroup U.S. Government Bond, World Government Bond, and U.S. Corporate Bond indexes—fall at the lower end of the risk-return spectrum measured by the capital market line, making them a conservative choice within an investor’s
future will likely have a very different strategy for assembling a fixed-income portfolio than someone whose goal is to maximize capital gains resulting from an anticipated shift in interest rates. Exhibit 19.3, which is based in part on the development in Leibowitz (1986a), indicates that bond portfolio strategies can be divided into the five broad groups mentioned above.

Exhibit 19.2

Exhibit 19.3

Chapter 19: Bond Portfolio Management Strategies

Overall asset allocation strategy. On the other hand, the U.S. High Yield Bond Index exhibited risk and return dynamics that made it more comparable to many of the equity indexes. Finally, notice that the relatively low historical correlation between fixed-income and equity securities—only 0.08 over this time period—have made bond portfolios an excellent tool for diversifying risk as well.

In Chapter 16, we saw that it was useful to classify the investment style of equity portfolios along two dimensions: market capitalization and relative valuation (i.e., value vs. growth). Similarly, the investment style of a bond portfolio can be summarized by its two most important characteristics: credit quality and interest rate sensitivity. Exhibit 19.2 shows how the 3 × 3 style grid can be adjusted to accommodate these dimensions. The average credit quality of the portfolio can be classified as high grade (e.g., government, agency, AAA-rated or AA-rated corporate bonds), medium grade (e.g., A-rated or BBB-rated), or low grade (e.g., below BBB-rated), based on the profile of the composite holding. We also established in the last chapter that average duration is an effective way to measure the portfolio’s price sensitivity to interest rate changes. The second dimension of the bond portfolio’s investment style can be separated as short term (e.g., duration less than 3.0 years), intermediate term (e.g., duration between 3.0 and 6.5 years), or long term (e.g., duration more than 6.5 years). For example, the Barclays Capital U.S. Aggregate Bond Index, one of the most widely used benchmarks, is purposely constructed to mimic the profile of the investment grade fixed-income security market in the United States, which typically consists of 70–80 percent government, agency, or AAA-rated bonds. The BCA Index is structured to maintain an average duration of between 4.0 and 5.0 years. Thus, it would plot in the middle cell of the top row of the style grid in Exhibit 19.2 and would be classified as a high-grade/intermediate-term portfolio.

Just as the inherent investment style of one bond portfolio compared to another can vary widely, so too can the underlying strategic approach adopted by the managers who formed those portfolios. The nature of the investor’s problem usually dictates the way in which the manager will think about designing the bond portfolio that solves that problem. Consequently, an investor who desires a specific amount of cash to fund a financial obligation in the near
Prior to the 1960s, only the first two strategic approaches—passive and active—were widely available, and most bond portfolios were managed on a buy-and-hold basis with the intention of producing a steady stream of cash flow for the investor. The early 1970s saw a growing level of curiosity with alternative active bond portfolio management approaches, while the late 1970s and early 1980s were characterized by record-breaking inflation and interest rates as well as extremely volatile yields across all spectrums of the bond market. This led to the introduction of many new financial instruments in response to the increase in rate volatility (e.g., adjustable-rate bonds and mortgages). Since the mid-1980s, matched-funding techniques, core-plus strategies, and contingent bond management approaches have been developed to meet the increased needs of institutional investors, such as pension funds and insurance companies. Finally, beginning in the mid-1990s, it has become increasingly common to see bonds combined with positions in derivative securities in the management of sophisticated fixed-income portfolios; this topic will be explored in later chapters.

   b. Dedicated: optimal cash match
   c. Classical immunization
   d. Horizon matching
5. Contingent & Structured Strategies
   a. Contingent immunization
   b. Structured management

Future will likely have a very different strategy for assembling a fixed-income portfolio than someone whose goal is to maximize capital gains resulting from an anticipated shift in interest rates. Exhibit 19.3, which is based in part on the development in Leibowitz (1986a), indicates that bond portfolio strategies can be divided into the five broad groups mentioned above.
Prior to the 1960s, only the first two strategic approaches—passive and active—were widely available, and most bond portfolios were managed on a buy-and-hold basis with the intention of producing a steady stream of cash flow for the investor. The early 1970s saw a growing level of curiosity with alternative active bond portfolio management approaches, while the late 1970s and early 1980s were characterized by record-breaking inflation and interest rates as well as extremely volatile yields across all spectrums of the bond market. This led to the introduction of many new financial instruments in response to the increase in rate volatility (e.g., adjustable-rate bonds and mortgages). Since the mid-1980s, matched-funding techniques, core-plus strategies, and contingent bond management approaches have been developed to meet the increased needs of institutional investors, such as pension funds and insurance companies. Finally, beginning in the mid-1990s, it has become increasingly common to see bonds combined with positions in derivative securities in the management of sophisticated fixed-income portfolios; this topic will be explored in later chapters.

19.2 Passive Management Strategies

Two specific passive portfolio management strategies exist. First, is a buy-and-hold strategy in which a manager selects a portfolio of bonds based on the objectives and constraints of the client with the intent of holding these bonds to maturity. In the second passive strategy—indexing—the objective is to construct a portfolio of bonds that will be matched as closely as possible to the performance of a specified bond index, such as the Barclays Capital U.S. Aggregate Bond Index described earlier.

19.2.1 Buy-and-Hold Strategy

The simplest fixed-income portfolio management strategy is to buy and hold. This approach involves finding securities with the desired levels of credit quality, coupon rate, term to maturity or duration, and other important indenture provisions, such as call and sinking fund features. Buy-and-hold investors do not consider active trading as a viable alternative to achieve abnormal returns but look for bond issue whose maturity/duration characteristics approximate their investment horizon in order to reduce price and reinvestment risk. Many successful bond investors and institutional portfolio managers follow a modified buy-and-hold strategy wherein they invest in an issue with the intention of holding it to maturity, but still look for opportunities to trade into a more desirable position should the occasion arise. Of course, if the buy-and-hold approach is modified too much, it becomes an active strategy.

Whether the manager follows a strict or modified buy-and-hold approach, the critical concept is finding investment vehicles that possess the appropriate maturity, yield, and credit quality attributes. The strategy does not restrict the investor to accept whatever the market has to offer, nor does it imply that selectivity is unimportant. Attractive high-yielding issues with desirable features and quality standards are actively sought. For example, these investors recognize that agency issues or asset-backed securities generally provide attractive incremental returns relative to Treasuries with little sacrifice in quality, or that various call and put features can materially impact the risk and realized yield of an issue. Thus, successful buy-and-hold investors use their knowledge of market and security characteristics to seek out attractive realized yields.

Finally, recognize that there is an important fundamental difference between managing a bond portfolio and a stock portfolio on a buy-and-hold basis. Since bonds eventually mature with the passing of time whereas stock shares do not, the bond manager is faced with the need to periodically reinvest the funds from a matured issue. However, the stock manager can employ a “pure” buy-and-hold strategy in which he never adjusts the portfolio’s composition once it is formed. Fixed-income portfolio managers often address this concern by forming a bond ladder, in which they divide their investment funds evenly across the
19.2.3 Bond Indexing in Practice: An Example

To see how two actual managers have responded to the challenge of forming a bond portfolio designed to track one of the leading indexes, we consider the several aspects of the Vanguard Total Bond Index Fund (ticker: VBMFX) and the iShares Barclays U.S. Aggregate (ticker: AGG) exchange-traded fund over a recent investment period. Both of these portfolios were created to mimic the performance of the Barclays Capital U.S. Aggregate Index—whose formal ticker symbol is LBUSTRUU—and represent the two methods widely used in practice to create indexed portfolios for retail investors (i.e., index mutual funds and ETFs).

Exhibit 19.4 summarizes many of the most important structural characteristics for these funds as well as for the underlying index. It is interesting to contrast the approaches these managers have adopted to replicate the index, which contains over 8,000 separate bond issues and would be difficult to recreate exactly. The manager of VBMFX actually holds more positions than the index (i.e., almost 14,000 names), whereas AGG’s manager follows a stratified sampling method and attempts to mimic the index by holding only 710 distinct security positions. Not surprisingly, AGG also has a substantially higher portfolio turnover statistic than VBMFX—488 percent versus 80 percent—which is undoubtedly a by-product of trying to keep the ETF’s portfolio composition aligned with that of the much larger index.

This difference in index replication approaches also leads to slight differences in the relevant investment characteristics of the portfolios. Generally speaking, the index mutual fund maintains a bond portfolio that is closer to the index in terms of average duration (LBUSTRUU: 4.9, VBMFX: 4.8, AGG: 4.6), but both of the managed funds deviate from the index in terms of credit quality, as measured by the percentage of the portfolio carrying a rating of AAA or higher (LBUSTRUU: 77.6, VBMFX: 75.9, AGG: 76.1). These discrepancies lead, in turn, to a sizeable difference in the tracking error statistic produced by each manager, with VBMFX and AGG having annualized values of 0.46 and 1.80 percent, respectively. Thus, the exchange-traded fund’s tracking error was roughly four times greater than that of index mutual fund and only the latter falls within the range of what is considered normal for a passive approach to investing. Finally, the expense ratios for both indexed vehicles are quite similar (i.e., 22–24 basis points) and much smaller than what would be typical for an actively managed bond portfolio.

### 19.2.2 Indexing Strategy

In the discussion of efficient capital markets earlier in the text, numerous empirical studies were cited that have demonstrated that the majority of money managers have not been able to match the risk-adjusted return performance of common stock and bond indexes. As a result, many investors have chosen to invest at least some of the funds dedicated to these asset classes on a passive basis. Rather than forming their own buy-and-hold portfolios, many investors prefer to hold a bond portfolio designed to mimic a selected fixed-income index. In such a case, the bond index manager is judged not on the basis of his ability to produce abnormal returns, but by how closely his portfolio produces returns that match those of the index. When describing similar concepts for stock index managers in Chapter 16, we saw that tracking error was a useful tool to judge how closely the returns of a managed portfolio match (i.e., “track”) those of the targeted index. Recall that tracking error is measured as the standard deviation of the difference in returns produced by the managed portfolio and the index over time. An annualized tracking error statistic of 1 percent or less usually indicates that an index fund manager is doing a good job matching the performance of the index.

As with stock index funds, when designing a bond portfolio to mimic a hypothetical index, managers can follow two different paths: full replication or stratified sampling. While it is quite common when constructing stock index funds to fully replicate the underlying index, the bond index fund manager often follows a sampling approach, wherein a smaller number of instruments are held in the actual portfolio than appear in the index. One reason for this is that bond indexes often contain several thousand specific issues and are adjusted frequently, making them both impractical and expensive to replicate precisely in practice. The goal of the stratified sampling approach is to create a bond portfolio that matches the important characteristics of the underlying index—such as credit quality, industry composition, maturity/duration, or coupon rate—while maintaining a portfolio that is more cost effective to manage. To the extent that the manager is not able to match these characteristics over time, the tracking error of the indexed portfolio will typically increase.

When initiating an indexing strategy, the selection of an appropriate market index is clearly a very important decision, chiefly because it directly determines the client’s risk-return results. Consequently, it is important for investors to be acquainted with the main characteristics (e.g., maturity/duration, credit quality) of their selected index. Reilly and Wright (1994, 1997, 2005) have examined many aspects of the major bond indexes, such as their risk-return characteristics and the correlation between them over time. Also, Dialynas and Murata (2006) and Volpert (2001) discuss how the characteristics of indexes affect their performance in different interest rate environments. Finally, recognize that the aggregate bond market and the indexes change over time. Reilly, Kao, and Wright (1992) demonstrated that the market experienced significant shifts in composition, maturity, and duration since 1975, which can significantly impact the tracking error performance of an indexed portfolio.¹

¹For further discussion on how bond market dynamics change over time, see Van Horne (2001). For more on how these changes impact the management of an indexed portfolio, see Mossavar-Rahmani (1991) and Fabozzi (2007, Chapter 23).
19.2.3 Bond Indexing in Practice: An Example

To see how two actual managers have responded to the challenge of forming a bond portfolio designed to track one of the leading indexes, we consider the several aspects of the Vanguard Total Bond Index Fund (ticker: VBMFX) and the iShares Barclays U.S. Aggregate (ticker: AGG) exchange-traded fund over a recent investment period. Both of these portfolios were created to mimic the performance of the Barclays Capital U.S. Aggregate Index—whose formal ticker symbol is LBUSTRUU—and represent the two methods widely used in practice to create indexed portfolios for retail investors (i.e., index mutual funds and ETFs).

Exhibit 19.4 summarizes many of the most important structural characteristics for these funds as well as for the underlying index. It is interesting to contrast the approaches these managers have adopted to replicate the index, which contains over 8,000 separate bond issues and would be difficult to recreate exactly. The manager of VBMFX actually holds more positions than the index (i.e., almost 14,000 names), whereas AGG’s manager follows a stratified sampling method and attempts to mimic the index by holding only 710 distinct security positions. Not surprisingly, AGG also has a substantially higher portfolio turnover statistic than VBMFX—488 percent versus 80 percent—which is undoubtedly a by-product of trying to keep the ETF’s portfolio composition aligned with that of the much larger index.

This difference in index replication approaches also leads to slight differences in the relevant investment characteristics of the portfolios. Generally speaking, the index mutual fund maintains a bond portfolio that is closer to the index in terms of average duration (LBUSTRUU: 4.9, VBMFX: 4.8, AGG: 4.6), but both of the managed funds deviate from the index in terms of credit quality, as measured by the percentage of the portfolio carrying a rating of AAA or higher (LBUSTRUU: 77.6, VBMFX: 75.9, AGG: 76.1). These discrepancies lead, in turn, to a sizeable difference in the tracking error statistic produced by each manager, with VBMFX and AGG having annualized values of 0.46 and 1.80 percent, respectively. Thus, the exchange-traded fund’s tracking error was roughly four times greater than that of index mutual fund and only the latter falls within the range of what is considered normal for a passive approach to investing. Finally, the expense ratios for both indexed vehicles are quite similar (i.e., 22–24 basis points) and much smaller than what would be typical for an actively managed bond portfolio.

Source: Prepared by the authors using data from Morningstar, Inc., and Fidelity Investments.
In the remainder of this section, we will explore four categories of active bond strategies—interest rate anticipation, valuation analysis, credit risk, and yield spread analysis—in more detail, as well as describe bond swaps as a means to implement a specific active strategic view.

19.3.1 Interest Rate Anticipation

Interest rate anticipation is perhaps the riskiest active management strategy because it involves relying on uncertain forecasts of future interest rates. The idea is to preserve capital when an increase in interest rates is anticipated and achieve attractive capital gains when interest rates are expected to decline. Such objectives usually are attained by altering the duration structure of the portfolio (i.e., reducing portfolio duration when interest rates are expected to increase and increasing the portfolio duration when a decline in yields is anticipated). Thus, the risk in such portfolio restructuring is largely a function of these duration alterations.

When durations are shortened, substantial income could be sacrificed and the opportunity for capital gains could be lost if interest rates decline rather than rise. Similarly, portfolio shifts prompted by anticipated rate declines are also risky. Assuming that we are at a peak in interest rates, it is likely that the yield curve is downward sloping, which means that bond coupons will decline with maturity. Therefore, the investor is sacrificing current income by shifting from high-coupon short bonds to longer-duration bonds. At the same time, the portfolio is purposely exposed to greater price volatility that could work against the portfolio if an unexpected increase in yields occurs. Note that the portfolio adjustments prompted by anticipation of an increase in rates involve less risk of an absolute capital loss. When you reduce the maturity, the worst that can happen is that interest income is reduced and/or capital gains are forgone (opportunity cost).

Once future (expected) interest rates have been determined, the procedure relies largely on technical matters. Assume that you expect an increase in interest rates and want to preserve your capital by reducing the duration of your portfolio. A popular choice would be high-yielding, short-term obligations, such as Treasury bills. Although your primary concern is to preserve capital, you would nevertheless look for the best return possible given the maturity constraint. Liquidity also is important because, after interest rates increase, yields may experience a period of stability before they decline, and you would want to shift positions quickly to benefit from the higher income and/or capital gains.

To illustrate this process, suppose that the yield curve for U.S. Treasury bonds is currently flat across all maturities at 4.75 percent. You have observed the following "paired" transaction by an active bond portfolio manager:

<table>
<thead>
<tr>
<th>Bond Transaction Type</th>
<th>Maturity (yrs.)</th>
<th>Coupon Rate (%)</th>
<th>Modified Duration</th>
</tr>
</thead>
<tbody>
<tr>
<td>Buy U.S. Govt.</td>
<td>1</td>
<td>5.438</td>
<td></td>
</tr>
<tr>
<td>Sell U.S. Govt.</td>
<td>2</td>
<td>12.698</td>
<td></td>
</tr>
</tbody>
</table>

What does this trade suggest about the manager’s view as to how the yield curve is likely to change in the future? First, by switching out of a long-maturity, zero-coupon bond into an intermediate-maturity, high-coupon bond, the manager has significantly shortened the modified duration of the position and, presumably, of the entire portfolio. Thus, this trade is consistent with a view that the yields will rise in the future (i.e., the yield curve will shift up). Exhibit 19.6 shows two potential situations for how this might happen. In Scenario #1, the manager forecasts that all rates will shift up by 50 basis points, keeping the yield curve flat. In Scenario #2, all future yields increase but rates on longer-term securities increase by more, meaning that the shape of the curve moves from flat to upward sloping. In either case, the manager will benefit from replacing a bond with a single cash flow paid out more than a decade in the future to one with a much shorter maturity that also makes payments every six months. Of course, the portfolio adjustments prompted by anticipation of an increase in rates involve less risk of an absolute capital loss. When you reduce the maturity, the worst that can happen is that interest income is reduced and/or capital gains are forgone (opportunity cost).

19.3 Active Management Strategies

As we have seen with active equity portfolio management, the active fixed-income manager attempts to form a portfolio of securities that will outperform her designated benchmark over time. That is, she will attempt to hold a collection of bonds that produce superior risk-adjusted returns (i.e., alpha) compared to the index against which her investment performance is measured. Of course, to beat a benchmark, the active manager must form a portfolio that differs from the holdings comprising the index in a meaningful way. Thus, active bond management strategies are closely tied to the manager’s view of what factors or market conditions will be the source of the incremental alpha returns she seeks.

Layard-Liesching (2001) analyzed the investment attributes of several potential sources of alpha for the active bond portfolio manager, all of which depend on some structural barrier that prevents the bond market from being fully efficient. These characteristics are summarized in Exhibit 19.5. He compares each active strategy on four dimensions: (1) scalability (i.e., how large a position can be taken); (2) sustainability (i.e., how far into the future the strategy can be successfully employed); (3) risk-adjusted performance; and (4) extreme values (i.e., how exposed the strategy is to the chance of a large loss). For instance, in the interest rate anticipation category, he argues that duration-based active bets—in which the manager increases or decreases the average duration level of the active portfolio on the belief that the yield curve will either shift down or up, respectively—are highly scalable since they can be implemented with virtually any securities available in the market. However, they also offer the lowest chance of sustainable performance as well as the worst risk-adjusted returns. By contrast, credit risk bets—where the manager takes a position in a bond that she thinks has a substantially different default potential than has been priced in by the market—are a much more sustainable and reliable source of potential alpha. Finally, notice that while valuation analysis offers the active manager reasonable alpha potential, it is a more limited strategy from a scalability standpoint since it relies on identifying pricing errors in specific bond issues.²

**Source:** Adapted from Ronald Layard-Liesching, “Exploiting Opportunities in Global Bond Markets,” in Core-Plus Bond Management (Charlottesville, VA: AimR), 2001.

²Additional discussions of active bond portfolio strategies can be found in Boyd and Mercer (2010), Malvey (2005), and Fong (2001).
In the remainder of this section, we will explore four categories of active bond strategies—interest rate anticipation, valuation analysis, credit risk, and yield spread analysis—in more detail, as well as describe bond swaps as a means to implement a specific active strategic view.

### 19.3.1 Interest Rate Anticipation

**Interest rate anticipation** is perhaps the riskiest active management strategy because it involves relying on uncertain forecasts of future interest rates. The idea is to preserve capital when an increase in interest rates is anticipated and achieve attractive capital gains when interest rates are expected to decline. Such objectives usually are attained by altering the duration structure of the portfolio (i.e., reducing portfolio duration when interest rates are expected to increase and increasing the portfolio duration when a decline in yields is anticipated). Thus, the risk in such portfolio restructuring is largely a function of these duration alterations. When durations are shortened, substantial income could be sacrificed and the opportunity for capital gains could be lost if interest rates decline rather than rise. Similarly, portfolio shifts prompted by anticipated rate declines are also risky. Assuming that we are at a peak in interest rates, it is likely that the yield curve is downward sloping, which means that bond coupons will decline with maturity. Therefore, the investor is sacrificing current income by shifting from high-coupon short bonds to longer-duration bonds. At the same time, the portfolio is purposely exposed to greater price volatility that could work against the portfolio if an unexpected increase in yields occurs. Note that the portfolio adjustments prompted by anticipation of an increase in rates involve less risk of an absolute capital loss. When you reduce the maturity, the worst that can happen is that interest income is reduced and/or capital gains are forgone (opportunity cost).

Once future (expected) interest rates have been determined, the procedure relies largely on technical matters. Assume that you expect an increase in interest rates and want to preserve your capital by reducing the duration of your portfolio. A popular choice would be high-yielding, short-term obligations, such as Treasury bills. Although your primary concern is to preserve capital, you would nevertheless look for the best return possible given the maturity constraint. Liquidity also is important because, after interest rates increase, yields may experience a period of stability before they decline, and you would want to shift positions quickly to benefit from the higher income and/or capital gains.

To illustrate this process, suppose that the yield curve for U.S. Treasury bonds is currently flat across all maturities at 4.75 percent. You have observed the following "paired" transaction by an active bond portfolio manager:

<table>
<thead>
<tr>
<th>Bond</th>
<th>Transaction</th>
<th>Type</th>
<th>Maturity (yrs.)</th>
<th>Coupon Rate (%)</th>
<th>Modified Duration</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Buy</td>
<td>U.S. Govt.</td>
<td>7</td>
<td>8</td>
<td>5.438</td>
</tr>
<tr>
<td>2</td>
<td>Sell</td>
<td>U.S. Govt.</td>
<td>13</td>
<td>0</td>
<td>12.698</td>
</tr>
</tbody>
</table>

What does this trade suggest about the manager’s view as to how the yield curve is likely to change in the future? First, by switching out of a long-maturity, zero-coupon bond into an intermediate-maturity, high-coupon bond, the manager has significantly shortened the modified duration of the position and, presumably, of the entire portfolio. Thus, this trade is consistent with a view that the yields will rise in the future (i.e., the yield curve will shift up). Exhibit 19.6 shows two potential situations for how this might happen. In Scenario #1, the manager forecasts that all rates will shift up by 50 basis points, keeping the yield curve flat. In Scenario #2, all future yields increase but rates on longer-term securities increase by more, meaning that the shape of the curve moves from flat to upward sloping. In either case, the manager will benefit from replacing a bond with a single cash flow paid out more than a decade in the future to one with a much shorter maturity that also makes payments every six months. Of course, the
19.3.2 Valuation Analysis

With valuation analysis, the portfolio manager attempts to select bonds based on their intrinsic value, which is determined based on their characteristics and the average value of these characteristics in the marketplace. As an example, a bond’s rating will dictate a certain spread relative to comparable Treasury bonds: Long maturity might be worth an added 60 basis points relative to short maturity (i.e., the maturity or term spread); a given deferred call feature might require a higher or lower yield; a specified sinking fund would likewise mean higher or lower required yields. Given all the characteristics of the bond and the normal cost of the characteristics in terms of yield, you would determine the bond’s required yield and, therefore, its implied intrinsic value. Doing this for a number of bonds, you would compare these derived bond values to the prevailing market prices to determine which bonds are undervalued or overvalued. Based on your confidence in the characteristic costs, you would buy the undervalued issues and ignore or sell the overvalued issues. Success in valuation analysis is based on understanding the characteristics that are important in valuation and being able to accurately estimate the yield cost of these characteristics with the understanding that these yield costs change over time.

19.3.3 Credit Analysis

A credit analysis strategy involves detailed analysis of the bond issuer to determine expected changes in its default risk. This involves attempting to project changes in the credit ratings assigned to bonds by the various rating agencies discussed in Chapter 17. These rating changes are affected by internal changes in the entity (e.g., changes in important financial ratios) and by changes in the external environment (i.e., changes in the firm’s industry and the economy).

During periods of strong economic expansion, even financially weak firms may survive and prosper. In contrast, during severe economic contractions, normally strong firms may find it very difficult to meet financial obligations. Therefore, historically there has been a strong cyclical pattern to rating changes: typically, downgrades increase during economic contractions and decline during economic expansions.

To use credit analysis as a bond management strategy, it is necessary to project rating changes prior to the announcement by the rating agencies. This can be quite challenging because the market adjusts rather quickly to bond rating changes, especially to downgrades. Therefore, you want to acquire bond issues expected to experience an upgrade and sell or avoid those bond issues expected to be downgraded.

Credit Analysis of High-Yield (Junk) Bonds

One of the most obvious opportunities for credit analysis is the analysis of high-yield (junk) bonds. As demonstrated by several studies, the yield differential between junk bonds that are rated below BBB and Treasury securities ranges from about 250 basis points to over 1,500 basis points. Notably, these yield differentials vary substantially over time, as shown by a time-series plot in Exhibit 19.7. Specifically, the average yield spread ranged from a low of less than 300 basis points in 1985 and 1997 to a high of almost 1,550 basis points during late 2008.

Although the spreads have changed, a study by Mody and Taylor (2003) indicated that the average credit quality of high-yield bonds also changed over time as indicated by interest coverage changes over the business cycle. Also, the credit quality of bonds within rating categories changed over the business cycle as demonstrated by Reilly, Wright, and Gentry (2009). These changes in credit quality make credit analysis of high-yield bonds more important, but also more difficult. This means that bond analysts and portfolio managers need to engage in detailed credit analysis to select bonds that will survive. Given the spread in promised yields, if a portfolio manager can—through rigorous credit analysis—avoid bonds with a high probability of default or downgrade, high-yield bonds will provide substantial rates of return for the investor; see Vine (2001) and Fabozzi (2005a).
19.3.2 Valuation Analysis

With valuation analysis, the portfolio manager attempts to select bonds based on their intrinsic value, which is determined based on their characteristics and the average value of these characteristics in the marketplace. As an example, a bond’s rating will dictate a certain spread relative to comparable Treasury bonds: Long maturity might be worth an added 60 basis points relative to short maturity (i.e., the maturity or term spread); a given deferred call feature might require a higher or lower yield; a specified sinking fund would likewise mean higher or lower required yields. Given all the characteristics of the bond and the normal cost of the characteristics in terms of yield, you would determine the bond’s required yield and, therefore, its implied intrinsic value. Doing this for a number of bonds, you would compare these derived bond values to the prevailing market prices to determine which bonds are undervalued or overvalued. Based on your confidence in the characteristic costs, you would buy the undervalued issues and ignore or sell the overvalued issues.

Success in valuation analysis is based on understanding the characteristics that are important in valuation and being able to accurately estimate the yield cost of these characteristics with the understanding that these yield costs change over time.

19.3.3 Credit Analysis

A credit analysis strategy involves detailed analysis of the bond issuer to determine expected changes in its default risk. This involves attempting to project changes in the credit ratings assigned to bonds by the various rating agencies discussed in Chapter 17. These rating changes are affected by internal changes in the entity (e.g., changes in important financial ratios) and by changes in the external environment (i.e., changes in the firm’s industry and the economy). During periods of strong economic expansion, even financially weak firms may survive and prosper. In contrast, during severe economic contractions, normally strong firms may find it very difficult to meet financial obligations. Therefore, historically there has been a strong cyclical pattern to rating changes: typically, downgrades increase during economic contractions and decline during economic expansions.

To use credit analysis as a bond management strategy, it is necessary to project rating changes prior to the announcement by the rating agencies. This can be quite challenging because the market adjusts rather quickly to bond rating changes, especially to downgrades. Therefore, you want to acquire bond issues expected to experience an upgrade and sell or avoid those bond issues expected to be downgraded.

Credit Analysis of High-Yield (Junk) Bonds One of the most obvious opportunities for credit analysis is the analysis of high-yield (junk) bonds. As demonstrated by several studies, the yield differential between junk bonds that are rated below BBB and Treasury securities ranges from about 250 basis points to over 1,500 basis points. Notably, these yield differentials vary substantially over time, as shown by a time-series plot in Exhibit 19.7. Specifically, the average yield spread ranged from a low of less than 300 basis points in 1985 and 1997 to a high of almost 1,550 basis points during late 2008.

Although the spreads have changed, a study by Mody and Taylor (2003) indicated that the average credit quality of high-yield bonds also changed over time as indicated by interest coverage changes over the business cycle. Also, the credit quality of bonds within rating categories changed over the business cycle as demonstrated by Reilly, Wright, and Gentry (2009).

These changes in credit quality make credit analysis of high-yield bonds more important, but also more difficult. This means that bond analysts and portfolio managers need to engage in detailed credit analysis to select bonds that will survive. Given the spread in promised yields, if a portfolio manager can—through rigorous credit analysis—avoid bonds with a high probability of default or downgrade, high-yield bonds will provide substantial rates of return for the investor; see Vine (2001) and Fabozzi (2005a).
In summary, substantial opportunity for generating high risk-adjusted returns can be derived by investing in high-yield bonds if you do the credit analysis required to avoid defaults, which occur with these bonds at substantially higher rates than the overall bond market, as shown by Asquith, Mullins, and Wolff (1989) and Altman (1992).

Exhibit 19.8 lists the cumulative average default rates for bonds with different ratings and for various time periods after issue. Over 10 years—the holding period that is widely used in practice for comparative purposes—the default rate for BBB investment-grade bonds is only 4.76 percent, but the default rate increases to over 16 percent for BB-rated bonds, to over 32 percent for B-rated bonds, and to over 53 percent for CCC-rated bonds. These default rates do not mean that investors should avoid high-yield bonds, but they do indicate that extensive credit analysis is a critical component for success within this risky sector of the fixed-income market.

**Investing in Defaulted Debt** Beyond high-yield bonds that have high credit risk and high default rates, a new set of investment opportunities has evolved—investing in defaulted debt. While this sector requires an understanding of legal procedures surrounding bankruptcy as well as economic analysis, the returns have generally been consistent with the risk, as demonstrated by Altman (1993), Altman and Simon (2001), Ward and Griepentrog (1993), and Reilly, Wright, and Altman (1998).

**Credit Analysis Models** The credit analysis of high-yield bonds can use a statistical model or basic fundamental analysis that recognizes some of the unique characteristics of these bonds. Altman-Namachek (1987) suggest that a modified Z-score model used to predict the probability of bankruptcy within two years can also be used to predict default for these high-yield bonds or as a gauge of changes in credit quality. The Z-score model combines traditional financial measures with a multivariate technique known as multiple discriminant analysis to
derive a set of weights for the specified variables. The result is an overall credit score ($Z$) for each firm. The model is of the form:

$$Z = a_0 + a_1 X_1 + a_2 X_2 + a_3 X_3 + \ldots + a_n X_n$$

where:

- $Z$ = the overall credit score
- $X_1$::: $X_n$ = the explanatory variables (ratios and market measures)
- $a_0$::: $a_n$ = the weightings or coefficients

The final model used in this analysis included the following seven financial measures:

- $X_1$ = profitability: earnings before interest and taxes (EBIT) = total assets (TA)
- $X_2$ = stability of profitability measure: the standard error of estimate of EBIT = TA (normalized for 10 years)
- $X_3$ = debt service capabilities (interest coverage): EBIT = interest charges
- $X_4$ = cumulative profitability: retained earnings = total assets
- $X_5$ = liquidity: current assets = current liabilities
- $X_6$ = capitalization levels: market value of equity = total capital (five-year average)
- $X_7$ = size: total tangible assets (normalized)

As an example of this process, Exhibit 19.9 illustrates the $Z$-score calculations for two companies whose bonds were rated below investment grade as of January 2011: Ford Motors (Ba2 rating), a multinational automobile manufacturer, and Kronos Worldwide (B2), a specialty chemical producer. $Z$-scores typically range from $-5.0$ to $+20.0$, with higher scores (i.e., above $+3.0$) indicating that bankruptcy over the next two years is unlikely, while lower scores (i.e., below $+1.8$) suggest an increased potential for business failure. In this case, Kronos’s $Z$-score shows that it is in stronger financial condition than Ford (i.e., $+2.25$ vs. $+0.75$), despite having the lower bond credit rating. It is important to note, however, that these scores are best interpreted as they change over time, rather than as a single observation. In that respect, the charts at the bottom of each panel of Exhibit 19.9 show that both companies’ $Z$-scores have improved substantially since the stock market crisis in late 2008.

Active bond managers following a credit analysis strategy might use this as a tool to help predict rating upgrades and downgrades before they occur. Jonszon and Fridson (1996) discuss predicting default rates for high-yield bonds in more detail.

In contrast to using a model that provides a composite credit score, many analysts simply adapt their basic corporate bond analysis techniques to the unique needs of high-yield bonds, which have characteristics of common stock as shown by Reilly and Wright (1994, 2001). Fabozzi (2005, Chapter 32) claims that the analysis of high-yield bonds is the same as with any bond except that the following areas of analysis should be expanded:

1. What is the firm’s competitive position in terms of cost and pricing? This can be critical to a small firm.
2. What is the firm’s cash flow relative to cash requirements for interest, research, growth, and periods of economic decline? Also, what is the firm’s borrowing capacity that can serve as a safety net and provide flexibility?
3. What is the liquidity value of the firm’s assets? Are these assets available for liquidation (are there any claims against them)? In many cases, asset sales are a critical part of the strategy for a leveraged buyout.
4. How good is the total management team? Is the management team committed to and capable of operating in the high-risk environment of this firm?
5. What is the firm’s financial leverage on an absolute basis and on a market-adjusted basis (using market value of equity and debt)?
derive a set of weights for the specified variables. The result is an overall credit score \( Z \) for each firm. The model is of the form:

\[
Z = a_0 + a_1 X_1 + a_2 X_2 + a_3 X_3 + \cdots + a_n X_n
\]

where:

\[
Z = \text{the overall credit score} \\
X_1 \ldots X_n = \text{the explanatory variables (ratios and market measures)} \\
a_0 \ldots a_n = \text{the weightings or coefficients}
\]

The final model used in this analysis included the following seven financial measures:

- \( X_1 = \) profitability: earnings before interest and taxes (EBIT)/total assets (TA)
- \( X_2 = \) stability of profitability measure: the standard error of estimate of EBIT/TA (normalized for 10 years)
- \( X_3 = \) debt service capabilities (interest coverage): EBIT/interest charges
- \( X_4 = \) cumulative profitability: retained earnings/total assets
- \( X_5 = \) liquidity: current assets/current liabilities
- \( X_6 = \) capitalization levels: market value of equity/total capital (five-year average)
- \( X_7 = \) size: total tangible assets (normalized)

As an example of this process, Exhibit 19.9 illustrates the \( Z \)-score calculations for two companies whose bonds were rated below investment grade as of January 2011: Ford Motors (Ba2 rating), a multinational automobile manufacturer, and Kronos Worldwide (B2), a specialty chemical producer. \( Z \)-scores typically range from \(-5.0\) to \(+20.0\), with higher scores (i.e., above \(+3.0\)) indicating that bankruptcy over the next two years is unlikely, while lower scores (i.e., below \(+1.8\)) suggest an increased potential for business failure. In this case, Kronos’s \( Z \)-score shows that it is in stronger financial condition than Ford (i.e., \(+2.25\) vs. \(+0.75\)), despite having the lower bond credit rating. It is important to note, however, that these scores are best interpreted as they change over time, rather than as a single observation. In that respect, the charts at the bottom of each panel of Exhibit 19.9 show that both companies’ \( Z \)-scores have improved substantially since the stock market crisis in late 2008.\(^3\) Active bond managers following a credit analysis strategy might use this as a tool to help predict rating upgrades and downgrades before they occur. Jonsson and Fridson (1996) discuss predicting default rates for high-yield bonds in more detail.

In contrast to using a model that provides a composite credit score, many analysts simply adapt their basic corporate bond analysis techniques to the unique needs of high-yield bonds, which have characteristics of common stock as shown by Reilly and Wright (1994, 2001). Fabozzi (2005, Chapter 32) claims that the analysis of high-yield bonds is the same as with any bond except that the following areas of analysis should be expanded:

1. What is the firm’s _competitive position_ in terms of cost and pricing? This can be critical to a small firm.
2. What is the firm’s _cash flow_ relative to cash requirements for interest, research, growth, and periods of economic decline? Also, what is the firm’s _borrowing capacity_ that can serve as a safety net and provide flexibility?
3. What is the _liquidity value of the firm’s assets_? Are these assets available for liquidation (are there any claims against them)? In many cases, asset sales are a critical part of the strategy for a leveraged buyout.
4. How good is the _total management team_? Is the management team committed to and capable of operating in the high-risk environment of this firm?
5. What is the firm’s _financial leverage_ on an absolute basis and on a market-adjusted basis (using market value of equity and debt)?

\(^3\)Exhibit 19.9 also reports a double prime \( Z \)-score for each company, which is just a modification of the \( Z \)-score that uses fewer of the financial measures in the discriminant analysis procedure described earlier.
In addition to the potentially higher financial risks, Sondhi (1995) and Squires (1998b) point out several factors that can also impact business risk. An increase in business risk may exist if the firm sells off some operations that have favorable risk characteristics with the remaining operations, such as a division that has low correlation of earnings with other units of the firm. Further, a change in management operating philosophy could have a negative impact on operating earnings. Asset divestiture plans often are a major element of a leveraged buyout because they provide necessary capital that is used to reduce the substantial debt taken on as part of the acquisition. Therefore, it is important to examine the liquidity of the assets, their estimated selling values, and the timing of these programs. If the divestiture program is successful wherein the prices received are above normal expectations and the assets are sold ahead of schedule, this can be grounds for upgrading the debt. Finally, it is necessary to constantly monitor the firm's refinancing flexibility. Specifically, what refinancing will be necessary, what does the schedule look like, and will the capital suppliers be receptive to the refinancing?

### 19.3.4 Yield Spread Analysis

As discussed in Chapter 18, spread analysis assumes normal relationships exist between the yields for bonds in alternative sectors (e.g., the spread between high-grade versus low-grade industrial or between industrial versus utility bonds). When an abnormal relationship occurs, a bond manager could execute various sector swaps. The crucial factor is developing the background to know the normal yield relationship and to evaluate the liquidity necessary to buy or sell the required issues quickly enough to take advantage of the temporary yield abnormality.

Dialynas and Edington (1992) consider several specific factors that affect the aggregate spread. The generally accepted explanation of changes in the yield spread is that it is related to the economic environment. The spread widens during periods of economic uncertainty and recession because investors require larger risk premiums (i.e., larger spreads). In contrast, the spread will decline during periods of economic confidence and expansion. The authors contend that a more encompassing factor is the impact of interest rate (yield) volatility, which will affect the spread via three effects: (1) yield volatility and the behavior of embedded options, (2) yield volatility and transactional liquidity, and (3) the effect of yield volatility on the business cycle.

Recall that the value of callable bonds is equal to the value of a noncallable bond minus the value of the call option. Therefore, if the value of the option goes up, the value of the callable bond will decline and its yield will increase. When yield volatility increases, the value of the call option increases, which causes a decline in the price of the callable bond and a rise in the bond's yield and its yield spread relative to Treasury bonds. Similarly, an increase in yield volatility will raise the uncertainty facing bond dealers and cause them to increase their bid-ask spreads that reflect the transactional liquidity for these bonds. This liquidity will have a bigger effect on nongovernment bonds, so their yield spread relative to Treasury bonds will increase. Finally, interest rate volatility causes uncertainty for business executives and consumers regarding their cost of funds. This typically will precede an economic decline that will, in turn, lead to an increase in the yield spread.

It is possible to have a change in yield spread for reasons other than economic uncertainty. If there is a period of greater yield volatility that is not a period of economic uncertainty, the yield spread will increase due to the embedded option effect and the transactional liquidity effect. This analysis implies that when examining yield spreads, you should pay particular attention to interest rate (yield) volatility.

### 19.3.5 Implementing an Active Bond Transaction

Once a bond manager has decided on the specifics of an active strategy, the next step is to create a portfolio (or alter an existing one) to take advantage of that view. A popular approach...
In addition to the potentially higher financial risks, Sondhi (1995) and Squires (1998b) point out several factors that can also impact business risk. The authors contend that a more encompassing factor is the impact of interest rate (yield) volatility, which will affect the spread via three effects: (1) yield volatility and the behavior of embedded options, (2) yield volatility and transactional liquidity, and (3) the effect of yield volatility on the business cycle.

Recall that the value of callable bonds is equal to the value of a noncallable bond minus the value of the call option. Therefore, if the value of the option goes up, the value of the callable bond will decline and its yield will increase. When yield volatility increases, the value of the call option increases, which causes a decline in the price of the callable bond and a rise in the bond’s yield and its yield spread relative to Treasury bonds. Similarly, an increase in yield volatility will raise the uncertainty facing bond dealers and cause them to increase their bid-ask spreads that reflect the transactional liquidity for these bonds. This liquidity will have a bigger effect on nongovernment bonds, so their yield spread relative to Treasury bonds will increase. Finally, interest rate volatility causes uncertainty for business executives and consumers regarding their cost of funds. This typically will precede an economic decline that will, in turn, lead to an increase in the yield spread.

It is possible to have a change in yield spread for reasons other than economic uncertainty. If there is a period of greater yield volatility that is not a period of economic uncertainty, the yield spread will increase due to the embedded option effect and the transactional liquidity effect. This analysis implies that when examining yield spreads, you should pay particular attention to interest rate (yield) volatility.

19.3.5 Implementing an Active Bond Transaction
Once a bond manager has decided on the specifics of an active strategy, the next step is to create a portfolio (or alter an existing one) to take advantage of that view. A popular approach
for implementing these adjustments involves the use of **bond swaps**, which entail liquidating a current position and simultaneously buying a different issue in its place with similar attributes and a better chance for improved return. These trades can be executed to increase current yield, to increase yield to maturity, to take advantage of shifts in interest rates or the realignment of yield spreads, to improve the quality of a portfolio, or for tax purposes. Some swaps are highly sophisticated and require a computer for calculation. However, most are fairly simple transactions with obvious goals and risk. They go by such names as **pure yield pickup swaps**, **substitution swaps**, **rate anticipation swaps**, or **tax swaps**. Although many of these transactions involve low risk (such as the pure yield pickup swap), others entail substantial risk (the rate anticipation swap). Regardless of the risk involved, all trades have one basic purpose: portfolio improvement. In fact, Boyd and Mercer (2010) demonstrate that these swaps lead to a substantial improvement in risk-adjusted performance relative to standard bond benchmarks.

Most bond swaps involve several different types of risk. One obvious risk is that the market will move against you while the transaction is in progress. Interest rates may move up over the holding period and cause you to incur a loss. Alternatively, yield spreads may fail to respond as anticipated. Possibly the new bond may not be a true substitute and so, even if your expectations and interest rate formulations are correct, the swap may be unsatisfactory because the wrong issue was selected. Finally, if the work-out time is longer than anticipated, the realized yield might be less than expected. As noted by Homer and Leibowitz (2004) and Fabozzi, Mann, and Choudhry (2005, Chapter 55), you must be willing to accept such risks to improve your portfolio. The following subsections consider three of the more popular bond swaps.

**Pure Yield Pickup Swap** The pure yield pickup swap involves trading out of a low-coupon bond into a comparable higher-coupon bond to realize an automatic and instantaneous increase in current yield and yield to maturity. An example would be an investor who currently holds a 30-year, AA-rated 10 percent issue that is trading at an 11.50 percent yield. Assume that a comparable 30-year, AA-rated obligation bearing a 12 percent coupon priced to yield 12 percent becomes available. The investor would report (and realize) some book loss if the original issue was bought at par but is able to improve current yield and yield to maturity simultaneously if the new obligation is held to maturity, as shown in Exhibit 19.10.

The investor need not predict rate changes, and the swap is not based on any imbalance in yield spread. The object simply is to seek higher yields. Quality and maturity stay the same as do all other factors except coupon. The major risk is that future reinvestment rates may not be as high as expected, and, therefore, the total terminal value of the investment (capital recovery, coupon receipts, and interest-on-interest) may not be as high as expected. This reinvestment risk can be evaluated by analyzing the results with a number of reinvestment rates to determine the minimum reinvestment rate that would make the swap viable.

**Substitution Swap** The substitution swap generally is short term and relies heavily on interest rate expectations. Consequently, it is subject to considerably more risk than pure yield pickup swaps. The procedure assumes a short-term imbalance in yield spreads between issues that are perfect substitutes. The imbalance in yield spread is expected to be corrected in the near future. For example, the investor might hold a 30-year, 12 percent issue that is yielding 12 percent and be offered a comparable 30-year, 12 percent bond that is yielding 12.20 percent. Because the issue offered will trade at a price less than $1,000 for every issue sold, the investor can buy more than one of the offered obligations.

You would expect the yield spread imbalance to be corrected by having the yield on the offering bond decline to the level of your current issue. Thus, you would realize capital gains by switching out of your current position into the higher-yielding obligation. This swap is described in Exhibit 19.11.
$100,000 with a current market value of $50,000, you could execute a tax swap to establish the $50,000 capital loss. By offsetting this capital loss and the comparable capital gain, you would reduce your income taxes.

Municipal bonds are considered particularly attractive tax swap candidates because you can increase your tax-free income and use the capital loss (subject to normal federal and state taxation) to reduce capital gains tax liability. To continue our illustration, assume you own $100,000 worth of New York City, 20-year, 7 percent bonds that you bought at par, but they have a current market value of $50,000. Given this tax loss, you need a comparable bond swap candidate. Suppose you find a 20-year New York City bond with a 7.1 percent coupon and a market value of 50. By selling your New York 7s and instantaneously reinvesting in the New York 7.1s, you would eliminate the capital gains tax from the corporate bond transaction. In effect, you have $50,000 of tax-free capital gains, and you have increased your current tax-free yield. The money saved by avoiding the tax liability can then be used to increase the portfolio's yield, as shown in Exhibit 19.12.

An important caveat is that you cannot swap identical issues (such as selling the New York 7s to establish a loss and then buying back the same New York 7s). If it is not a different issue, the IRS considers the transaction a wash sale and does not allow the loss. It is easier to avoid wash sales in the bond market than it is in the stock market because every bond issue, even

---

**Exhibit 19.10 A Pure Yield Pickup Swap**

*Pure yield pickup swap:* A bond swap involving a switch—from a low-coupon bond to a higher-coupon bond of similar quality and maturity—in order to pick up a higher current yield and a better yield to maturity.

**Example:** Currently hold: 30-year, 10.0% coupon priced at 874.12 to yield 11.5%

Swap candidate: 30-year, AA 12% coupon priced at $1,000 to yield 12.0%

<table>
<thead>
<tr>
<th>Current Bond</th>
<th>Candidate Bond</th>
</tr>
</thead>
<tbody>
<tr>
<td>Dollar investment</td>
<td>$874.12</td>
</tr>
<tr>
<td>Coupon</td>
<td>100.00</td>
</tr>
<tr>
<td>i on one coupon (12.0% for 6 months)</td>
<td>3.00</td>
</tr>
<tr>
<td>Principal value at year end</td>
<td>874.66</td>
</tr>
<tr>
<td>Total accrued</td>
<td>977.66</td>
</tr>
<tr>
<td>Realized compound yield</td>
<td>11.514%</td>
</tr>
<tr>
<td>Value of swap: 48.6 basis points in one year (assuming a 12.0% reinvestment rate)</td>
<td></td>
</tr>
</tbody>
</table>

The rewards for a pure yield pickup swap are automatic and instantaneous in that both a higher-coupon yield and a higher yield to maturity are realized from the swap. Other advantages include:

1. No specific work-out period needed because the investor is assumed to hold the new bond to maturity
2. No need for interest rate speculation
3. No need to analyze prices for overvaluation or undervaluation

A major disadvantage of the pure yield pickup swap is the book loss involved in the swap. In this example, if the current bond were bought at par, the book loss would be $125.88 ($1,000 – 874.12). Other risks involved in the pure yield pickup swap include:

1. Increased risk of call in the event interest rates decline
2. Greater reinvestment risk with higher-coupon bonds

*Obviously, the investor can invest $874.12—the amount obtained from the sale of the bond currently held—and still obtain a realized compound yield of 12.0%. Swap evaluation procedure is patterned after a technique suggested by Sidney Homer and Martin L. Leibowitz.

Although a modest increase in current income occurs as the yield imbalance is corrected, attractive capital gains are possible, causing a differential in realized yield. The work-out time will have an important effect on the differential realized return. Even if the yield is not corrected until maturity, 30 years later, you will still experience a small increase in realized yield (about 10 basis points). In contrast, if the correction takes place in one year (as shown in Exhibit 19.11), the differential realized return is much greater. After the correction has occurred, you would have additional capital for a subsequent swap or other investment. Several risks are involved in this swap. In addition to the pressure of the work-out time, market interest rates could move against you, the yield spread may not be temporary, and the issue may not be a viable swap candidate (i.e., the spread may be due to the issue's lower quality).

**Tax Swap** The tax swap is popular with individual investors because it is a relatively simple procedure that involves no interest rate projections and few risks. Investors enter into tax swaps due to tax laws and realized capital gains in their portfolios. Assume you acquired $100,000 worth of corporate bonds and after two years sold the securities for $150,000, implying a capital gain of $50,000. One way to eliminate the tax liability of that capital gain is to sell an issue that has a comparable long-term capital loss. If you had a long-term investment of
with identical coupons and maturities, is considered distinct. Likewise, it is easier to find comparable bond issues with only modest differences in coupon, maturity, and quality. Tax swaps are common at year end as investors establish capital losses because the capital loss must occur in the same taxable year as the capital gain.

19.3.6 Active Global Bond Investing: An Example

An active approach to global fixed-income management must consider three interrelated factors: (1) the local economy in each country that includes the effect of domestic and international demand, (2) the impact of this total demand and domestic monetary policy on inflation and interest rates, and (3) the effect of the economy, inflation, and interest rates on the exchange rates among countries.

Based on the evaluation of these factors, a portfolio manager must decide on the relative weight for each country. In addition, one might consider an allocation within each country among government, municipal, and corporate bonds. In the example that follows, most portfolio recommendations concentrate on the country allocation and do not become more specific except in the case of the United States.

Exhibit 19.13 is from UBS Global Asset Management, a global institutional asset manager. The table’s Benchmark column indicates what the asset allocation would be if UBS had no opinion regarding the expected bond market performance in the alternative countries. In most cases, the exhibit shows an allocation where UBS recommends an asset allocation in each country.

<td>12.00%</td>
</tr>
</tbody>
</table>

The rewards for the substitution swap are additional basis-point pickups for YTM, additional realized compound yield, and capital gains that accrue when the anomaly in yield corrects itself. In the substitution swap, any basis-point pickup (171 points in this example) will be realized only during the work-out period. Thus, in our example, to obtain the 171 basis-point increase in realized compound yield, you must swap an average of once a year and pick up an average of 20 basis points in yield to maturity on each swap.

Potential risks associated with the substitution swap include:

1. A yield spread thought to be temporary may, in fact, be permanent, thus reducing capital gains advantages.
2. The market rate may change adversely.

Swap evaluation procedure is patterned after a technique suggested by Sidney Homer and Martin L. Leibowitz.

$100,000 with a current market value of $50,000, you could execute a tax swap to establish the $50,000 capital loss. By offsetting this capital loss and the comparable capital gain, you would reduce your income taxes.

Municipal bonds are considered particularly attractive tax swap candidates because you can increase your tax-free income and use the capital loss (subject to normal federal and state taxation) to reduce capital gains tax liability. To continue our illustration, assume you own $100,000 worth of New York City, 20-year, 7 percent bonds that you bought at par, but they have a current market value of $50,000. Given this tax loss, you need a comparable bond swap candidate. Suppose you find a 20-year New York City bond with a 7.1 percent coupon and a market value of 50. By selling your New York 7s and instantaneously reinvesting in the New York 7.1s, you would eliminate the capital gains tax from the corporate bond transaction. In effect, you have $50,000 of tax-free capital gains, and you have increased your current tax-free yield. The money saved by avoiding the tax liability can then be used to increase the portfolio’s yield, as shown in Exhibit 19.12.

An important caveat is that you cannot swap identical issues (such as selling the New York 7s to establish a loss and then buying back the same New York 7s). If it is not a different issue, the IRS considers the transaction a wash sale and does not allow the loss. It is easier to avoid wash sales in the bond market than it is in the stock market because every bond issue, even
### Exhibit 19.12 A Tax Swap

*Tax swap:* A swap undertaken when you wish to offset capital gains in other securities through the sale of a bond currently held and selling at a discount from the price paid at purchase. By swapping into a bond with as nearly identical features as possible, you can use the capital loss on the sale of the bond for tax purposes and still maintain your current position in the market.

**Example:** Currently hold: $100,000 worth of corporate bonds with current market value of $150,000 and $100,000 in NY 20-year, 7% bonds with current market value of $50,000

Swap candidate: $50,000 in NY 20-year, 7.1% bonds

*NY 7.1s will result in substantial capital gains when liquidated at maturity (because they were bought at deep discounts) and, therefore, will be subject to future capital gains tax liability. The swap is designed to use the capital loss resulting from the swap to offset capital gains from other investments. At the same time, your funds remain in a security almost identical to your previous holding while you receive a slight increase in both current income and YTM. Because the tax swap involved no projections in terms of work-out period, interest rate changes, etc., the risks involved are minimal. Your major concern should be to avoid potential wash sales.

with identical coupons and maturities, is considered distinct. Likewise, it is easier to find comparable bond issues with only modest differences in coupon, maturity, and quality. Tax swaps are common at year end as investors establish capital losses because the capital loss must occur in the same taxable year as the capital gain.

### 19.3.6 Active Global Bond Investing: An Example

An active approach to global fixed-income management must consider three interrelated factors: (1) the local economy in each country that includes the effect of domestic and international demand, (2) the impact of this total demand and domestic monetary policy on inflation and interest rates, and (3) the effect of the economy, inflation, and interest rates on the exchange rates among countries. Based on the evaluation of these factors, a portfolio manager must decide on the relative weight for each country. In addition, one might consider an allocation within each country among government, municipal, and corporate bonds. In the example that follows, most portfolio recommendations concentrate on the country allocation and do not become more specific except in the case of the United States.

Exhibit 19.13 is from UBS Global Asset Management, a global institutional asset manager. The table’s “Benchmark” column indicates what the asset allocation would be if UBS had no opinion regarding the expected bond market performance in the alternative countries. In most cases, the

---

*For a detailed discussion of the benefits of international bond investing as well as what is involved in the analysis, see Steward (2005); Malvey (2005); Steward, Lynch, and Fabozzi (2005a); Nemerever (2010); and Jost (2002).*
normal allocation is based on the country’s relative market value. Specifically, the normal allocation is 20.1 percent for the United States, 29.0 percent for Japan, and the remaining 50.9 percent for the other countries, including 40.0 percent for the combined EMU countries. Clearly, UBS does have an opinion regarding these countries (as shown in its implied market strategy, which equals the benchmark percentage plus or minus the over-/underweight percentage). For example, at this point in time, it overweighted the EMU block of countries bond markets with a market strategy allocation of 42.9 percent (versus the benchmark allocation of 40.0 percent) and underweighted the UK bond market with a market strategy allocation of only 3 percent (versus the benchmark of 5 percent). Another country overweighted was Australia, while several were underweighted, including Denmark, Norway, Poland, and Switzerland. In addition, UBS does a specific currency allocation between countries, which would likewise be based on the normal policy weight unless the firm had an opinion on currencies. Again, UBS has an opinion: It heavily underweighted the U.K. pound and overweighted the currencies of Japan and Singapore.

In making your own allocations based on these specific expectations, you would look for U.S. securities in which yields were expected to decline relative to Treasury securities and for bond markets in foreign countries that likewise had bullish interest rate expectations. Finally, you would look for countries in which the currency was expected to be strong relative to the United States.

19.4 CORE-PLUS MANAGEMENT STRATEGIES

Beyond a pure passive strategy or any of the several active management strategies we have just seen, recently there has been increased interest among professional bond investors in a management approach that combines the two styles. Core-plus bond portfolio management places a significant part (i.e., 70 to 80 percent) of the available funds in a passively managed portfolio of high-grade securities reflecting a broad representation of the overall bond market; this is the "core" of the strategy. The remainder of the funds would then be managed actively in the "plus" portion of the portfolio, where it is felt that the manager’s selection skills offer a higher probability of achieving positive abnormal rates of return.

The core portion of a portfolio following this combination approach is effectively managed as an index fund based on the belief that the designated core sectors of the bond market are efficient to where it is not worth the time and cost to attempt to derive substantial excess returns from them. Examples of market sectors that are often included in this definition include the U.S. broad market sector or the U.S. government/corporate sector, both of which have been dominated historically by issues that carry a credit rating of AAA or higher. (The difference between these two core sectors is that the former includes the rapidly growing markets for mortgage-backed and asset-backed bonds.) The plus sectors included in the portfolio consist of those segments of the global bond market that are regarded as being less efficient and therefore more likely to be sources of alpha in the managed portfolio. This would include high-yield bonds, non-U.S. bonds from developed countries, and emerging market debt.

From the preceding description, it should be clear that a core-plus approach to bond management can also be considered a form of enhanced indexing, depending on how much of the portfolio is placed in the core portion and how actively the plus sectors are managed. As Davidson (2001) points out, the core-plus bond manager attempts to combine a substantial beta investment—that is, the funds invested to mimic the systematic risk exposure of the benchmark index—with the alpha potential associated with selecting bonds from the actively managed sectors. Thus, an important feature of a potential security position coming from the plus sectors is that it has the possibility of delivering high risk-adjusted returns over time that are not driven by systematic movements in the general bond market. This means that plus sector investments often have high total risk, as measured by their standard deviation of returns, but also low correlations with the other fixed-income sectors that represent the core of the strategy.
normal allocation is based on the country’s relative market value. Specifically, the normal allocation is 20.1 percent for the United States, 29.0 percent for Japan, and the remaining 50.9 percent for the other countries, including 40.0 percent for the combined EMU countries. Clearly, UBS does have an opinion regarding these countries (as shown in its implied market strategy, which equals the benchmark percentage plus or minus the over-/underweight percentage). For example, at this point in time, it overweighted the EMU block of countries bond markets with a market strategy allocation of 42.9 percent (versus the benchmark allocation of 40.0 percent) and underweighted the UK bond market with a market strategy allocation of only 3 percent (versus the benchmark of 5 percent). Another country overweighted was Australia, while several were underweighted, including Denmark, Norway, Poland, and Switzerland. In addition, UBS does a specific currency allocation between countries, which would likewise be based on the normal policy weight unless the firm had an opinion on currencies. 19.4 Core-Plus Management Strategies

Beyond a pure passive strategy or any of the several active management strategies we have just seen, recently there has been increased interest among professional bond investors in a management approach that combines the two styles. Core-plus bond portfolio management places a significant part (i.e., 70 to 80 percent) of the available funds in a passively managed portfolio of high-grade securities reflecting a broad representation of the overall bond market; this is the “core” of the strategy. The remainder of the funds would then be managed actively in the “plus” portion of the portfolio, where it is felt that the manager’s selection skills offer a higher probability of achieving positive abnormal rates of return.

The core portion of a portfolio following this combination approach is effectively managed as an index fund based on the belief that the designated core sectors of the bond market are efficient to where it is not worth the time and cost to attempt to derive substantial excess returns from them. Examples of market sectors that are often included in this definition include the U.S. broad market sector or the U.S. government/corporate sector, both of which have been dominated historically by issues that carry a credit rating of AAA or higher. (The difference between these two core sectors is that the former includes the rapidly growing markets for mortgage-backed and asset-backed bonds.) The plus sectors included in the portfolio consist of those segments of the global bond market that are regarded as being less efficient and therefore more likely to be sources of alpha in the managed portfolio. This would include high-yield bonds, non-U.S. bonds from developed countries, and emerging market debt.

From the preceding description, it should be clear that a core-plus approach to bond management can also be considered a form of enhanced indexing, depending on how much of the portfolio is placed in the core portion and how actively the plus sectors are managed. As Davidson (2001) points out, the core-plus bond manager attempts to combine a substantial beta investment—that is, the funds invested to mimic the systematic risk exposure of the benchmark index—with the alpha potential associated with selecting bonds from the actively managed sectors. Thus, an important feature of a potential security position coming from the plus sectors is that it has the possibility of delivering high risk-adjusted returns over time that are not driven by systematic movements in the general bond market. This means that plus sector investments often have high total risk, as measured by their standard deviation of returns, but also low correlations with the other fixed-income sectors that represent the core of the
portfolio. High-yield bonds are a good example of a plus sector since they tend to have very high standard deviations that make them equivalent to equity investments in many respects, but have very low correlations (e.g., 0.30 or lower) with the investment-grade bond sector.

Relative to a passive index strategy, a core-plus approach to managing a bond portfolio offers three potential advantages: (1) higher returns that occur from exploiting market inefficiencies outside the traditional core sectors, (2) increased opportunities for exploiting the manager’s security selection skills, and (3) the ability to alter the composition of the fixed-income asset class in a manner consistent with the insights and views of the manager. Of course, these additional sources of alpha come with additional sources of risk. The incremental risk that the core-plus approach introduces into the passive portfolio can be particularly significant in no-growth or declining-growth economic scenarios, given that much of the plus investing is likely to be done in lower credit-grade instruments whose market values will be affected the most under those circumstances. Further, there may be a number of other risks associated with investments in the plus sectors—such as prepayment and liquidity risks—that are not as prevalent in the core portion of the portfolio. Finally, Dopfel (2003) cautions asset managers against the risks associated with changing correlations between stock and bond markets.

Hersey (2001) analyzed the composition and investment mandates for a broad sample of core and core-plus portfolios managed by leading U.S.-based fixed-income investment organizations. Exhibit 19.14 summarizes these findings. While both core and core-plus managers are

given some investment latitude relative to the index—the Barclays U.S. Aggregate was the benchmark for the majority of these managers—the plus sectors were given substantially more. For instance, while core portfolios are allowed to hold an average of 5 percent of its positions in non benchmark exposures, core-plus managers can maintain 15 to 40 percent. Although the index contained no high-yield positions, the typical core and core-plus portfolio invested 1 and 7 percent in this bond market segment, respectively. Both types of portfolios also contained larger allocations in asset-backed bonds than the index. Thus, to the extent that these sectors outperform—and that the managers exhibit good selection skills in these areas—the managed portfolios will be able to produce superior risk-adjusted returns. However, it is also important to note that core-plus managers face strict constraints on their ability to take on additional risk in the pursuit of these abnormal returns. The lower panel of Exhibit 19.14 shows that core-plus portfolios are expected to produce excess returns of 100 to 125 basis points while maintaining tracking errors that do not exceed 1.50 percent. Given Allford, Jones, and Winkelmänn’s (2003) description of the portfolio risk budgeting process, this mandate is consistent with the view that core-plus portfolio management is a combination strategy.

### 19.5 Matched-Funding Management Strategies

The goal for many participants in the bond market is simply to increase the wealth of their overall portfolios while providing risk diversification benefits across asset classes. For these investors, the passive, active, and core-plus strategies we have just seen are all potentially appropriate management styles, depending on their underlying beliefs about how efficient the bond market is. Other investors, however, face a more precise investment problem in which a specific set of liabilities needs to be met. For instance, life insurance companies have a series of future cash flow payments they are obligated to make, which they can predict in advance with a reasonable degree of accuracy given their actuarial forecasts. Further, defined-benefit pension funds can also predict fairly precisely the future retirement benefits they will be required to pay—in both amount and timing—to their constituents. For investors in these situations, the bond portfolios they form clearly should take into account the nature of the liabilities that those assets are intended to fund.

**Matched-funding** strategies are a form of **asset-liability management** whereby the characteristics of the bonds that are held in the portfolio are coordinated with those of the liabilities the investor is obligated to pay. These matching techniques can range from an attempt to exactly match the levels and timing of the required cash payments to more general approaches that focus on other investment characteristics, such as setting the average duration or investment horizon of the bond portfolio equal to that of the underlying liabilities. An important assumption underlying all matched-funding techniques is that the investor’s liabilities are predictable with some degree of precision. As long as the fixed-income manager knows the obligations he faces, he can create a portfolio specifically designed to meet those needs in an optimal way.5

### 19.5.1 Dedicated Portfolios

**Dedication** refers to bond portfolio management techniques that are used to service a prescribed set of liabilities. Such a “dedicated” portfolio can be created in several ways. We will discuss two alternatives. A **pure cash-matched dedicated portfolio** is the most conservative strategy. The objective of pure cash matching is to develop a portfolio of bonds that will provide a stream of payments from coupons, sinking funds, and maturing principal payments that

---

5Additional discussion of the matched-funding approach to bond portfolio management can be found in Leibowitz (1986a) and Fabozzi (2005).
rates caused many dedicated portfolios to be underfunded. Therefore, it is necessary to find bonds with complete call protection or to consider deep discount bonds under conservative interest rate conditions.

Although quality also is a legitimate concern, it is probably not necessary to invest only in Treasury bonds if the portfolio manager diversifies across industries and sectors. A diversified portfolio of AA or A industrial bonds can provide a current and total annual return substantially above Treasuries, which can have a significant impact on the net cost of funding a liability stream.

19.5.2 Immunization Strategies

Instead of using a dedicated portfolio technique, a portfolio manager may decide that the optimal strategy is to immunize the portfolio from interest rate changes.

Immunization techniques attempt to derive a specified rate of return (generally quite close to the current market rate) during a given investment horizon, regardless of what happens to the future level of interest rates.

Components of Interest Rate Risk

A major problem encountered in bond portfolio management is deriving a given rate of return to satisfy an ending-wealth requirement at a future specific date—that is, the investment horizon. If the term structure of interest rates were flat and market rates never changed between the time of purchase and the horizon date when funds were required, you could acquire a bond with a term to maturity equal to the desired investment horizon, and the ending wealth from the bond would equal the promised wealth position implied by the promised yield to maturity. For example, assume you acquire a 10-year, $1 million bond with an 8 percent coupon at its par value. If the yield curve was flat with no changes, your wealth position at the end of your 10-year investment horizon (assuming semiannual compounding) would be:

\[
\text{\$1,000,000} \times (1.04)^{20} = \text{\$2,191,123}
\]

You can get the same answer by taking the $40,000 interest payment every six months and compounding it semiannually to the end of the period at 4 percent and adding the $1,000,000 principal at maturity. Unfortunately, in the real world, the term structure of interest rates typically is not flat and the level of interest rates is constantly changing. Consequently, the bond portfolio manager faces interest rate risk between the time of investment and the future target date. Interest rate risk is the uncertainty regarding the ending-wealth value of the portfolio due to changes in market interest rates between the time of purchase and the investor’s horizon date. Notably, interest rate risk involves two component risks: price risk and coupon reinvestment risk.

The price risk occurs because if interest rates change before the horizon date and the bond is sold before maturity, the realized market price for the bond will differ from the expected price, assuming no change in rates. If rates increased after the time of purchase, the realized price for the bond in the secondary market would be below expectations, whereas if rates declined, the realized price for the bond would be above expectations. Because you do not know whether interest rates will increase or decrease, you are uncertain about the bond’s future price.

The coupon reinvestment risk arises because the yield to maturity computation implicitly assumes that all coupon cash flows will be reinvested at the promised yield to maturity. If, after the purchase of the bond, interest rates decline, the coupon cash flows will be reinvested at rates below the initial promised yield, and the ending wealth will be below expectations. In contrast, if interest rates increase, the coupon cash flows will be reinvested at rates above expectations, and the ending wealth will be above expectations. Again, because you are uncertain about future rates, you are uncertain about these reinvestment rates.

Potential problems exist with both of these approaches to a dedicated portfolio. When selecting potential bonds for these portfolios, it is critical to be aware of call/prepayment possibilities (refundings, calls, sinking funds) with specific bonds or mortgage-backed securities. These prepayment possibilities become very important following periods of historically high rates. A prime example was the period 1982 to 1986, when interest rates went from over 18 percent to under 8 percent. Because of this substantial change in rates, many dedicated portfolios constructed without adequate concern for call protection were negatively affected when numerous bonds were called that were not expected to be called under normal conditions. For example, bonds selling at deep discounts (which typically provide implicit call protection), when rates were 16 percent to 18 percent, went to par and above when rates declined to under 10 percent and were then called. Obviously, the reinvestment of these proceeds at the lower

---

**Exhibit 19.15 A Prescribed Schedule of Liabilities**

![Payouts (Dollars in Millions)](chart)

rates caused many dedicated portfolios to be underfunded. Therefore, it is necessary to find bonds with complete call protection or to consider deep discount bonds under conservative interest rate conditions.

Although quality also is a legitimate concern, it is probably not necessary to invest only in Treasury bonds if the portfolio manager diversifies across industries and sectors. A diversified portfolio of AA or A industrial bonds can provide a current and total annual return substantially above Treasuries, which can have a significant impact on the net cost of funding a liability stream.

19.5.2 Immunization Strategies

Instead of using a dedicated portfolio technique, a portfolio manager may decide that the optimal strategy is to immunize the portfolio from interest rate changes. Immunization techniques attempt to derive a specified rate of return (generally quite close to the current market rate) during a given investment horizon, regardless of what happens to the future level of interest rates.

Components of Interest Rate Risk

A major problem encountered in bond portfolio management is deriving a given rate of return to satisfy an ending-wealth requirement at a future specific date—that is, the investment horizon. If the term structure of interest rates were flat and market rates never changed between the time of purchase and the horizon date when funds were required, you could acquire a bond with a term to maturity equal to the desired investment horizon, and the ending wealth from the bond would equal the promised wealth position implied by the promised yield to maturity. For example, assume you acquire a 10-year, $1 million bond with an 8 percent coupon at its par value. If the yield curve was flat with no changes, your wealth position at the end of your 10-year investment horizon (assuming semiannual compounding) would be:

\[ \$1,000,000 \times (1.04)^{20} = \$2,191,123 \]

You can get the same answer by taking the $40,000 interest payment every six months and compounding it semiannually to the end of the period at 4 percent and adding the $1,000,000 principal at maturity. Unfortunately, in the real world, the term structure of interest rates typically is not flat and the level of interest rates is constantly changing. Consequently, the bond portfolio manager faces interest rate risk between the time of investment and the future target date. Interest rate risk is the uncertainty regarding the ending-wealth value of the portfolio due to changes in market interest rates between the time of purchase and the investor’s horizon date. Notably, interest rate risk involves two component risks: price risk and coupon reinvestment risk.

The price risk occurs because if interest rates change before the horizon date and the bond is sold before maturity, the realized market price for the bond will differ from the expected price, assuming no change in rates. If rates increased after the time of purchase, the realized price for the bond in the secondary market would be below expectations, whereas if rates declined, the realized price for the bond would be above expectations. Because you do not know whether interest rates will increase or decrease, you are uncertain about the bond’s future price.

The coupon reinvestment risk arises because the yield to maturity computation implicitly assumes that all coupon cash flows will be reinvested at the promised yield to maturity. If, after the purchase of the bond, interest rates decline, the coupon cash flows will be reinvested at rates below the initial promised yield, and the ending wealth will be below expectations. In contrast, if interest rates increase, the coupon cash flows will be reinvested at rates above expectations, and the ending wealth will be above expectations. Again, because you are uncertain about future rates, you are uncertain about these reinvestment rates.
For Bond A, the initial investment (per $1,000 of face value) is:

\[ P_0 = X^{10} t=190(1 + .10)^{t} + 1000(1 + .10)^{10} = $938.55 \]

Since this position will not have matured by Year 3, it will have to be sold at the prevailing market rate (assumed to then be 8 percent). Also, she will be able to reinvest the coupons she receives prior to her planning horizon. Thus, the ending-wealth in this position is the combination of:

1. Sale of Bond:
   \[ P_3 = X^{7} t=190(1 + .08)^{t} + 1000(1 + .08)^{7} = $1052.06, \]
2. Reinvested Coupon Payments:
   \[ 90(1 + .08)^{2} + 90(1 + .08) + 90 = $292.18 \]

or $1344.24. This means the investor’s realized yield in Bond A would be:

\[ R_Y^A = \sqrt[3]{\frac{1344.24}{938.55}} - 1 = 27.72 \text{ percent} \]

For Bond B, assume for simplicity that the bondholder invests $1,000 initially at 10 percent and then reinvests the total annual proceeds for two more years at 8 percent:

Year 1:
\[ (1000 + 1000)(1 + .10) = $1100.00 \]

Year 2:
\[ (1100 + 1100)(1 + .08) = $1188.00 \]

Year 3:
\[ (1188 + 1188)(1 + .08) = $1283.04 \]

Thus, her realized yield from this “rollover” strategy would be:

\[ R_Y^B = \sqrt[3]{\frac{1283.04}{1000}} - 1 = 6.66 \text{ percent} \]

The initial purchase price of Bond C (per $1,000 face value) is:

\[ P_0 = \frac{1000}{1 + .10}^3 = $751.31 \]

so, the realized yield would be:

\[ R_Y^C = \sqrt[3]{\frac{1000}{751.31}} - 1 = 10.00 \text{ percent} \]

Finally, Bond D is similar to Bond A in that it must be sold prior to maturity and its coupons must be reinvested. The initial price for this security is:

\[ P_0 = X^{4} t=1348.50(1 + .10)^{t} + 1000(1 + .10)^{4} = $1787.71 \]

The ending-wealth level in Year 3 combines:

1. Sale of Bond:
   \[ P_3 = \frac{1000 + 348.50}{1 + .08} = $1248.61 \]
2. Coupon Payments:
   \[ 348.50(1 + .08)^{2} + 348.50(1 + .08) + 348.50 = $1131.37 \]

### Classical Immunization and Interest Rate Risk

Fisher and Weil (1971), as well as Bierwag and Kaufman (1977) and Bierwag (1977), showed that price risk and reinvestment risk are affected inversely by a change in market rates and that duration is the time period when these two risks are of equal magnitude, but in opposite directions. An increase in interest rates will cause an ending price below expectations, but the reinvestment rate for interim cash flows will be above expectations. A decline in market interest rates will cause the reverse situation. Clearly, a bond portfolio manager with a specific target date (investment horizon) will attempt to eliminate these two components of interest rate risk. The process intended to eliminate interest rate risk is referred to as **immunization** and was discussed by Redington (1952). It has been specified in detail by Fisher and Weil (1971) as follows:

A portfolio of investments in bonds is immunized for a holding period if its value at the end of the holding period, regardless of the course of interest rates during the holding period, must be at least as large as it would have been had the interest-rate function been constant throughout the holding period.

If the realized return on an investment in bonds is sure to be at least as large as the appropriately computed yield to the horizon, then that investment is immunized [p. 411]

Fisher and Weil found a significant difference between the promised yields and the realized returns on bonds for the period 1925 to 1968, indicating the importance of immunizing a bond portfolio. They showed that it is possible to immunize a bond portfolio if you can assume that any change in interest rates will be the same for all maturities (i.e., there is a parallel shift of the yield curve). Given this assumption, Fisher and Weil proved that a portfolio of bonds is immunized from interest rate risk if the duration of the portfolio is always equal to the desired investment horizon.

The authors simulated the effects of applying the immunization concept (a duration-matched strategy) compared to a naive portfolio strategy, where the portfolio’s maturity was equal to the investment horizon. They compared the ending-wealth ratio for the duration-matched and naive strategy portfolios to a wealth ratio that assumed no change in the interest rate structure. In a perfectly immunized portfolio, the actual ending wealth should equal the expected ending wealth implied by the promised yield. The duration-matched strategy results were consistently closer to the promised yield results; however, the results were not perfect. The duration portfolio was not perfectly immunized because the basic assumption did not always hold; that is, when interest rates changed, all interest rates did not change by the same amount.

### The Mechanics of Bond Immunization: A Simple Illustration

Suppose that an investor has a liability that she needs to pay off in exactly three years. Thus, her desired investment horizon is three years, which can also be considered as the duration of the liability she faces. Suppose also that the yield curve is currently flat at 10 percent but that it declines to 8 percent as soon as her initial investment is made. She considers four alternative bond investments to fund this liability:

1. **(A)** Purchase a 10-year bond paying a 9 percent annual coupon and sell it in three years
2. **(B)** Purchase three consecutive one-year “pure discount” (i.e., zero-coupon) bonds
3. **(C)** Purchase a three-year, pure discount bond
4. **(D)** Purchase a four-year bond paying a 34.85 percent annual coupon and sell it in three years

Under these assumptions, the promised yield for each of these prospective investments is 10 percent at the time she makes her initial decision. So, the relevant question to consider is: What are the realized yields (RY) for all four positions at the end of her three-year investment horizon?

---

6The authors gratefully acknowledge Professor Robert Radcliffe’s contribution to this example.
or $2379.98 and, thus, the realized yield would be:

\[
R_Y = \sqrt[1787.71]{2379.98} = 10.00\% 
\]

Notice that only for Bonds C and D does the yield to maturity prevailing at the time of the original investment decision (i.e., the promised or expected return) equal the actual rate of return over the three-year investment horizon. To see why this is the case, it is easy to confirm that the duration statistics for each of these bonds are:

- Bond A: 6.89 years
- Bond B: 1.00 year (per bond)
- Bond C: 3.00 years
- Bond D: 3.00 years

Because the investor’s planning horizon was three years, the only bonds that actually produced the expected yield of 10 percent were the two that have durations of three years. Put another way, by investing in a bond that pays out the “average” cash flow at precisely the time it is desired, it is possible to completely offset the effects of a subsequent change in interest rates. If interest rates fall (rise) after purchase, the bond price will rise (fall) by exactly enough to offset the decline (increase) in income from reinvested coupons. Once again, this selection process is known as immunization.

On the other hand, when the investor tried to fund a three-year liability with a longer-duration bond (i.e., Bond A), she had to sell the bond to get the majority of her cash out of the position. This resulted in a situation where the price risk component dominated the reinvestment risk component (i.e., net price risk). This produced a higher actual return than she was promised (12.72 versus 10 percent) because rates in the market fell, which benefited the bond’s price more than it hurt coupon reinvestment potential. Conversely, when she tried to fund the three-year liability with a series of shorter-duration positions (i.e., Bond B), she received her cash back sooner than she needed it and therefore faced a net reinvestment risk problem, which in this case led to a lower realized yield as rates fell. However, the important point here is that with either Bond A or Bond B, the investor faces uncertainty over the outcome of her investment, as can be seen from the fact that her realized yield differed from her promised yield.

In summary, given that bond risk caused by changing interest rates can be split into price risk and reinvestment risk, the following general statements can be made:

- If \( \text{Duration} > \text{Investment Horizon} \), the investor faces Net Price Risk (Bond A).
- If \( \text{Duration} < \text{Investment Horizon} \), the investor faces Net Reinvestment Risk (Bond B).
- If \( \text{Duration} = \text{Investment Horizon} \), the investor is immunized (Bonds C and D).

Finally, it should be noted that setting the duration of an asset equal to the duration of the liability (i.e., investment horizon) will just immunize an investment against the next interest rate movement. However, the position will remain immunized to subsequent yield changes as long as it is rebalanced promptly; this is demonstrated in the appendix to this chapter.

**Another View of Immunization**

An earlier example assumed that bond positions were acquired and held to the end of the desired investment horizon. An alternative way to envision what will happen with an immunized portfolio would be to examine the specific growth path that converts the beginning-wealth position into the ending-wealth position and then consider what happens when interest rates change.

Suppose you have the following conditions to begin with: an initial-wealth position of $1 million, your investment horizon is 10 years, and the coupon and current YTM are both 8 percent. From an earlier computation, this implies an ending-wealth position (assuming semiannual compounding) of $2,191,123; Exhibit 19.16A illustrates this compound growth.

For Bond A, the initial investment (per $1,000 of face value) is:

\[
P_0 = \sum_{t=1}^{10} \frac{90}{(1 + .10)^t} + \frac{1000}{(1 + .10)^{10}} = 938.55
\]

Since this position will not have matured by Year 3, it will have to be sold at the prevailing market rate (assumed to then be 8 percent). Also, she will be able to reinvest the coupons she receives prior to her planning horizon. Thus, the ending-wealth in this position is the combination of:

1. Sale of Bond:

   \[
P_A = \sum_{t=1}^{3} \frac{90}{(1 + .08)^t} + \frac{1000}{(1 + .08)^3} = 1052.06, \text{ and}
\]

2. Reinvested Coupon Payments:

   \[
   90(1 + .08)^2 + 90(1 + .08) + 90 = 292.18
   \]

or $1344.24. This means the investor’s realized yield in Bond A would be:

\[
R_{Y_A} = \sqrt[1344.24]{938.55} - 1 = 12.72\% 
\]

For Bond B, assume for simplicity that the bondholder invests $1,000 initially at 10 percent and then reinvests the total annual proceeds for two more years at 8 percent:

Year 1: \((1000.00)(1 + .10) = 1100.00\)

Year 2: \((1100.00)(1 + .08) = 1188.00\)

Year 3: \((1188.00)(1 + .08) = 1283.04\)

Thus, her realized yield from this “rollover” strategy would be:

\[
R_{Y_B} = \sqrt[1283.04]{1000.00} - 1 = 8.66\% 
\]

The initial purchase price of Bond C (per $1,000 face value) is:

\[
P_0 = (1000) \times (1 + .10)^3 = 751.31
\]

so, the realized yield would be:

\[
R_{Y_C} = \sqrt[751.31]{1000.00} - 1 = 10.00\% 
\]

Finally, Bond D is similar to Bond A in that it must be sold prior to maturity and its coupons must be reinvested. The initial price for this security is:

\[
P_0 = \sum_{t=1}^{4} \frac{348.50}{(1 + .10)^t} + \frac{1000}{(1 + .10)^3} = 1787.71
\]

The ending-wealth level in Year 3 combines:

1. Sale of Bond:

   \[
P_A = (1000 + 348.50)(1 + .08) = 1248.61, \text{ and}
\]

2. Coupon Payments:

   \[
   348.50(1 + .08)^2 + 348.50(1 + .08) + 348.50 = 1131.37
   \]
or $2379.98 and, thus, the realized yield would be:

$$RY_D = \sqrt[4]{\frac{2379.98}{1787.71}} - 1 = 10.00 \text{ percent}$$

Notice that only for Bonds C and D does the yield to maturity prevailing at the time of the original investment decision (i.e., the promised or expected return) equal the actual rate of return over the three-year investment horizon. To see why this is the case, it is easy to confirm that the duration statistics for each of these bonds are:

- Bond A: 6.89 years
- Bond B: 1.00 year (per bond)
- Bond C: 3.00 years
- Bond D: 3.00 years

Because the investor’s planning horizon was three years, the only bonds that actually produced the expected yield of 10 percent were the two that have durations of three years. Put another way, by investing in a bond that pays out the “average” cash flow at precisely the time it is desired, it is possible to completely offset the effects of a subsequent change in interest rates. If interest rates fall (rise) after purchase, the bond price will rise (fall) by exactly enough to offset the decline (increase) in income from reinvested coupons. Once again, this selection process is known as immunization.

On the other hand, when the investor tried to fund a three-year liability with a longer-duration bond (i.e., Bond A), she had to sell the bond to get the majority of her cash out of the position. This resulted in a situation where the price risk component dominated the reinvestment risk component (i.e., net price risk). This produced a higher actual return than she was promised (12.72 versus 10 percent) because rates in the market fell, which benefited the bond’s price more than it hurt coupon reinvestment potential. Conversely, when she tried to fund the three-year liability with a series of shorter-duration positions (i.e., Bond B), she received her cash back sooner than she needed it and therefore faced a net reinvestment risk problem, which in this case led to a lower realized yield as rates fell. However, the important point here is that with either Bond A or Bond B, the investor faces uncertainty over the outcome of her investment, as can be seen from the fact that her realized yield differed from her promised yield.

In summary, given that bond risk caused by changing interest rates can be split into price risk and reinvestment risk, the following general statements can be made:

- If $Duration > Investment \text{ Horizon}$, the investor faces Net Price Risk (Bond A).
- If $Duration < Investment \text{ Horizon}$, the investor faces Net Reinvestment Risk (Bond B).
- If $Duration = Investment \text{ Horizon}$, the investor is immunized (Bonds C and D).

Finally, it should be noted that setting the duration of an asset equal to the duration of the liability (i.e., investment horizon) will just immunize an investment against the next interest rate movement. However, the position will remain immunized to subsequent yield changes as long as it is rebalanced promptly; this is demonstrated in the appendix to this chapter.

Another View of Immunization An earlier example assumed that bond positions were acquired and held to the end of the desired investment horizon. An alternative way to envision what will happen with an immunized portfolio would be to examine the specific growth path that converts the beginning-wealth position into the ending-wealth position and then consider what happens when interest rates change.

Suppose you have the following conditions to begin with: an initial-wealth position of $1 million, your investment horizon is 10 years, and the coupon and current YTM are both 8 percent. From an earlier computation, this implies an ending-wealth position (assuming semiannual compounding) of $2,191,123; Exhibit 19.16A illustrates this compound growth
value will still grow to the original expected ending-wealth position. In this example, the actual Year 2 value of the portfolio after the rate increase will be $1,003,779. If this new portfolio value grows at 10 percent a year for eight years, the projected ending-wealth value will be:

\[ \$1,003,779 \times (1.05)^{16} = \$2,191,123 \]

Thus, the price decline is exactly offset by the higher reinvestment rate, assuming that the duration of the portfolio at the time of the yield movement was equal to the remaining investment horizon.

What happens if the duration of the portfolio is not properly matched to the desired investment horizon? If, for instance, duration is greater than eight years, the price change will exceed the impact of a new reinvestment rate as you face net price risk. Thus, if interest rates increase, the value of the portfolio after the rate change will be less than $1,003,779. In this case, even if the new value of the portfolio grew at the higher growth rate of 10 percent a year, it would not reach the original expected ending-wealth value. This scenario is shown in Exhibit 19.16C, where it is assumed that the value of the portfolio with a duration greater than eight years declined to $950,000. Assuming that this new portfolio value then grew at the higher growth rate for the rest of the investment horizon, its ending value would be:

\[ \$950,000 \times (1.05)^{16} = \$2,073,731 \]

Therefore, the shortfall of $117,392 between the original expected ending-wealth level and the realized position is due to the fact that the portfolio was not properly duration matched (i.e., immunized) when the interest rate change occurred.

Alternatively, assume that at Year 2 interest rates had declined at a time when portfolio duration was greater than eight years. The value of the position would have increased to the point that, even when reinvested at a lower growth rate, the ending-wealth level would exceed $2,191,123. Exhibit 19.16D shows what can happen if the portfolio is not properly matched and interest rates decline by 200 basis points to 6 percent. First, assuming that the portfolio is properly duration matched, its Year 2 value will increase to $1,365,435. If this amount subsequently grows at 6 percent for eight years, its ending value will be:

\[ \$1,365,435 \times (1.03)^{16} = \$2,191,123 \]

Instead, if duration exceeds eight years, the Year 2 portfolio value would be greater than the required value of $1,365,435. Supposing this amount to be $1,450,000, the revised ending-wealth position would be:

\[ \$1,450,000 \times (1.03)^{16} = \$2,326,824 \]

In this scenario, the projected ending-wealth value is greater than the original expected level because your portfolio was mismatched to your intended investment horizon and interest rates moved in your favor. The important point here is that when you are not duration matched, you are effectively speculating on interest rate changes and the result can be either very good or very bad. The purpose of immunization is to avoid this uncertainty and to lock in the expected ending-wealth level (i.e., $2,191,123), regardless of future interest rate movements.

### Exhibit 19.16 The Growth Path to the Expected Ending-Wealth Value and the Effect of Immunization

#### A. Constant 8 Percent Growth Rate

<table>
<thead>
<tr>
<th>Years</th>
<th>$1,000,000</th>

</tr>
</thead>
</table>

#### B. Effect of Interest Rate Increase after Two Years with Duration Equal to Investment Horizon

- 8% Growth Rate
  - Year 2 Value: $1,169,859
  - Year 10 Value: $2,191,123
- 10% Growth Rate
  - Year 2 Value: $1,003,779
  - Year 10 Value: $2,191,123

#### C. Effect of Interest Rate Increase with Duration Greater than Investment Horizon

- 8% Growth Rate
  - Year 2 Value: $1,169,859
  - Year 10 Value: $2,073,731
- 10% Growth Rate
  - Year 2 Value: $1,003,779
  - Year 10 Value: $2,191,123

#### D. Effect of Interest Rate Decline with Duration Greater than Investment Horizon

- 6% Growth Rate
  - Year 2 Value: $1,365,435
  - Year 10 Value: $2,191,123
- 8% Growth Rate
  - Year 2 Value: $1,169,859
  - Year 10 Value: $2,326,824

path. In Exhibit 19.16B, it is assumed that at the end of Year 2, interest rates increase by 200 basis points, from 8 percent to 10 percent. With no prior rate changes, at the end of Year 2 the value of the portfolio would have grown at an 8 percent compound rate to $1,169,859 ([1.04]^8 × $1 million). The rate change in Year 2 will impact the portfolio in two ways: (1) the market value (i.e., price) will decline to reflect the higher interest rates, and (2) the reinvestment potential, which is the future growth rate of the portfolio, will increase. The important question therefore is: What will be the new ending-wealth position of the portfolio? As we have seen, the answer depends on the duration of the position when rates change. Fisher and Weil (1971) showed that if portfolio duration is equal to the remaining investment horizon, the price decline will be such that, at the new reinvestment (i.e., growth) rate of 10 percent, the new portfolio
value will still grow to the original expected ending-wealth position. In this example, the actual Year 2 value of the portfolio after the rate increase will be $1,003,779. If this new portfolio value grows at 10 percent a year for eight years, the projected ending-wealth value will be:

$$1,003,779 \times (1.05)^{16} = 2,191,123$$

Thus, the price decline is exactly offset by the higher reinvestment rate, assuming that the duration of the portfolio at the time of the yield movement was equal to the remaining investment horizon.

What happens if the duration of the portfolio is not properly matched to the desired investment horizon? If, for instance, duration is greater than eight years, the price change will exceed the impact of a new reinvestment rate as you face net price risk. Thus, if interest rates increase, the value of the portfolio after the rate change will be less than $1,003,779. In this case, even if the new value of the portfolio grew at the higher growth rate of 10 percent a year, it would not reach the original expected ending-wealth value. This scenario is shown in Exhibit 19.16C, where it is assumed that the value of the portfolio with a duration greater than eight years declined to $950,000. Assuming that this new portfolio value then grew at the higher growth rate for the rest of the investment horizon, its ending value would be:

$$950,000 \times (1.05)^{16} = 2,073,731$$

Therefore, the shortfall of $117,392 between the original expected ending-wealth level and the realized position is due to the fact that the portfolio was not properly duration matched (i.e., immunized) when the interest rate change occurred.

Alternatively, assume that at Year 2 interest rates had declined at a time when portfolio duration was greater than eight years. The value of the position would have increased to the point that, even when reinvested at a lower growth rate, the ending-wealth level would exceed $2,191,123. Exhibit 19.16D shows what can happen if the portfolio is not properly matched and interest rates decline by 200 basis points to 6 percent. First, assuming that the portfolio is properly duration matched, its Year 2 value will increase to $1,365,435. If this amount subsequently grows at 6 percent for eight years, its ending value will be:

$$1,365,435 \times (1.03)^{16} = 2,191,123$$

Instead, if duration exceeds eight years, the Year 2 portfolio value would be greater than the required value of $1,365,435. Supposing this amount to be $1,450,000, the revised ending-wealth position would be:

$$1,450,000 \times (1.03)^{16} = 2,326,824$$

In this scenario, the projected ending-wealth value is greater than the original expected level because your portfolio was mismatched to your intended investment horizon and interest rates moved in your favor. The important point here is that when you are not duration matched, you are effectively speculating on interest rate changes and the result can be either very good or very bad. The purpose of immunization is to avoid this uncertainty and to lock in the expected ending-wealth level (i.e., $2,191,123), regardless of future interest rate movements.

**Application of Classical Immunization** Stonewall Insurance Ltd. (a pseudonym for a real company) is a property and casualty insurance firm that operates as an offshore subsidiary of a construction firm based in the United States. Stonewall’s primary function is to provide worker’s compensation insurance benefits to the employees of the parent firm. Although the construction firm has an excellent safety record, there are nevertheless occasional worksite accidents that require payment of compensation benefits. These benefit payments can continue for anywhere from a few months to several years; the parent firm conservatively plans for payments to continue an average of 3.5 to 4.5 years. Thus, they consider this to be the duration range of the potential liabilities (i.e., planning horizon) they face.
Chapter 19: Bond Portfolio Management Strategies

The uncertainty of both the size and length of the benefit claims that Stonewall is liable for makes the implementation of a cash-matched portfolio solution impractical. (It is typically the case that property and casualty insurance firms have less predictable liabilities than life insurance companies.) Their solution to this asset-liability management problem is to assemble a bond portfolio that has a duration statistic (expressed in modified form, in this case) of around 4.00 years. Details of the specific securities they held as of January 2011 are shown in Exhibit 19.17. Notice in particular that the portfolio holds 31 separate positions—mostly corporate bonds—with an aggregate market value of $32 million and an average credit grade of A1 (Moody’s) and A+ (Standard & Poor’s). More importantly, however, the portfolio has been assembled to have a modified duration of 3.96 years, which closely matches the target horizon period implied by their projected liabilities. Thus, the position is effectively immunized; an unexpected increase or decrease in interest rates at this point in time would have approximately equal and offsetting effects on the value of both Stonewall’s assets and liabilities, leaving the firm’s net worth unaffected by the rate movement.

This example also helps highlight some practical challenges an investor must face when designing an immunization strategy. First of all, except for the special case of a zero-coupon bond, an immunized portfolio will require frequent rebalancing. As shown in the appendix to this chapter, rebalancing will be necessary with every significant shift in the yield curve, but it will also be required by the passing of time. For instance, even if market rates do not change, after a year has passed (i.e., January 2012) the modified duration of the bond portfolio will be substantially lower than 3.96 years. (Because duration declines more slowly than maturity as time passes, the January 2012 modified duration level for the firm will be somewhat higher than 2.96 years.) Of course, since the target investment horizon would still be 4.00 years, this decay in portfolio duration would leave the firm in a position of net reinvestment risk and therefore adversely exposed to a subsequent downward movement in the yield curve. Thus, to remain immunized over time, the bond manager for Stonewall will periodically need to rebalance the portfolio to maintain the original duration target.

Second, in Chapter 18 we discussed the fact that duration changes inversely with changes in interest rates. This is the property that makes the relationship between a bond’s price and its yield a curved (i.e., convex) function rather than a straight line. Consequently, the manager of an immunized bond portfolio should also pay attention to the convexity statistic of the position. Specifically, in addition to duration matching the company’s assets and liabilities, the manager should attempt to construct a bond portfolio that has greater convexity than the firm’s liabilities. When the convexity of the assets exceeds that of the liabilities at a time when the durations are matched, the actual decline in value for an upward rate movement will be less severe for the assets than for the liabilities. While it is difficult to know if the convexity level of 23.92 for Stonewall’s portfolio accomplishes that goal without knowing more about the precise characteristics of its projected obligations, Kritzman (1992) demonstrates that for two portfolios with the same duration, the one with cash flows that are more spread out (i.e., less concentrated around the duration date) will have greater convexity. Thus, the bond ladder approach adopted by Stonewall’s managers (e.g., maturity dates ranging from 2012 to 2021) is likely to produce a more successful outcome than a portfolio that concentrated its cash flow payments around January 2015 (i.e., the current date plus 4.00 years).

Finally, because certain segments of the fixed-income market can be illiquid, there sometimes is a problem acquiring the bonds you have identified as optimal positions for your portfolio. For example, can you purchase the long-duration bonds you have targeted at a price that you consider to be acceptable? Further, bonds possessing the particular characteristics you need to match the target horizon exactly may not be available. Thus, Stonewall’s modified duration statistic of 3.96 is likely as close as the manager could get to the target horizon of 4.00, given the nature of the bond market at the time of the example. In summary, it is important to recognize that classical immunization is generally not a passive strategy because it is subject to all of these practical issues that demand the attention of the manager.
19.5.3 Horizon Matching

Horizon matching is a combination of two of the techniques just discussed: cash-matching dedication and immunization. As shown in Exhibit 19.18, the liability stream is divided into two segments. In the first segment, the portfolio is constructed to provide a cash match for the liabilities during this horizon period (e.g., the first five years). The second segment is the remaining liability stream following the end of the horizon period—in the example, it is the 25 years following 2018. During this second time period, the liabilities are covered by a duration-matched strategy based on immunization principles. As a result, Leibowitz (1986b) contends that the client receives the certainty of cash matching during the early years and the cost saving and flexibility of duration-matched flows thereafter.

The combination technique also helps alleviate one of the problems with classical immunization: the potential for nonparallel shifts in the yield curve. Most of the problems related to nonparallel shifts are concentrated in the short end of the yield curve because this is where the most severe curve reshaping typically occurs. Because the near-term horizon is cash-matched, however, these irregular rate changes are not of concern. Further, we know that the long end of the yield curve tends toward parallel shifts.

As part of their discussion on horizon matching, Leibowitz, Klaffky, Mandel, and Weinberger (1983) point out that it also is possible to consider rolling out the cash-matched segment over time. Specifically, after the first year the portfolio manager would restructure the portfolio to provide a cash match during the original Year 6, which means that you would still have Exhibit 19.18

Chapter 19: Bond Portfolio Management Strategies
19.5.3 Horizon Matching

Horizon matching is a combination of two of the techniques just discussed: cash-matching dedication and immunization. As shown in Exhibit 19.18, the liability stream is divided into two segments. In the first segment, the portfolio is constructed to provide a cash match for the liabilities during this horizon period (e.g., the first five years). The second segment is the remaining liability stream following the end of the horizon period—in the example, it is the 25 years following 2018. During this second time period, the liabilities are covered by a duration-matched strategy based on immunization principles. As a result, Leibowitz (1986b) contends that the client receives the certainty of cash matching during the early years and the cost saving and flexibility of duration-matched flows thereafter.

The combination technique also helps alleviate one of the problems with classical immunization: the potential for nonparallel shifts in the yield curve. Most of the problems related to nonparallel shifts are concentrated in the short end of the yield curve because this is where the most severe curve reshaping typically occurs. Because the near-term horizon is cash-matched, however, these irregular rate changes are not of concern. Further, we know that the long end of the yield curve tends toward parallel shifts.

As part of their discussion on horizon matching, Leibowitz, Klaftky, Mandel, and Weinberger (1983) point out that it also is possible to consider rolling out the cash-matched segment over time. Specifically, after the first year the portfolio manager would restructure the portfolio to provide a cash match during the original Year 6, which means that you would still have a

fifteen-year horizon. The ability and cost of rolling out depends on movements in interest rates; ideally, you would still want to see parallel shifts in the yield curve.

**19.6 Contingent and Structured Management Strategies**

Contingent procedures for managing bond portfolios are a form of what has come to be called structured active management. The specific contingent procedure we discuss here is contingent immunization, which is a strategy that allows the bond manager flexibility to actively manage the portfolio subject to an overriding constraint that the portfolio remains immunized at some predetermined yield level. Other structured bond strategies, which typically involve using derivative securities (e.g., futures or option contracts), will be discussed in Chapters 20–23.

**19.6.1 Contingent Immunization**

Subsequent to the developments of classical immunization, Leibowitz and Weinberger (1982, 1983) suggest a portfolio strategy that allows a bond portfolio manager to pursue the highest returns available through active strategies while relying on classical bond immunization techniques to ensure a given minimal return over the investment horizon. To understand contingent immunization, recall from our earlier discussion that when the portfolio duration is equal to the investment horizon, a change in interest rates will cause a change in the dollar value of the portfolio such that when the new asset value is compounded at the new market interest rate, it will equal the expected (desired) ending wealth value. This required change in value occurs only when the modified duration of the portfolio is equal to the remaining time horizon, which is why the modified duration of the portfolio must be maintained at the horizon value.

Consider the following example of this process. Assume that your desired ending-wealth value is $206.3 million and we want to determine how much you must invest today to attain that ending value if you assume a rate of return on the portfolio. In this case, we assume a fifteen-year horizon and a 15 percent return, meaning that we compute the present value of $206.3 million at 15 percent for five years or 7.5 percent for 10 periods assuming semiannual compounding, which equals $100 million—this is the required initial investment under these assumptions to attain the desired ending value. Assuming the five-year horizon, we can do the same calculation for other interest rates as follows:

<table>

<sup>a</sup>Present value for 10 periods (5 years) at one-half the annual percentage rate.

Exhibit 19.19 reflects these calculations—the dark line indicates the required initial amount that must be invested at every yield level to attain $206.3 million in five years. Clearly, at lower yields you need a larger initial investment (e.g., $126.65 million at 10 percent), and it declines with higher yields (e.g., it is less than $80 million at 20 percent). The dotted line indicates that the price sensitivity of a portfolio with a modified duration of five years will have almost exactly the price sensitivity required.
the portfolio manager might consider acquiring a 30-year bond that has a modified duration greater than the investment horizon of five years and, therefore, has greater price sensitivity to changes in market rates. Hence, if rates decline as expected, the value of the long-duration portfolio will experience a rapid increase above the initial value. In contrast, if rates increase, the value of the portfolio will decline rapidly. In this case, depending on how high rates go, the value of the portfolio could decline to a value below that needed to reach the desired ending-wealth value of $196.72 million.

Exhibit 19.21 shows what happens to the value of this portfolio if we assume an instantaneous change in interest rates when the fund is established. Specifically, if rates decline from 15 percent, the portfolio of long-duration, 30-year bonds would experience a large increase in value and develop a safety margin—a portfolio value above the required value. In contrast, if rates increase, the value of the portfolio will decline until it reaches the asset value required at 14 percent. When the value of the portfolio reaches this point of minimum return (referred to as a trigger point), it is necessary to stop active portfolio management and use classical immunization with the remaining assets to ensure that you attain the desired ending-wealth value (i.e., $196.72 million).

Potential Return

The concept of potential return is helpful in understanding the objective of contingent immunization. This is the return the portfolio would achieve over the entire investment horizon if, at any point, the assets on hand were immunized at the prevailing market rate. Contingent immunization requires that the client be willing to accept a potential return below the current market return. This is referred to as a cushion spread, or the difference between the current market return and some floor rate. This cushion spread in required yield provides flexibility for the portfolio manager to engage in active portfolio strategies. For example, if current market rates are 15 percent, the client might be willing to accept a floor rate of 14 percent. If we assume the client initiated the fund with $100 million, the acceptance of this lower rate will mean that the portfolio manager does not have the same ending-asset requirements. Specifically, at 14 percent the required ending-wealth value would be $196.72 million (7 percent per period for 10 periods) compared to the $206.3 million at 15 percent. Because of this lower floor rate (and lower ending-wealth value), it is possible to experience some declines in the value of the portfolio while attempting to do better than the market through active management strategies.

Exhibit 19.20 shows the value of assets that are required at the beginning, assuming a 14 percent required return and the implied ending-wealth value of $196.72 million. Assuming current market rates of 15 percent, the required value of assets at the beginning would be $95.56 million, which is the present value of $196.72 million at 15 percent for five years. The difference between the client’s initial fund of $100 million and the required assets of $95.56 million is the dollar cushion available to the portfolio manager. As noted, this dollar cushion arises because the client has agreed to a lower investment rate and, therefore, a lower ending-wealth value. Therefore, the manager effectively now has a $4.44 million ($100,000,000 – 95.56) “side fund” with which to pursue active management strategies in an attempt to add alpha to the overall portfolio.

At this point, the portfolio manager can engage in active management strategies to increase the ending-wealth value of the portfolio above that required at 14 percent. As an example, assume that the portfolio manager believes that market rates will decline. Under such conditions,
the portfolio manager might consider acquiring a 30-year bond that has a modified duration greater than the investment horizon of five years and, therefore, has greater price sensitivity to changes in market rates. Hence, if rates decline as expected, the value of the long-duration portfolio will experience a rapid increase above the initial value. In contrast, if rates increase, the value of the portfolio will decline rapidly. In this case, depending on how high rates go, the value of the portfolio could decline to a value below that needed to reach the desired ending-wealth value of $196.72 million.

Exhibit 19.21 shows what happens to the value of this portfolio if we assume an instantaneous change in interest rates when the fund is established. Specifically, if rates decline from 15 percent, the portfolio of long-duration, 30-year bonds would experience a large increase in value and develop a safety margin—a portfolio value above the required value. In contrast, if rates increase, the value of the portfolio will decline until it reaches the asset value required at 14 percent. When the value of the portfolio reaches this point of minimum return (referred to as a trigger point), it is necessary to stop active portfolio management and use classical immunization with the remaining assets to ensure that you attain the desired ending-wealth value (i.e., $196.72 million).

Potential Return The concept of potential return is helpful in understanding the objective of contingent immunization. This is the return the portfolio would achieve over the entire investment horizon if, at any point, the assets on hand were immunized at the prevailing market
rate. Exhibit 19.22 contains the various potential rates of return based on dollar asset values shown in Exhibit 19.21. If the portfolio were immediately immunized when market rates were 15 percent, its potential return would naturally be 15 percent. Alternatively, if yields declined instantaneously to 10 percent, the portfolio’s asset value would increase to $147 million, which if immunized at the market rate of 10 percent over the remaining five-year period, would grow to a total value of $239.45 million ($147 million × 1.6289, which is the compound growth factor for 5 percent and 10 periods). This ending value of $239.45 million represents an 18.25 percent realized (horizon) rate of return on the original $100 million portfolio.

In contrast, if interest rates increase, the value of the portfolio will decline substantially and the potential return will decline. For example, if market rates rise to 17 percent (i.e., a yield change of 2 percent), the asset value of the 30-year bond portfolio will decline to $88 million. If this portfolio of $88 million were immunized for the remaining five years at the prevailing market rate of 17 percent, the ending value would be $199 million. This ending value implies a potential return of 14.32 percent for the total period.

As Exhibit 19.21 shows, if interest rates rose to 18.50 percent, the 30-year bonds would decline to a value of $81.16 million (the trigger point) and the portfolio would have to be immunized. At this point, if the remaining assets of $81.16 million were immunized at the current market rate of 18.50 percent, the value of the portfolio would grow to $196.73 million ($81.16 × 2.424, which is the compound value factor for 9.25 percent for 10 periods). This ending value implies that the potential return for the portfolio would be exactly 14 percent. Regardless of what happens
to subsequent market rates, the portfolio has been immunized at the floor rate of 14 percent. That is a major characteristic of the contingent immunized portfolio; if there is proper monitoring, you will always know the trigger point where you must immunize to be assured of receiving no less than the minimum specified rate of return.

**Monitoring the Immunized Portfolio** Clearly, monitoring the contingent immunized portfolio is crucial to ensure that, if the asset value falls to the trigger point, the appropriate action is taken to ensure that the portfolio is immunized at the floor-level rate. This can be done using a chart, as in Exhibit 19.23. The top line is the current market value of the portfolio over time. The bottom line is the required value of the portfolio if we were to immunize at today’s rates to attain the necessary ending-wealth value. This required minimum value for the portfolio is calculated by computing the present value of the promised ending-wealth value at the prevailing market rate.

To demonstrate how this floor portfolio would be constructed, consider again our example with a promised ending-wealth value in five years of $196.72 million, based on an initial investment of $100 million and an acceptable floor rate of 14 percent. If one year after the initiation of the portfolio, market rates were 10 percent, you would need a minimum portfolio value of approximately $133.14 million to get to $196.72 million in four years. To compute this minimum required value, you multiply the $196.72 million (promised ending-wealth value) times the present value factor for 5 percent for eight periods, assuming semiannual compounding (0.6768). The logic is that $133.14 million ($196.72 × 0.6768) invested at 10 percent for four years will equal $196.72 million.

If you originally predicted correctly that market rates would decline and had structured a long-duration portfolio under these conditions, the actual value of the portfolio would be much higher than this minimum required value, and there would be a safety margin. A year later (after Year 2), you would determine the assets needed at the rate prevailing at that point

---

In time. Assuming interest rates had by then increased to 12 percent, you could determine that you would need a floor portfolio of about $138.69 million, which is the present value of the $196.72 million for three years at 12 percent, assuming semiannual compounding. Again, you would expect the actual value of the portfolio to be greater than this required floor portfolio, so you still have a safety margin. If you ever reached the point where the actual value of the portfolio was equal to the required floor value, you would stop the active management and immunize what was left at the current market rate to ensure that the ending value of the portfolio would be $196.72 million.

**SUMMARY**

- During the past few decades, there has been a significant increase in the number and variety of bond portfolio strategies available to individual investors and professional managers. These strategies, which range from being quite simple to quite complex to implement and maintain, can be classified into five separate categories: passive management techniques, active management techniques, core-plus management techniques, matched-funding techniques, and contingent and structured techniques.

- Passive approaches to managing a bond portfolio can take two forms. Buy-and-hold investors simply choose a selection of bonds with the desired set of characteristics (e.g., duration, coupon rate, credit quality) and replace them when they mature. By contrast, an investor following an indexed approach constructs a portfolio that mimics the contents of a particular bond index. The construction of an indexed portfolio can either fully replicate the underlying benchmark or follow a stratified sampling approach that attempts to...
reproduce the index characteristics, usually with a smaller number of instruments.

- Active bond management strategies attempt to exceed the risk-return performance produced by a bond index over time. The active manager does this by assembling a collection of bonds that differs from those in the benchmark in a manner consistent with his view of future bond market conditions. There are many active strategies available, including interest rate anticipation, credit analysis, valuation analysis, yield spread analysis, and global and tactical techniques. Core-plus bond management can be viewed as type of enhanced indexing that combines passive and active techniques.

- Many institutional investors (e.g., pension funds, insurance companies) employ matched-funding strategies when the investment problem they confront involves forming a portfolio of assets designed to pay off a specific set of liabilities. Immunization techniques based on matching the durations of the organization’s assets and liabilities are particularly useful in providing protection against adverse interest rate movements. Finally, contingent immunization is a form of structured active management that combines a classical immunization approach with some active management techniques.

**SUGGESTED READINGS**

**QUESTIONS**

1. Bond index mutual funds and exchange-traded funds (ETFs) using bonds have become increasingly popular in recent years.
   a. Would it be more or less difficult to construct a bond index mutual fund than an equity index mutual fund? Give three reasons to support your argument.
   b. Would it be more or less difficult to maintain a bond index ETF than an equity index ETF? Give three reasons to support your argument.

2. After determining the appropriate asset allocation to meet Lucinda Kennedy’s needs, Richard Bulloch, CFA, invests a portion of Kennedy’s assets in two fixed-income investment funds:
   - **Trinity Index Fund**: A passively managed portfolio of global bonds designed to track the Barclays Global Aggregate Bond (LGAB) Index using a pure bond indexing strategy. The management fee is 15 basis points annually.
   - **Montego Global Bond Fund**: An actively managed portfolio of global bonds designed to outperform the LGAB net of fees. The management fee is 50 basis points annually.

   Six months after investing in these funds, Kennedy and Bulloch review the performance data shown in the following exhibit:

<table>

8. The ability to immunize a bond portfolio is very desirable for bond portfolio managers in some instances.

a. Discuss the components of interest rate risk. Assuming a change in interest rates over time, explain the two risks faced by the holder of a bond.

b. Define immunization, and discuss why a bond manager would immunize a portfolio.

c. Explain why a duration-matching strategy is a superior technique to a maturity-matching strategy for the minimization of interest rate risk.

d. Explain in specific terms how you would use a zero-coupon bond to immunize a bond portfolio. Discuss why a zero-coupon bond is an ideal instrument in this regard.

e. Explain how contingent immunization, another bond portfolio management technique, differs from classical immunization. Discuss why a bond portfolio manager would engage in contingent immunization.

9. During the past several years, there has been substantial growth in the dollar amount of portfolios managed using immunization and dedication techniques. Assume a client wants to know the basic differences between (1) classical immunization, (2) contingent immunization, (3) cash-matched dedication, and (4) duration-matched dedication.

a. Briefly describe each of these four techniques.

b. Briefly discuss the ongoing investment action you would have to carry out if managing an immunized portfolio.

c. Briefly discuss three of the major considerations involved with creating a cash-matched dedicated portfolio.

d. Describe two parameters that should be specified when using contingent immunization.

e. Select one of the four alternative techniques that you believe requires the least degree of active management and justify your selection.

10. A large charitable endowment fund constructed a fixed-income portfolio at the time it was established and has kept its allocation unchanged over the years. While the charitable founder asks you whether it may be possible for the fund to improve its initial allocation by restructuring, the founder emphasizes the importance of maintaining its primary investment objective. Under what conditions would such structuring be beneficial to the charitable fund? Give three reasons to support your answers, and provide an example for each reason.

11. Robert Devlin and Neil Parish are portfolio managers at the Broward Investment Group. At their regular Monday strategy meeting, the topic of adding international bonds to one of their portfolios came up. The portfolio, an ERISA-qualified pension account for a U.S. client, was currently 90 percent invested in U.S. Treasury bonds and 10 percent invested in 10-year Canadian government bonds.

Devlin suggested buying a position in 10-year German government bonds, while Parish argued for a position in 10-year Australian government bonds.

a. Briefly discuss the three major issues that Devlin and Parish should address in their analyses of the return prospects for German and Australian bonds relative to those of U.S. bonds.

b. Identify and discuss two reasons for adding a broader mix of international bonds to the pension portfolio.

12. A consultant suggests that the weighted-average portfolio duration calculation for a global bond portfolio is the same as for a domestic bond portfolio.

a. State whether the use of portfolio duration in international bond portfolio management is more limiting than in domestic bond portfolio management. Support your conclusion with two reasons.
8. The ability to immunize a bond portfolio is very desirable for bond portfolio managers in some instances.
   a. Discuss the components of interest rate risk. Assuming a change in interest rates over time, explain the two risks faced by the holder of a bond.
   b. Define immunization, and discuss why a bond manager would immunize a portfolio.
   c. Explain why a duration-matching strategy is a superior technique to a maturity-matching strategy for the minimization of interest rate risk.
   d. Explain in specific terms how you would use a zero-coupon bond to immunize a bond portfolio. Discuss why a zero-coupon bond is an ideal instrument in this regard.
   e. Explain how contingent immunization, another bond portfolio management technique, differs from classical immunization. Discuss why a bond portfolio manager would engage in contingent immunization.

9. During the past several years, there has been substantial growth in the dollar amount of portfolios managed using immunization and dedication techniques. Assume a client wants to know the basic differences between (1) classical immunization, (2) contingent immunization, (3) cash-matched dedication, and (4) duration-matched dedication.
   a. Briefly describe each of these four techniques.
   b. Briefly discuss the ongoing investment action you would have to carry out if managing an immunized portfolio.
   c. Briefly discuss three of the major considerations involved with creating a cash-matched dedicated portfolio.
   d. Describe two parameters that should be specified when using contingent immunization.
   e. Select one of the four alternative techniques that you believe requires the least degree of active management and justify your selection.

10. A large charitable endowment fund constructed a fixed-income portfolio at the time it was established and has kept its allocation unchanged over the years. While the charitable founder asks you whether it may be possible for the fund to improve its initial allocation by restructuring, the founder emphasizes the importance of maintaining its primary investment objective. Under what conditions would such structuring be beneficial to the charitable fund? Give three reasons to support your answers, and provide an example for each reason.

11. Robert Devlin and Neil Parish are portfolio managers at the Broward Investment Group. At their regular Monday strategy meeting, the topic of adding international bonds to one of their portfolios came up. The portfolio, an ERISA-qualified pension account for a U.S. client, was currently 90 percent invested in U.S. Treasury bonds and 10 percent invested in 10-year Canadian government bonds.
    Devlin suggested buying a position in 10-year German government bonds, while Parish argued for a position in 10-year Australian government bonds.
    a. Briefly discuss the three major issues that Devlin and Parish should address in their analyses of the return prospects for German and Australian bonds relative to those of U.S. bonds.
    Having made no changes to the original portfolio, Devlin and Parish hold a subsequent strategy meeting and decide to add positions in the government bonds of Japan, the United Kingdom, France, Germany, and Australia.
    b. Identify and discuss two reasons for adding a broader mix of international bonds to the pension portfolio.

12. A consultant suggests that the weighted-average portfolio duration calculation for a global bond portfolio is the same as for a domestic bond portfolio.
   a. State whether the use of portfolio duration in international bond portfolio management is more limiting than in domestic bond portfolio management. Support your conclusion with two reasons.
The consultant recognizes that currency, duration, and investing outside the benchmark are possible sources of excess return in global bond management. He is also curious about additional methods of adding value through global bond management.

b. List and discuss two additional potential sources of excess return.

## PROBLEMS

1. The par yield curve for U.S. Treasury bonds is currently flat across all maturities at 5.50 percent. You have observed following “paired” transaction by your bond portfolio manager:

<table>
<thead>
<tr>
<th>Bond</th>
<th>Transaction</th>
<th>Type</th>
<th>Credit Spread (bp)</th>
<th>Maturity (yrs.)</th>
<th>Coupon Rate (%)</th>
<th>Modified Duration</th>
</tr>
</thead>
<tbody>
<tr>
<td>G</td>
<td>Buy</td>
<td>U.S. Govt.</td>
<td>—</td>
<td>15</td>
<td>0</td>
<td>14.599</td>
</tr>
<tr>
<td>H</td>
<td>Sell</td>
<td>Corporate</td>
<td>100</td>
<td>7</td>
<td>8</td>
<td>5.386</td>
</tr>
</tbody>
</table>

Briefly discuss what this paired trade suggests to you about the manager’s implied view as to: (1) the general direction of future interest rate movement, (2) the future shape of the par yield curve, and (3) the future level of corporate bond credit spreads.

2. Answer the following questions assuming that at the initiation of an investment account, the market value of your portfolio is $200 million, and you immunize the portfolio at 12 percent for six years. During the first year, interest rates are constant at 12 percent.
   a. What is the market value of the portfolio at the end of Year 1?
   b. Immediately after the end of the year, interest rates decline to 10 percent. Estimate the new value of the portfolio, assuming you did the required rebalancing (use only modified duration).

3. Compute the Macaulay duration under the following conditions:
   a. A bond with a five-year term to maturity, a 12 percent coupon (annual payments), and a market yield of 10 percent.
   b. A bond with a four-year term to maturity, a 12 percent coupon (annual payments), and a market yield of 10 percent.
   c. Compare your answers to Parts a and b, and discuss the implications of this for classical immunization.

4. Compute the Macaulay duration under the following conditions:
   a. A bond with a four-year term to maturity, a 10 percent coupon (annual payments), and a market yield of 8 percent.
   b. A bond with a four-year term to maturity, a 10 percent coupon (annual payments), and a market yield of 12 percent.
   c. Compare your answers to Parts a and b. Assuming it was an immediate shift in yields, discuss the implications of this for classical immunization.

5. Evaluate the following pure-yield pickup swap: You currently hold a 20-year, AA-rated, 9.0 percent coupon bond priced to yield 11.0 percent. As a swap candidate, you are considering a 20-year, AA-rated, 11 percent coupon bond priced to yield 11.5 percent. (Assume reinvestment at 11.5 percent.)
and the required value of the floor portfolio. This difference is defined as the margin of error. In this regard, assume a $300 million portfolio with a time horizon of five years. The available market rate at the initiation of the portfolio is 12 percent, but the client is willing to accept 10 percent as a floor rate to allow use of active management strategies. The current market values and current market rates at the end of Years 1, 2, and 3 are as follows:

<table>
<thead>
<tr>
<th>End of Year</th>
<th>Market Value ($ Mil)</th>
<th>Market Yield</th>
<th>Required Floor Portfolio ($ Mil)</th>
<th>Margin of Error ($ Mil)</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>$340.9</td>
<td>10%</td>
<td></td>
<td></td>
</tr>
<tr>
<td>2</td>
<td>$405.5</td>
<td>8%</td>
<td></td>
<td></td>
</tr>
<tr>
<td>3</td>
<td>$395.2</td>
<td>12%</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Assuming semiannual compounding:

a. Calculate the required ending-wealth value for this portfolio.

b. Calculate the value of the required floor portfolios at the end of Years 1, 2, and 3.

c. Compute the margin of error at the end of Years 1, 2, and 3.

d. Indicate the action that a portfolio manager utilizing a contingent immunization policy would take if the margin of error at the end of any year had been zero or negative.

9. Mike Smith, CFA, an analyst with Blue River Investments, is considering buying a Montrose Cable Company Corporate bond. He has collected the balance sheet and income statement information for Montrose, as shown in Exhibit 19.24. He has also calculated the three ratios shown in Exhibit 19.25, which indicate that the bond is currently rated “A,” according to the firm’s internal bond-rating criteria shown in Exhibit 19.27. Smith has decided to consider some off-balance-sheet items in his credit analysis, as shown in Exhibit 19.26. Specifically, Smith wishes to evaluate the impact of each of the off-balance-sheet items on each of the ratios found in Exhibit 19.25.

| Exhibit 19.24 Montrose Cable Company: Year Ended March 31, 1999 (USD Thousand) |
|---------------------------------|-----------------|-----------------|-----------------|-----------------|
| **Balance Sheet**               |                 |                 |                 |                 |
| Current assets                  | $4,735          |                 |                 |                 |
| Fixed assets                    |                 | $43,225         |                 |                 |
| Total assets                    | $47,960         |                 |                 |                 |
| Current liabilities             | $4,500          |                 |                 |                 |
| Long-term debt                  |                 | $10,000         |                 |                 |
| Total liabilities               | $14,500         |                 |                 |                 |
| Shareholder’s equity            |                 | $33,460         |                 |                 |
| Total liabilities and shareholder’s equity | $47,960 |                 |                 |                 |

| **Income Statement**            |                 |                 |                 |                 |
| Revenue                         | $18,500         |                 |                 |                 |
| Operating and administrative expenses | $14,050   |                 |                 |                 |
| Operating income                | $4,450          |                 |                 |                 |
| Depreciation and amortization    | $1,675          |                 |                 |                 |
| Interest expense                | $942            |                 |                 |                 |
| Income before income taxes      | $1,833          |                 |                 |                 |
| Taxes                           | $641            |                 |                 |                 |
| Net income                      | $1,192          |                 |                 |                 |

6. Evaluate the following substitution swap: You currently hold a 25-year, 9.0 percent coupon bond priced to yield 10.5 percent. As a swap candidate, you are considering a 25-year, AA-rated, 9.0 percent coupon bond priced to yield 10.75 percent. (Assume a one-year work-out period and reinvestment at 10.5 percent.)

$150,000

a. Calculate the modified duration for this portfolio (i.e., Mod Dp).

b. Suppose you learn that the implied sensitivity (i.e., modified duration) of the endowment’s liabilities is about 6.50 years. Identify whether the bond portfolio is: (1) immunized against interest rate risk, (2) exposed to net price risk, or (3) exposed to net reinvestment risk. Briefly explain what will happen to the net position of the endowment fund if in the future there is a significant parallel upward shift in the yield curve.

c. Briefly describe how you could increase the convexity of the portfolio while keeping the modified duration at the same level.

d. Your current active view for the fixed-income market over the coming months is that Treasury yields will decline and corporate credit spreads will also decrease. Briefly discuss how you could restructure the existing portfolio to take advantage of this view.

8. A major requirement in managing a fixed-income portfolio using a contingent immunization policy is monitoring the relationship between the current market value of the portfolio
and the required value of the floor portfolio. This difference is defined as the *margin of error*. In this regard, assume a $300 million portfolio with a time horizon of five years. The available market rate at the initiation of the portfolio is 12 percent, but the client is willing to accept 10 percent as a floor rate to allow use of active management strategies. The current market values and current market rates at the end of Years 1, 2, and 3 are as follows:

<table>
<thead>
<tr>
<th>End of Year</th>
<th>Market Value ($ Mil)</th>
<th>Market Yield</th>
<th>Required Floor Portfolio ($ Mil)</th>
<th>Margin of Error ($ Mil)</th>
</tr>

<td></td>
</tr>
</tbody>
</table>

Assuming semiannual compounding:

a. Calculate the required ending-wealth value for this portfolio.

b. Calculate the value of the required floor portfolios at the end of Years 1, 2, and 3.

c. Compute the margin of error at the end of Years 1, 2, and 3.

d. Indicate the action that a portfolio manager utilizing a *contingent immunization* policy would take if the margin of error at the end of any year had been zero or negative.

9. Mike Smith, CFA, an analyst with Blue River Investments, is considering buying a Montrose Cable Company Corporate bond. He has collected the balance sheet and income statement information for Montrose, as shown in Exhibit 19.24. He has also calculated the three ratios shown in Exhibit 19.25, which indicate that the bond is currently rated “A,” according to the firm’s internal bond-rating criteria shown in Exhibit 19.27. Smith has decided to consider some off-balance-sheet items in his credit analysis, as shown in Exhibit 19.26. Specifically, Smith wishes to evaluate the impact of each of the off-balance-sheet items on each of the ratios found in Exhibit 19.25.

---

**Exhibit 19.24 Montrose Cable Company: Year Ended March 31, 1999**

(USD Thousand)

**Balance Sheet**

| Current assets | $4,735 |
| Fixed assets   | 42,225 |
| Total assets   | $47,960 |
| Current liabilities | $4,500 |
| Long-term debt | 10,000 |
| Total liabilities | $14,500 |
| Shareholder’s equity | 33,460 |
| Total liabilities and shareholder’s equity | $47,960 |

**Income Statement**

| Revenue | $18,500 |
| Operating and administrative expenses | 14,050 |
| Operating income | $4,450 |
| Depreciation and amortization | 1,675 |
| Interest expense | 942 |
| Income before income taxes | $1,833 |
| Taxes | 641 |
| Net income | $1,192 |
Bond Immunization and Portfolio Rebalancing

Suppose that you have decided to fund a three-year liability with a portfolio consisting of positions in a two-year zero-coupon bond and a four-year zero-coupon bond. The current interest rate is 10 percent. Therefore:

Price of 2-year bond \( \left( \frac{1000}{1.10} \right) = 826.45 \)

Price of 4-year bond \( \left( \frac{1000}{1.10} \right)^4 = 683.01 \)

In order to form a portfolio with duration of three years, you must purchase identical amounts of Bond 2 and Bond 4 since each of these zero-coupon instruments will have duration equal to its maturity. Consequently, you will need to buy 1.0 units of Bond 2 and \( \frac{826.45}{683.01} = 1.21 \) units of Bond 4 for a total initial investment of \( 826.45 + (1.21)(683.01) = 1652.89 \) dollars.

The duration of your bond portfolio can then be calculated:

\[
D_p = \left( \frac{826.45}{1652.89} \right)D_2 + \left( \frac{826.45}{1652.89} \right)D_4 = \frac{5}{2}D_2 + \frac{5}{4}D_4 = 3 \]

Immediately after you make your initial purchases, interest rates fall to 8 percent. If you do not rebalance your portfolio, what is your realized yield after three years? Compute:

Terminal Value of Portfolio:

1. Allow two-year bond to mature and reinvest for one year: \( (1000)(1.08) = 1080.00 \)
2. Sell 1.21 four-year bonds: \( (1.21)(1000 ÷ 1.08) = 1120.37 \)

so that your total terminal value is \( 2200.37 \) dollars, and the realized yield is:

\[
f = \sqrt[3]{\frac{2200.37}{1652.89}} - 1 = 10.00\% 
\]

Therefore, your actual return is equal to the original promised return (i.e., the yield to maturity) of 10 percent. By investing so that the duration of the portfolio is equal to your horizon date, you have immunized yourself against the first interest rate change and locked in the initial promised yield of 10 percent.

Now, continuing with the assumption that interest rates decline immediately after your initial purchases, suppose that you decide to rebalance your portfolio. To understand this, you need to first establish the new bond prices:

Price of Bond 2 \( \left( \frac{1000}{1.08} \right)^2 = 857.34 \)

Price of Bond 4 \( \left( \frac{1000}{1.08} \right)^4 = 735.03 \)

To see why you need to rebalance, calculate the new duration of your portfolio:

\[
D_p = \left( \frac{857.34}{1746.73} \right)D_2 + \left( \frac{889.39}{1746.73} \right)D_4 = \frac{4908}{737}D_2 + \frac{5092}{737}D_4 = 3.02
\]

a. Calculate the combined effect of the three off-balance-sheet items in Exhibit 19.26 on each of the following three financial ratios shown in Exhibit 19.25.

1. EBITDA/interest expense
2. Long-term debt/equity
3. Current assets/current liabilities

The bond is currently trading at a credit premium of 55 basis points. Using the internal bond-rating criteria in Exhibit 19.27, Smith wants to evaluate whether or not the credit yield premium incorporates the effect of the off-balance-sheet items.

b. State and justify whether or not the current credit yield premium compensates Smith for the credit risk of the bond, based on the internal bond-rating criteria found in Exhibit 19.27.
Bond Immunization and Portfolio Rebalancing

Suppose that you have decided to fund a three-year liability with a portfolio consisting of positions in a two-year zero-coupon bond and a four-year zero-coupon bond. The current interest rate is 10 percent. Therefore:

\[
\text{Price of 2-year bond (i.e., Bond 2)} = (1000) \times (1.1)^2 = $826.45
\]
\[
\text{Price of 4-year bond (i.e., Bond 4)} = (1000) \times (1.1)^4 = $683.01
\]

In order to form a portfolio with duration of three years, you must purchase identical amounts of Bond 2 and Bond 4 since each of these zero-coupon instruments will have duration equal to its maturity. Consequently, you will need to buy 1.0 units of Bond 2 and \((826.45 + 683.01) = 1.21\) units of Bond 4 for a total initial investment of $1652.89 \([826.45 + (1.21)(683.01)]\). The duration of your bond portfolio can then be calculated:

\[
D_p = (826.45 + 1652.89)(D_2) + (826.45 + 1652.89)(D_4)
\]
\[
= (.5)(2.00) + (.5)(4.00) = 3.00
\]

Immediately after you make your initial purchases, interest rates fall to 8 percent. If you do not rebalance your portfolio, what is your realized yield after three years? Compute:

Terminal Value of Portfolio:

1. Allow two-year bond to mature and reinvest for one year: \((1000)(1.08) = $1080.00\)
2. Sell 1.21 four-year bonds: \((1.21)(1000 + 1.08) = $1120.37\)

so that your total terminal value is $2200.37, and the realized yield is:

\[
\sqrt[3]{\frac{2200.37}{1652.89}} - 1 = 10.00\text{ percent}
\]

Therefore, your actual return is equal to the original promised return (i.e., the yield to maturity) of 10 percent. By investing so that the duration of the portfolio is equal to your horizon date, you have immunized yourself against the first interest rate change and locked in the initial promised yield of 10 percent.

Now, continuing with the assumption that interest rates decline immediately after your initial purchases, suppose that you decide to rebalance your portfolio. To understand this, you need to first establish the new bond prices:

\[
\text{Price of Bond 2} = (1000) \times (1.08)^2 = $857.34
\]
\[
\text{Price of Bond 4} = (1000) \times (1.08)^4 = $735.03
\]

To see why you need to rebalance, calculate the new duration of your portfolio:

\[
\text{Value of Investment in Bond 2} = \$857.34
\]
\[
\text{Value of Investment in Bond 4} = (1.21)(735.03) = \$889.39
\]
\[
\text{Value of Total Investment} = \$1746.73
\]

so:

\[
D_p = (857.34 + 1746.73)(D_2) + (889.39 + 1746.73)(D_4)
\]
\[
= (.4908)(2.00) + (.5092)(4.00) = 3.02
\]
Even though the change in interest rates didn’t change the duration of the individual bonds, it did increase the duration of the portfolio slightly since it altered the relative market values of Bond 2 and Bond 4. To correct the problem (i.e., to rebalance the portfolio), you need to shorten the overall duration by selling some of Bond 4 and purchasing some more of Bond 2. To accomplish this, you must once again invest equal dollar amounts in each security, or $873.365 [(1.5)(1746.73)]. This, in turn, means that you must own the following number of each instrument:

\[
\text{Number of Bond 2 to be held} = \frac{873.365 \times 857.39}{1000} = 1.0186
\]

\[
\text{Number of Bond 4 to be held} = \frac{873.365 \times 735.03}{1000} = 1.1882
\]

After completing this step, you have rebalanced your portfolio to immunize against future changes in interest rate movements. By once again holding equal amounts of each bond, you have reset the duration of the portfolio to your original investment horizon of three years. An important assumption here is that this rebalancing can be done costlessly. If you must pay brokerage fees, the total dollar value of your portfolio and hence your actual return will be reduced accordingly.

By rebalancing your portfolio, you have tampered with the composition of your initial investment. However, by doing so, have you also changed the realized yield that you will receive? Put another way, when you rebalance your portfolio at the new yield to maturity of 8 percent, will you still end up with the original yield of 10 percent? To answer this, calculate the terminal value of the rebalanced portfolio: (1) Allow 1.0182 two-year bonds to mature and reinvest for one year; \((1.0182)(1000)(1.08) = 1100.12\); and (2) sell 1.1882 four-year bonds; \((1.1882)(1000 \div 1.08) = 1100.19\). Thus, your total terminal value of the rebalanced investment is $2200.31, and the realized yield is:

\[
\sqrt[3]{\frac{2200.31}{1652.89}} - 1 = 10.00 \text{ percent}
\]

Therefore, rebalancing your portfolio when interest rates change has two effects: (1) you immunize yourself against the next interest rate change, and (2) your actual return is still equal to the yield to maturity that prevailed at the time of your original investment. Finally, it should be noted that although we assumed that the interest rate changed immediately after the initial purchase, the fundamentals of rebalancing also apply to yield curve shifts that occur at any point in the duration of the investment.
In recent years, it has been difficult to read the financial press without encountering at least a passing reference to an economic scandal attributed to trading in derivative securities. Procter & Gamble’s ill-fated swap transactions and the equity index futures trades that brought down Barings Bank give the casual reader the impression that derivatives are highly volatile instruments used only by those investors interested in placing speculative “bets.” Of course, nothing could be further from the truth. Although it is true that the companies in these examples either miscalculated or misunderstood the nature of their investment positions, the vast majority of derivative transactions are used by individuals and institutions seeking to reduce the risk exposures generated by their other business ventures. Derivatives, in their many forms, have become a vital part of modern security markets, trailing only stocks and bonds in terms of importance. Unlike stocks and bonds, however, their widespread use is a relatively recent phenomenon, and misconceptions still exist about how derivatives work and the proper way for investors to trade them. The chapters in this section address this concern by providing the investor with a framework for understanding how derivatives are valued and used in practice. Chapter 20 begins this process by detailing the mechanics of the two basic forms of derivative contract—fowards and options. After providing an initial description of these instruments and the markets in which they trade, we present the fundamental principles that determine their prices. The chapter concludes with several specific examples of how investors use derivatives to adjust the risk-return characteristics of their stock and bond portfolios. Chapter 21 analyzes forward and futures contracts—the most prevalent form of derivative instrument. The similarities and differences between forward and futures contracts are described, with particular emphasis on the creation of (and subsequent adjustments to) margin accounts and the concept of basis risk. In addition, the calculation of the optimal hedge ratio and the arbitrage-free approach to determining the contract delivery price are discussed. The chapter concludes with an examination of the features of forward and futures contracts that are designed to offset financial (as opposed to commodity) risk exposures, including interest rate, equity, and currency price movements. Applications and investment strategies involving each of these contract types illustrate this discussion. In Chapter 22, the focus turns to option contracting. The discussion begins with a consideration of how option markets are organized and how both puts and calls—the two basic types of option contracts—are quoted and traded. Several different option-based investment and hedging strategies are described, as well as how these contracts can be used in conjunction with other securities to create customized payoff distributions. The chapter also includes a formal treatment of how option contracts are valued in an efficient market. Starting with the simple two-state option pricing model, which contains the essence of the basic valuation argument, the discussion progresses to include state-of-the-art approaches such as the binomial and the Black-Scholes models. In this development, special attention is paid to the role that price volatility plays in the valuation process. Chapter 23, the last chapter of this section, considers four additional classes of derivative products. First, the rapidly developing market for swap, cap, and floor agreements is examined. After describing how these instruments are related to typical forward and option contracts, the discussion concentrates on the many ways in which investors and corporate risk managers use these products in practice. In particular, applications involving three different exposures—interest rates, equity prices, and credit risk—are developed. Second, the fundamentals of warrants and convertible securities are described. The emphasis of this discussion is on the option-like features of these instruments and how they alter the risk-return dynamics of traditional debt and equity products. Third, we examine the market for structured notes—instruments that can be viewed as “straight” bond issues into which derivatives have been embedded. Finally, the chapter concludes with a brief discussion of how understanding real options can help investors value certain types of complex investments that have embedded derivative-like features, such as oil fields or gold mines.
In recent years, it has been difficult to read the financial press without encountering at least a passing reference to an economic scandal attributed to trading in derivative securities. Finally, the chapter concludes with a brief discussion of how understanding real options can help investors value certain types of complex investments that have embedded derivative-like features, such as oil fields or gold mines.
An Introduction to Derivative Markets and Securities

After you read this chapter, you should be able to answer the following questions:

- What distinguishes a derivative security, such as a forward, futures, or option contract, from more fundamental securities, such as stocks and bonds?
- What are the important characteristics of forward, futures, and option contracts, and in what sense can they be interpreted as insurance policies?
- How are the markets for derivative securities organized, and how do they differ from other security markets?
- What terminology is used to describe derivative market transactions?
- How are prices for derivative securities quoted, and how should this information be interpreted?
- What are the similarities and differences between forward and futures contracts?
- What do the payoff and profit diagrams look like for forward and futures contracts?
- What do the payoff and profit diagrams look like for put and call option contracts?
- How are forward contracts, put options, and call options related to one another?
- How can derivatives be used in conjunction with stock and Treasury bills to replicate the payoffs to other securities and create arbitrage opportunities for an investor?
- How can derivative contracts be used to restructure cash flow patterns and modify the risks in existing investment portfolios?

So far, we have seen several ways in which individuals and institutions can design their investments to take advantage of future market conditions. We have also seen how investors can control the volatility associated with their stock and bond positions—at least in part—by forming well-diversified portfolios of securities to reduce or eliminate a security’s unsystematic risk.

In this chapter, we begin our investigation of the role played by derivative securities in modern investment portfolios. A derivative instrument is one for which the ultimate payoff to the investor depends directly on the value of another security or commodity. Earlier in the text, we briefly described two basic types of derivatives: (1) forward and futures contracts, and (2) option contracts. A call option, for example, gives its owner the right to purchase an underlying security, such as a stock or a bond, at a fixed price within a certain amount of time. So the option’s ultimate value can be said to depend on—and thus derive from—that of the other asset. Similarly, a forward contract to sell a bond for a fixed price at a future date will see its value to the investor rise or fall with decreases or increases in the market price of the underlying bond.

The growth of the markets in which derivative securities are created and exchanged has been nothing short of phenomenal. The last few decades have seen the emergence of contracts to trade such fundamental products as agricultural commodities, energy,
precious metals, currencies, common stock, and bonds. There are even derivatives to trade hypothetical underlying assets (e.g., option and futures contracts on the Standard & Poor’s stock indexes) as well as combination derivatives, such as option contracts that allow the investor to decide at a later date to enter into a futures contract involving another security or commodity. Interest rate swaps, which will be shown in Chapter 23 to be forward contracts on a short-term borrowing or lending rate, are a good example of the prodigious growth of these markets. Starting with the first swap in 1981, the volume of swap market activity grew in size to almost $400 trillion by the year 2010.

As we will see, derivative securities can be used by investors in the same way as the underlying assets; an investor believing that a certain common stock will increase in value can benefit from either a purchase of the stock directly or an option to purchase that stock at a predetermined price. The exact returns will not be equal for these two alternatives, but both will gain from an upward movement in the stock’s price. Ultimately, however, the real key to understanding how and why derivatives are used lies in their ability to modify the risk and expected return characteristics of existing investment portfolios. That is, options and futures allow investors to hedge (or even increase) the risk of a collection of stocks in ways that go far beyond the diversification results presented in the preceding chapters. Also, derivative securities allow for the duplication of cash flow patterns that already exist in other forms, creating the possibility of arbitrage if two otherwise identical series of cash flows do not carry the same current price.

The balance of this chapter describes the fundamental nature and uses of forward, futures, and option contracts on common stock and bonds. (Subsequent chapters deal with more advanced forms of these products and valuation issues.) In the next section, we describe the basic terminology associated with these markets, while the second section explains the payoff structures created by each of these instruments. The third section develops the formal relationship between forwards and options, a series of conditions collectively known as put-call parity. In the final section, we briefly introduce three popular ways in which derivatives are used to manage the risks in stock and bond portfolios.

**20.1 Overview of Derivative Markets**

As with any financial product, derivative transactions have a specific terminology that must be understood in order to use these instruments effectively. The language used to describe forward, futures, and option contracts is often a confusing blend of jargon drawn from the equity, debt, and insurance markets, with some unique expressions thrown in for good measure. Thus, we begin by summarizing the most important aspects of these products and the markets in which they trade.

It is useful to first consider the basic types of positions that an investor can hold in these markets. Exhibit 20.1 illustrates the possibilities. The chart reinforces the point made earlier that, at the broadest level, there are only two kinds of derivatives available: (1) forward and futures contracts, and (2) option contracts. Further, as we will explain shortly, while only one forward contract is needed for any particular maturity date and underlying asset, there must be two types of options—calls and puts—in order to offer investors a full range of choices. Finally, for each of these derivative arrangements (i.e., the forward contract, the call option, and the put option), an investor can enter into a transaction as either the long position
One important way in which spot and forward market transactions are similar is the conditions under which the long and short positions will profit. Assume that at Date $T$, the long position in a bond forward contract is obligated to pay $F_0, T = 1,000$ for a bond that is worth $S_T = 1,050$ (i.e., the spot price at Date $T$). Since $F_0, T < S_T$, this will result in a profitable settlement for the long position in the contract since he will be able to acquire the bond for $50$ less than its current market value. On the other hand, the short position must deliver the bond at Date $T$ and will lose $50$ on her forward position; she would have profited if $S_T$ had been below the contract price of $F_0, T$. Thus, just as if the bond had been purchased at Date 0, the long position benefits when bond prices rise, at least relative to the contract price $F_0, T$.

Conversely, the short position to the forward contract will gain from falling bond prices, just as if she had short sold the bond at Date 0. Even though the timing of the trade’s settlement has shifted, “buy low, sell high” is still the way to make a profit in the forward market.

Forward and Futures Markets

Forward contracts are negotiated in the over-the-counter market. This means that forward contracts are agreements between two private parties—one of which is often a derivatives intermediary, such as a bank—rather than traded through a formal exchange. One advantage of this private arrangement is that the terms of the contract are completely flexible; they can be whatever any two mutually consenting counterparties agree to. Another desirable feature to many counterparties is that these arrangements may not require collateral; instead, the long and short positions sometimes trust each other to honor their respective commitments at Date $T$. This lack of collateral means that forward contracts involve credit (or default) risk, which is one reason why banks are often market makers in these instruments.

One disadvantage of a forward contract is that it is quite often illiquid, meaning that it might be difficult or costly for a counterparty to exit the contract before it matures. Illiquidity is really a by-product of the contract’s flexibility because the more specifically tailored an agreement is to the needs of a particular individual, the less marketable it will be to someone else.

Futures contracts try to solve this problem by standardizing the terms of the agreement (e.g., expiration date, identity, and amount of the underlying asset) and having both parties trade through a centralized market, called a futures exchange. Although the standardization of contracts reduces the ability of the ultimate end users to select the most desirable terms, it does create contract homogeneity, whereby the counterparties can always unwind a previous commitment prior to expiration by simply trading their existing position back to the exchange at the prevailing market price.

The futures price is analogous to the forward contract price and, at any time during the life of a contract, is set at a level such that a brand-new long or short position would not have to pay an initial premium. However, the futures exchange will require both counterparties to post collateral, or margin, to protect itself against the possibility of default. (A futures exchange is not a credit-granting institution.) These margin accounts are held by the exchange’s clearing-house and are marked to market (i.e., adjusted for contract price movements) on a daily basis to ensure that both end users always maintain sufficient collateral to guarantee their eventual participation.

A list of some popular futures contracts, along with the markets where they trade, is shown in Exhibit 20.2. Although generally quite diverse, all of these underlying assets have two things in common: volatile price movements and strong interest from both buyers and sellers.

20.1.1 The Language and Structure of Forward and Futures Markets

To most investors, the forward contract is the most basic derivative product available. A forward contract gives its holder both the right and the full obligation to conduct a transaction involving another security or commodity—the underlying asset—at a predetermined future date and at a predetermined price. The future date on which the transaction is to be consummated is called the contract’s maturity (or expiration) date, while the predetermined price at which the trade takes place is the forward contract price. Notice there must always be two parties (sometimes called counterparties) to a forward transaction: the eventual buyer (or long position), who pays the contract price and receives the underlying security, and the eventual seller (or short position), who delivers the security for the fixed price.

Forward and Spot Markets Forward contracts are not securities in the traditional sense; they are more appropriately viewed as trade agreements negotiated directly between two parties for a transaction that is scheduled to take place in the future. Suppose that two investors agree at Date 0 (the present) to transfer a bond from one party to the other at the future Date $T$. The two parties must agree on which bond and how much of it is to be exchanged, the date and location at which this exchange will take place, and the price at which the bond will be bought and sold. So, the terms that must be considered in forming a forward contract are the same as those necessary for a bond transaction that settled immediately (i.e., a spot market transaction) with two exceptions. First, the settlement date agreed to in the contract is purposefully set to be in the future. Second, the contract price—which we will represent as $F_{0,T}$—meaning a forward price set at Date 0 for a contract that matures at Date $T$—is usually different from the prevailing spot price ($S_0$) because of the different time frames involved.
One important way in which spot and forward market transactions are similar is the conditions under which the long and short positions will profit. Assume that at Date $T$, the long position in a bond forward contract is obligated to pay $1,000 (= F_{0,T})$ for a bond that is worth $S_T = 1,050$ (i.e., the spot price at Date $T$). Since $F_{0,T} < S_T$, this will result in a profitable settlement for the long position in the contract since he will be able to acquire the bond for $50 less than its current market value. On the other hand, the short position must deliver the bond at Date $T$ and will lose $50 on her forward position; she would have profited if $S_T$ had been below the contract price of $1,000. Thus, just as if the bond had been purchased at Date 0, the long position benefits when bond prices rise, at least relative to the contract price $F_{0,T}$. Conversely, the short position to the forward contract will gain from falling bond prices, just as if she had short sold the bond at Date 0. Even though the timing of the trade’s settlement has shifted, “buy low, sell high” is still the way to make a profit in the forward market.

**Forward and Futures Markets** Forward contracts are negotiated in the over-the-counter market. This means that forward contracts are agreements between two private parties—one of which is often a derivatives intermediary, such as a bank—rather than traded through a formal exchange. One advantage of this private arrangement is that the terms of the contract are completely flexible; they can be whatever any two mutually consenting counterparties agree to. Another desirable feature for many counterparties is that these arrangements may not require collateral; instead, the long and short positions sometimes trust each other to honor their respective commitments at Date $T$. This lack of collateral means that forward contracts involve credit (or default) risk, which is one reason why banks are often market makers in these instruments.

One disadvantage of a forward contract is that it is quite often illiquid, meaning that it might be difficult or costly for a counterparty to exit the contract before it matures. Illiquidity is really a by-product of the contract’s flexibility because the more specifically tailored an agreement is to the needs of a particular individual, the less marketable it will be to someone else. Futures contracts try to solve this problem by standardizing the terms of the agreement (e.g., expiration date, identity, and amount of the underlying asset) and having both parties trade through a centralized market, called a futures exchange. Although the standardization of contracts reduces the ability of the ultimate end users to select the most desirable terms, it does create contract homogeneity, whereby the counterparties can always unwind a previous commitment prior to expiration by simply trading their existing position back to the exchange at the prevailing market price.

The futures price is analogous to the forward contract price and, at any time during the life of a contract, is set at a level such that a brand-new long or short position would not have to pay an initial premium. However, the futures exchange will require both counterparties to post collateral, or margin, to protect itself against the possibility of default. (A futures exchange is not a credit-granting institution.) These margin accounts are held by the exchange’s clearing house and are marked to market (i.e., adjusted for contract price movements) on a daily basis to ensure that both end users always maintain sufficient collateral to guarantee their eventual participation. A list of some popular futures contracts, along with the markets where they trade, is shown in Exhibit 20.2. Although generally quite diverse, all of these underlying assets have two things in common: volatile price movements and strong interest from both buyers and sellers.

### 20.1.2 Interpreting Futures Price Quotations: An Example

To illustrate how futures prices are typically quoted in financial markets, consider Exhibit 20.3, which lists spot and futures prices for contracts on the Standard & Poor’s 500 Index as of January 4, 2011. Recall from Chapter 5 that the S&P 500 is a value-weighted index of a broad collection of industrial, financial, utility, and transportation companies representing the U.S. stock market. At the close of trading on this particular day, the index level stood at 1,270.20,
which can be considered as the spot price of one “share” of the S&P index (i.e., $S_T$). Exhibit 20.3 gives futures contract prices for eight different expiration dates falling in the months of March, June, September, and December for the years 2011 and 2012, as well as three others that expire in December of 2013, 2014, and 2015.

Consider the futures contract that expires in March 2011. The closing (or last) contract price is listed as 1,265.30 (i.e., $F_{0,T}$). This means that an investor taking a long position in this contract would be committing in January to buy a certain number of shares in the S&P 500 Index—250 shares in this case—at a price of $1,265.30 per share on the expiration date in March. Conversely, the short position in this contract would be committing to sell 250 S&P shares under the same conditions. Note that, except for the margin posted with the futures exchange (i.e., the Chicago Mercantile Exchange for this contract), no money changes hands between the long and short positions at the origination of the contract in January.

Exhibit 20.4 summarizes the payoff and net profit for this contract from the long position’s point of view, assuming a hypothetical set of S&P index levels on the March expiration date.

---

1In reality, purchasing a portfolio of the 500 S&P index stocks would cost considerably more than $1,270.20. However, as the eventual profit or loss from a stock index futures contract is determined by the difference between the futures contract price and the spot price prevailing at contract expiration, this interpretation is valid. The trading mechanics of these contracts will be described in greater detail in Chapter 21.
The data displayed in Exhibit 20.3 contains other information useful to investors as well. First, recognize that the spot index level fell slightly from the previous day but that all of the futures contract prices listed remained unchanged; this can be seen from the entries in the "Change" column, which compare the "Last" and "Previous" prices. This suggests that although other factors matter as well, the futures contract prices are strongly linked to the prevailing level of the underlying spot index. Second, notice that the contract prices decrease the further into the future the expiration date occurs. That is, although all 12 closing prices listed (i.e., the spot and the 11 futures contracts) were set on the same day and correspond to the same S&P index share, the cost of that share gets steadily less expensive the further forward in time the delivery date is set. We will see later that this relationship is common for some securities but not for others. Third, the display also lists the open interest and trading volume for each contract. Open interest is the number of outstanding contracts, while trading volume is the number of those contracts that changed hands that day. Thus, it appears in this case that the nearest-term contract (i.e., March 2011) is by far the most abundant and that only about 5 percent (= 12,850 ÷ 276,482) of the total number of S&P contracts in existence were traded on January 4, 2011.

20.1.3 The Language and Structure of Option Markets

An option contract gives its holder the right—but not the obligation—to conduct a transaction involving an underlying security or commodity at a predetermined future date and at a predetermined price. Unlike the forward contract, the option gives the long position the right to decide whether the trade will eventually take place. On the other hand, the seller (or writer) of the option must perform on his side of the agreement if the buyer chooses to exercise the option. Thus, the obligation in the option market is inherently one-sided; buyers can do as they please, but sellers are obligated to the buyers under the terms of the agreement. As a consequence, two different types of options are needed to cover all potential transactions: a call option—the right to buy the underlying security—and a put option—the right to sell that same asset.

Option Contract Terms

Two prices are important in evaluating an option position. The exercise, or striking, price is the price the call buyer will pay to—or the put buyer will receive from—the option seller if the option is exercised. The exercise price (represented here as \(X\)) is to an option what the contract price (i.e., \(F_0\)) is to a forward agreement. The second price of interest is what the option buyer must pay to the seller at Date 0 to acquire the contract itself. To avoid confusion, this second price is typically referred to as the option premium. A basic difference between options and forwards is that an option requires this upfront premium payment from buyer to seller while the forward ordinarily does not. This is because the forward contract allowed both the long and the short positions to "win" at Date \(T\) (depending on where \(S_T\) settled, relative to \(F_0\)), but the option agreement will only be exercised in the buyer’s favor; hence the seller must be compensated at Date 0, or she would never agree to the deal. Notice also that although both puts and calls require premium payments, it is quite likely that these two prices will differ. In the analysis that follows, we will define the Date 0 premium to acquire an option expiring at Date \(T\) as \(C_0, T\) for a call and \(P_0, T\) for a put. For example, instead of a long position in a bond forward contract, the investor in an earlier example could have paid $20 (\(= C_0, T\)) at Date 0 for a call option that would have given him the right to buy the bond for $1,000 (\(= X\)) at Date \(T\), but would not require him to do so if \(S_T < 1,000\).
Options can be designed to provide a choice of when the contract can be exercised. European options can only be exercised at maturity \( T \), while American options can be executed any time up to expiration. For a European-style call option, the buyer will only exercise when the expiration date market value of the underlying asset is greater than the exercise price. On the other hand, a European-style put option will only be rationally exercised when the date \( T \) price of the asset is lower than \( X \). The decision to exercise an American-style contract is more complex and will be considered in a later chapter.

### Option Valuation Basics

The option premium can be divided into two components: intrinsic value and time premium. Intrinsic value represents the value that the buyer could extract from the option if she exercised it immediately. For a call, this is the greater of either zero or the difference between the price of the underlying asset and the exercise price (i.e., \( \max(0, S_0 - X) \)). For a put, intrinsic value would be \( \max(0, X - S_0) \), as \( X \) would now represent the proceeds generated from the asset's sale. An option with positive intrinsic value is said to be in the money, while one with zero intrinsic value is out of the money. For the specific case where \( S_0 = X \), the option is at the money. The time premium component is then simply the difference between the whole option premium and the intrinsic component: \( C_0, T - \max(0, S_0 - X) \) for a call and \( P_0, T - \max(0, X - S_0) \) for a put. The buyer is willing to pay this amount in excess of the option's immediate exercise value because of her ability to complete the transaction at a price of \( X \) that will remain in force until Date \( T \). Thus, the time premium is connected to the likelihood that the underlying asset's price will move in the anticipated direction by the contract's maturity.

Chapter 22 contains a more complete discussion of valuing option premiums, but several basic relationships can be seen now. First, because the buyer of a call option is never obligated to exercise, the contract should always at least be worth its intrinsic value. (The situation for put option prices or when the underlying asset pays a dividend can be more complicated and will be discussed later.) In any event, neither a call nor a put option can be worth less than zero. Second, for call options having the same maturity and the same underlying asset, the lower the exercise price, the higher will be the contract's intrinsic value and, hence, the greater its overall premium. Conversely, for the same reason, put options with higher exercise prices are more valuable than those with lower striking prices. Third, increasing the amount of time until any option expires will increase the contract's time premium because it allows the price of the underlying security more opportunity to move in the direction anticipated by the investor (i.e., up for a call option, down for a put option). Finally, because they provide investors with more choices about exercising the agreement, American-style options are at least as valuable as otherwise comparable European-style contracts.

### Option Trading Markets

Like forwards and futures, options trade both in over-the-counter markets and on exchanges. When exchange-traded, just the seller of the contract is required to post a margin account because he is the only one obligated to perform on the contract at a later date. Also, options can be based on a wide variety of underlying securities, including futures contracts or other options. Exhibit 20.5 lists the underlying assets and exchanges where a number of popular option contracts trade.

### 20.1.4 Interpreting Option Price Quotations: An Example

Exhibit 20.6 shows data for a variety of call and put options on the S&P 500 Index as of January 4, 2011. All of the contracts listed expire in March 2011, making them comparable to the S&P 500 futures contracts considered above. However, unlike the futures contracts, for which there was a single contract price for a given expiration month, Exhibit 20.6 indicates that there are several March 2011 options having different exercise prices. The display lists bid and ask premium quotes for both puts and calls having striking prices ranging from...
Options can be designed to provide a choice of when the contract can be exercised. European options can only be exercised at maturity (Date T), while American options can be exercised any time up to expiration. For a European-style call option, the buyer will only exercise when the expiration date market value of the underlying asset is greater than the exercise price. On the other hand, a European-style put option will only be rationally exercised when the Date T price of the asset is lower than X. (The decision to exercise an American-style contract is more complex and will be considered in a later chapter.)

**Option Valuation Basics** The Date 0 option premium can be divided into two components: intrinsic value and time premium. 1,225 to 1,315. As noted earlier, calls become more valuable (e.g., higher ask premiums) as the exercise price declines, with the opposite holding true for put options.

Consider the outcomes of two different investors, one of whom purchases a March S&P call struck at 1,265 (i.e., $X$) and the other who buys a March 1,265 put. At the origination of the transaction in January, these investors will pay their sellers the ask prices of $40.00 (i.e., $C_{0,T}$) and $39.40 (i.e., $P_{0,T}$), respectively. In return, the investor holding the call option has the right, but not the obligation, to buy one S&P share for $1,265 at the expiration date in March. Since the current (i.e., spot) price of the index is 1,270.20, this call option is in the money. Thus, the total call premium of $40.00 can be divided into an intrinsic value component of $5.20 (= 1270.20 − 1265.00) and a time premium of $34.80 (= 40.00 − 5.20). Similarly, the investor holding the put option has the right, but not the obligation, to sell one S&P share for $1,265 at the expiration date in March. The put is out of the money, however, as this exercise price is lower than the current index level. Thus, the put option has no intrinsic value so the entire $39.40 ask price is a time premium.

The expiration date payoffs and net profits to these long option positions are listed in Exhibit 20.7 for a variety of possible S&P index levels. Looking first at the call option payoffs in Panel A, recall that the investor will only exercise the contract to buy a share of the S&P index when the March S&P level is above 1,265; at index levels at or below 1,265, the investor

---

2Recall that an investor buys a security from a dealer—in this case, the options exchange—at the ask price and sells securities to the dealer at the bid price. The difference in these prices, the bid-ask spread, represents part of the compensation to the exchange for making a market in these contracts.
Stock forward contracts and call options are available with the market prices of \( F_0, T \) and \( C_0, T \) (where \( T = 0.50 \text{ year} \)) and that the exercise price of the call option, \( X \), is equal to \( F_0, T \). Thus, if the investor wants to lock in the price now at which the stock purchase will eventually take place, he has two choices: a long position in the forward or the purchase of the call option. Exhibit 20.8 compares the Date 0 and Date \( T \) cash flow exchanges for both possibilities.

The clear difference between these strategies is that the forward position requires no initial payment or receipt by either party to the transaction, whereas the investor (i.e., the call buyer) must pay a cash premium to the seller of the option. As noted, this front-end option payment releases the investor from the obligation to purchase SAS stock at Date \( T \) if the terms of the contract turn out to be unfavorable (i.e., \( S_T < X \)).

When the expiration date price of SAS stock exceeds the exercise price, the investor will exercise the call and purchase the share of stock. However, this leads to exactly the same exchange as the long forward contract. It is only when the stock price falls below \( X \) (and \( F_0, T \)) on Date \( T \) that there is a difference between the two positions; under this condition, the right provided by the option not to purchase SAS stock is valuable since the investor in the forward contract will be required to execute that position at a loss.

This is the critical distinction between forward and option contracts. Both the long forward and the long call positions provide the investor with exactly the same amount of "insurance" against the price of SAS stock rising over the next six months. That is, both contracts provide

will let the option expire worthless and simply lose his initial investment. However, while the call is in the money at index levels above 1,265, the investor will not realize a net profit until the March index level rises above 1,305.00, an amount equal to the exercise price plus the call premium (i.e., \( X + C_{0,T} \)). For the put option payoffs shown in Panel B, the holder will exercise the contract at March index levels below the exercise price, using the contract to sell for $1,265 an S&P share that is worth less than that. However, the display also documents that the put investor will not realize a positive net profit until the index level falls below 1,225.60 (i.e., \( X - P_{0,T} \)). For March S&P values above 1,265, the put option expires out of the money.

### 20.2 Investing with Derivative Securities

Although the preceding section highlighted many of the differences between forward and option agreements, the two types of derivatives are quite similar in terms of the benefits they produce for investors. The ultimate difference between forwards and options lies in the way the investor must pay to acquire those benefits. This concept, along with an examination of the basic payoff and net profit structures that exist in these markets, is described below.

#### 20.2.1 The Basic Nature of Derivative Investing

Consider Investor 1 who decides at Date 0 to purchase a share of stock in SAS Corporation six months from now, coinciding with an anticipated receipt of funds. We assume that both SAS
stock forward contracts and call options are available with the market prices of $F_{0,T}$ and $C_{0,T}$ (where $T = 0.50$ year) and that the exercise price of the call option, $X$, is equal to $F_{0,T}$. Thus, if the investor wants to lock in the price now at which the stock purchase will eventually take place, he has two choices: a long position in the forward or the purchase of the call option. Exhibit 20.8 compares the Date 0 and Date $T$ cash flow exchanges for both possibilities.

The clear difference between these strategies is that the forward position requires no initial payment or receipt by either party to the transaction, whereas the investor (i.e., the call buyer) must pay a cash premium to the seller of the option. As noted, this front-end option payment releases the investor from the obligation to purchase SAS stock at Date $T$ if the terms of the contract turn out to be unfavorable (i.e., $S_T < X$). This is shown in Panel B of Exhibit 20.8. When the expiration date price of SAS stock exceeds the exercise price, the investor will exercise the call and purchase the share of stock. However, this leads to exactly the same exchange as the long forward contract. It is only when the stock price falls below $X$ (and $F_{0,T}$) on Date $T$ that there is a difference between the two positions; under this condition, the right provided by the option not to purchase SAS stock is valuable since the investor in the forward contract will be required to execute that position at a loss. Thus, the call option can be viewed as the “good hall” of the long forward position because it allows for the future acquisition of SAS stock at a fixed price but doesn’t require the transaction to take place.

This is the critical distinction between forward and option contracts. Both the long forward and the long call positions provide the investor with exactly the same amount of “insurance” against the price of SAS stock rising over the next six months. That is, both contracts provide
That is, when the stock settled above $45 (i.e., the common value for $F_0$, $T$, and $X$), both the long forward and the long call positions provided the same protection against rising prices. On the other hand, if $S_T = $40.75, the forward contract would require the investor to pay $4.25 (= 40.75 \cdot 45)$ to his counterparty, raising once again the net cost of his shares to $45. With the call option, however, he could have let the contract expire without exercising it and purchased his SAS shares in the market for only $40.75. Thus, in exchange for the option’s front-end expense of $3.24, the investor retains the possibility of paying less than $45 for his eventual stock purchase.

The connection between forward contracts and put options can be made in a similar fashion. Suppose a different investor—call her Investor 2—has decided to liquidate a share of SAS stock from her portfolio in six months’ time. Rather than risk a falling stock price over that period, she could arrange now to sell the share at that future date for a predetermined fixed price in one of two ways: a short forward position or the purchase of a put option. Exhibit 20.9 illustrates these alternatives. Similar to before, for the same insurance against SAS stock price declines, the choice comes down to the certainty of paying the put option premium versus the possibility of making a potentially larger payment with the forward contract by having to sell her stock for $X(= F_0, T)$ when that value is considerably less than the stock’s Date T market price. Notice once again that the put option allows the investor to walk away from her obligation under the short forward position to sell her stock on the expiration date under disadvantageous conditions. Thus, in exchange for a front-end premium payment, the put option enables the investor to acquire the “good half” of the short position in a forward contract.

</tbody>
</table>

A payoff of $[S_T - X] = [S_T - F_{0,T}]$ whenever $S_T$ exceeds $X$, which reduces the effective purchase price for the stock back to $X$. The difference is how the investor is required to pay for that price insurance. With a forward contract, no money is paid up front, but the investor will have to complete the purchase at the expiration date, even if the stock price falls below $F_{0,T}$. Conversely, the call option will never require a future settlement payment, but the investor will have to pay the premium at origination. Thus, for the same Date $T$ benefit, the investor’s decision between these two “insurance policies” comes down to choosing the certainty of a present premium payment (i.e., long call) versus the possibility of a future payment (i.e., long forward) that could potentially be much larger.

To make this distinction clearer, suppose that Investor 1 plans to buy SAS stock in six months when some of the bonds in his portfolio mature. He is concerned that share values could rise substantially between now and the time he receives his investment funds, and so to hedge that risk he considers two insurance strategies to lock in the eventual purchase price: (1) pay nothing now to take the long position in a six-month SAS stock forward contract with a contract price of $F_{0,T} = $45, or (2) pay a premium of $C_{0,T} = $3.24 for a six-month, European-style call option with an exercise price of $X = $45. If at the time of his decision the price of SAS stock is $S_0 = $40, the call option is out of the money, meaning that its intrinsic value is zero and the entire $3.24 is time premium.

As mentioned earlier, an obvious difference between these two strategies is that the option entails a front-end expense while the forward position does not. The other difference occurs at the expiration date, depending on whether the SAS stock price is above or below $45. If, for instance, $S_T = $51, both the long forward position and the call option will be worth $6 (i.e., $51 - 45$) to the investor, reducing his net purchase price for SAS shares to $45 (= 51 - 6).
That is, when the stock settled above $45 (i.e., the common value for $F_{0,T}$ and $X$), both the long forward and the long call positions provided the same protection against rising prices. On the other hand, if $S_T = 40.75$, the forward contract would require the investor to pay $4.25 (= 40.75 – 45)$ to his counterparty, raising once again the net cost of his shares to $45$. With the call option, however, he could have let the contract expire without exercising it and purchased his SAS shares in the market for only $40.75. Thus, in exchange for the option's front-end expense of $3.24, the investor retains the possibility of paying less than $45 for his eventual stock purchase.

The connection between forward contracts and put options can be made in a similar fashion. Suppose a different investor—call her Investor 2—has decided to liquidate a share of SAS stock from her portfolio in six months' time. Rather than risk a falling stock price over that period, she could arrange now to sell the share at that future date for a predetermined fixed price in one of two ways: a short forward position or the purchase of a put option. Exhibit 20.9 illustrates these alternatives. Similar to before, for the same insurance against SAS stock price declines, the choice comes down to the certainty of paying the put option premium versus the possibility of making a potentially larger payment with the forward contract by having to sell her stock for $X (= F_{0,T})$ when that value is considerably less than the stock's Date $T$ market price. Notice once again that the put option allows the investor to walk away from her obligation under the short forward position to sell her stock on the expiration date under disadvantageous conditions. Thus, in exchange for a front-end premium payment, the put option enables the investor to acquire the "good half" of the short position in a forward contract.

20.2.2 Basic Payoff and Profit Diagrams for Forward Contracts

Exhibit 20.8 and Exhibit 20.9 show that the respective expiration date payoffs for long and short positions in a forward contract are \( S_T - F_{0,T} \) and \( F_{0,T} - S_T \) and that these values could be either positive or negative, depending on the spot price prevailing at Date \( T \). These terminal payoffs are plotted against the possible expiration date values of the underlying security price in Exhibit 20.10. There are two interesting items in this display.

First, the payoffs to both long and short positions in the forward contract are symmetric, or two-sided, around the contract price. This is a direct result of a contract that fully obligates each party to complete the agreed-upon transaction—even at a financial loss. For instance, in the last example, the investor holding a long position in a SAS stock forward contract with a contract price of $45 lost $4.25 when the Date \( T \) price of SAS stock was $40.75 but gained $6 when \( S_T = $51 \). Also, since no front-end premiums were paid, the contract payoffs shown in Exhibit 20.10 are also the net profits to the investors.

Second, the Date \( T \) payoffs to the short and long positions are mirror images of each other; in market jargon, forward contracts are zero-sum games because the long position gains must be paid by the short position and vice versa. This illustration shows that when the Date \( T \) spot price is lower than the contract price (i.e., \( S_1 \)), the short position will receive the net payoff of \( [F_{0,T} - S_1] \) from the long position while the settlement is reversed at \( S_2 \), where the security price is above \( F_{0,T} \).
price is above $F_{0,T}$. Thus, forward markets reinforce the fundamental financial tenet that long positions benefit from rising prices while short positions benefit from falling prices. Finally, notice that these gains and losses can be quite large. In fact, the short forward position has the potential for unlimited loss, while the long forward position has the potential for unlimited gain since there is no theoretical limit on how high the price for the underlying security can rise. Conversely, the loss potential for the long position (and the gain potential for the short position) is limited because the price of the underlying security cannot fall below zero.

### 20.2.3 Basic Payoff and Profit Diagrams for Call and Put Options

Exhibits 20.8 and 20.9 also show that options differ from forward contracts in two fundamental ways: (1) the expense of purchasing either a put or a call represents a sunk cost to the investor, reducing the upside return relative to the comparable forward position, and (2) the investor receives expiration date payoffs that are decidedly asymmetric, or one-sided. Exhibit 20.11 shows the terminal payoffs and net profits to both long and short positions in call options, while Exhibit 20.12 provides a similar illustration for put option traders. This analysis assumes that both options are European style and cannot be exercised prematurely.

For call option positions, notice again that the buyer of the contract receives a payoff whenever the terminal security price (i.e., $S_T$) exceeds the contract purchase (i.e., exercise) price of $X$. However, given an initial premium of $C_{0,T}$, the position doesn’t generate a positive profit until $S_T$ is greater than $X$ by the amount of the premium paid. Put another way, although the call option is in the money (and hence will be exercised) when $S_T > X$, it will not produce a capital gain for the buyer until $S_T > (X + C_{0,T})$. (Recall that this result was shown for the S&P 500 Index option example in Exhibit 20.7.) When $X < S_T < (X + C_{0,T})$, the option is exercised at a loss, but this loss will be less than the full initial cost of the option, which is what the long position would incur if the call were not exercised. In fact, when $S_T < X$, the option is out of the money and the buyer who makes the rational decision to let the contract expire will lose $C_{0,T}$.

Notice, then, that the buyer of the call option has unlimited gain potential as the security price could rise indefinitely with losses limited to the option premium, no matter how far prices fall. On the other hand, the option seller benefits when the terminal price of the underlying asset is lower than $X$ but only to the extent that he gets to keep the full amount of the option premium. When $S_T > X$, the seller of the call has unlimited liability. Like forward contracts, the call option is a zero-sum game between the long and short positions.

For the put option positions shown in Exhibit 20.12, the buyer benefits whenever $X > S_T$ and receives a positive profit when the Date $T$ price of the underlying security falls below the exercise price, less the cost of the option. In this case, the put buyer’s maximum capital gain is limited to $X - P_{0,T}$ as the underlying security itself is limited to a minimum price of zero; the best the put holder can hope for is to force the seller of the contract to buy worthless stock for $X$ at the expiration date. As with the call option, the owner of an out-of-the-money put can only lose his initial investment of $P_{0,T}$ which will occur when $S_T > X$. Not surprisingly, the profit and loss opportunities for the put seller are exactly opposite of those for the put buyer. The contract seller will gain when $S_T > (X - P_{0,T})$, but this gain is limited to the amount of the option premium. A short position in a put also has limited loss potential; but, at a maximum of $X - P_{0,T}$, this can still be a large amount.

In summary, when held as investments, options are directional views on movements in the price of the underlying security. Call buyers and put sellers count on $S_T$ to rise (or remain) above $X$, while put buyers and call sellers hope for $S_T$ to fall (or remain) below the exercise price.

---

2 The expiration date profits shown in Exhibits 20.11 and 20.12 are somewhat inaccurate in that they show the net of the Date $T$ value of the option and its initial cost, which was paid at Date 0. Thus, although this is an accurate way of portraying capital gains and losses from an accounting standpoint, it ignores the difference in the timing of the two payments.

Chapter 20: An Introduction to Derivative Markets and Securities
Importantly, option buyers — whether a put or a call — always have limited liability since they do not have to exercise an out-of-the-money position. Conversely, option sellers have limited gain potential but considerable — in fact, infinite, for short call positions — loss potential.

20.2.4 Option Profit Diagrams: An Example

We have seen that option contracts can be designed with several different values for the exercise price. We now consider how the choice of the exercise price affects the investor’s expiration date profit. Extending the last example, suppose that a share of SAS stock currently sells for $40, and six different SAS options — three calls and three puts — are available to investors. The options all expire on the same date in the future and have exercise prices of either $35, $40, or $45. Current market prices for these contracts, which are assumed to be European style, are shown in Exhibit 20.13, where they are broken down into their intrinsic value and time premium components.

Given that $S_0 = $40, Call 1 (with $X = 35$) and Put 3 (with $X = 45$) are both $5 in the money, which leaves $3.07 and $1.47, respectively, of time premium. Call 3 and Put 1 are both currently $5 out of the money, so their market prices are purely time premium; someone buying either of these two contracts anticipates that stock prices will move in the desired direction by at least the option price plus $5. Neither of the two at-the-money options, Call 2 and Put 2, has any intrinsic value, but they still sell in the market for different prices. Specifically, the call with $X = $40 is more valuable than the comparable put option. As we will see shortly, this occurs because of put-call parity, which is the formal relationship that must exist between put and call options in efficient capital markets. Finally, the last column of Exhibit 20.13 shows that the time premium is largest for the at-the-money options because, at this point, the greatest amount of uncertainty exists as to whether the option will be in or out of the money (and hence valuable, or not) at expiration.

Exhibit 20.14 compares the expiration date profit diagrams for options on the same security with varying exercise prices but similar in every other respect. For simplicity, only the profits for the long positions in these contracts are shown. The call option profits portrayed in Panel A indicate that, although it is the most expensive, the deepest in-the-money contract (Call 1) becomes profitable the quickest, requiring only that $S_T$ rise to $43.07 (= 35 + 8.07). Call 3 is the least expensive to purchase but requires the greatest movement in the price of the underlying stock — to $48.24, in this example — before it provides a positive profit to the investor. The put options illustrated in Panel B tell the same story, with Put 1 (the out-of-the-money contract) costing the least but needing the largest price decline to be profitable at expiration. In general, by varying the exercise price on a series of options with otherwise identical contract terms, an investor can create just as many different risk-reward trade-offs for herself. This is one of several ways in which derivatives can be used to modify investment risk and to customize a desired payoff structure.

the initial price of $40. For the option positions, the terminal payoffs of max\[0, S_T - 40\] for the call and max\[0, 40 - S_T\] for the put are listed relative to the contract’s purchase price. The key point is that both put and call options magnify the possible positive and negative returns of investing in the underlying security. With the long call option position, for an initial cost of $5.24, the investor can retain the right to obtain the price appreciation of a share of SAS stock without spending $40 to own the share outright. This degree of financial leverage manifests itself in a 100 percent loss when the stock price falls by a quarter of that amount and a 91 percent gain when SAS shares increase in value from $40 to $50. Notably, if the stock price remains at $40, the owner of the share would not have lost anything, while the at-the-money call holder would have lost his entire investment. This suggests that in addition to anticipating the direction of the subsequent underlying stock price movement, the option investor also is taking a view on the timing of that movement. If the price of SAS stock had stayed at $40 through Date $T$ and then rose to $50 on the following day, the stockholder would have experienced a 25 percent gain, while the buyer of the call option would have seen the instrument expire worthless.

**Options and Leverage** As a final extension of this example, we compare the returns to an investment in either a put or a call option with a direct investment (or short sale) in a share of the underlying SAS stock. We will limit the analysis to Call 2 and Put 2, the two at-the-money contracts. Exhibit 20.15 summarizes the holding period returns for various positions assuming three different expiration date stock prices: $30, $40, and $50. Two different comparisons are made: (1) long stock versus long call and (2) short stock versus long put. In calculating the returns to the stock positions, we have measured the change in value of the SAS share as a percentage of

**Exhibit 20.15 Stock and Option Investment Returns**

| **A. Long Stock versus Long Call** |
|---|---|---|
| Terminal Stock Price | Long Stock | Long Call |
| 30 | $30 - 1 = -25.0\%$ | $0.524 - 1 = -100.0\%$ |
| 40 | $40 - 1 = 0.0\%$ | $0.524 - 1 = -100.0\%$ |
| 50 | $50 - 1 = 25.0\%$ | $10.524 - 1 = -90.8\%$ |

| **B. Short Stock versus Long Put** |
|---|---|---|
| Terminal Stock Price | Short Stock | Long Put |
| 30 | $1 - \frac{30}{40} = 25.0\%$ | $10.367 - 1 = -172.5\%$ |
| 40 | $1 - \frac{40}{40} = 0.0\%$ | $0.367 - 1 = -100.0\%$ |
| 50 | $1 - \frac{50}{40} = -25.0\%$ | $0.367 - 1 = -100.0\%$ |

The development of the relationships linking put and call option prices is commonly attributed to Stoll (1969). Others have embellished Stoll’s findings in many interesting ways; those subsequent studies include Merton (1973a), Klemkosky and Resnick (1979), and Cremers and Weinbaum (2010).
the initial price of $40. For the option positions, the terminal payoffs of \( \max[0, S_T - 40] \) for the call and \( \max[0, 40 - S_T] \) for the put are listed relative to the contract’s purchase price.

The key point is that both put and call options magnify the possible positive and negative returns of investing in the underlying security. With the long call option position, for an initial cost of $5.24, the investor can retain the right to obtain the price appreciation of a share of SAS stock without spending $40 to own the share outright. This degree of financial leverage manifests itself in a 100 percent loss when the stock price falls by a quarter of that amount and a 91 percent gain when SAS shares increase in value from $40 to $50. Notably, if the stock price remains at $40, the owner of the share would not have lost anything, while the at-the-money call holder would have lost his entire investment. This suggests that in addition to anticipating the direction of the subsequent underlying stock price movement, the option investor also is taking a view on the timing of that movement. If the price of SAS stock had stayed at $40 through Date \( T \) and then rose to $50 on the following day, the stockholder would have experienced a 25 percent gain, while the buyer of the call option would have seen the instrument expire worthless.

### 20.3 The Relationship Between Forward and Option Contracts

The preceding discussion showed that positions in forward and option contracts can lead to similar investment payoffs if the price of the underlying security moves in the anticipated direction. This similarity in payoff structures suggests that these instruments are connected. In fact, we will see that the values of five different securities can be linked: a risk-free bond, an underlying asset, a forward contract for the future purchase or sale of that asset, a call option, and a put option. These relationships, known as put-call parity, specify how the put and call premiums should be set relative to one another. Further, these conditions can be expressed in terms of these two option types and either the spot or the forward market price for the underlying asset. They depend on the assumption that financial markets are free from arbitrage opportunities, meaning that securities (or portfolios of securities) offering identical payoffs with identical risks must sell for the same current price. As such, put-call parity represents a crucial first step in understanding how derivatives are valued in an efficient capital market.4

#### 20.3.1 Put-Call-Spot Parity

Suppose that at Date 0 an investor forms the following portfolio involving three securities related to Company WYZ:

- **Long in a share of WYZ common stock at a purchase price of** \( S_0 \).
- **Long in a put option to deliver one share of WYZ stock at an exercise price of** \( X \) **on the Expiration Date** \( T \). This put could be purchased for the price of \( P_{0,T} \).
- **Short in a call option allowing the purchase of one share of WYZ stock at an exercise price of** \( X \) **on the Expiration Date** \( T \). This call could be sold for the price of \( C_{0,T} \).

In this example, both of the WYZ options are European style and have the same expiration date and exercise price. However, the specific values of the expiration date and exercise price do not matter in the analysis that follows. Further, we will assume initially that WYZ stock does not pay a dividend during the life of the options.

Panel A of Exhibit 20.16 lists the Date 0 investment necessary to acquire this portfolio as \( (S_0 + P_{0,T} - C_{0,T}) \), which is the cost of the long positions in the stock and the put option less

\[ \text{Exhibit 20.16 Put-Call-Spot Parity} \]

---

4The development of the relationships linking put and call option prices is commonly attributed to Stoll (1969). Others have embellished Stoll’s findings in many interesting ways; those subsequent studies include Merton (1973a), Klemkosky and Resnick (1979), and Cremers and Weinbaum (2010).
In either form, this condition—known as the put-call-spot parity condition—represents the efficient market linkages between prices for stock, T-bills, put options, and call options.

20.3.2 Put-Call Parity: An Example

Suppose that WYZ stock is currently valued at $53 and that call and put options on WYZ stock with an exercise price of $50 sell for $6.74 and $2.51, respectively. If both options can only be exercised in exactly six months, Equation 20.1 suggests that we can create a synthetic T-bill by purchasing the stock, purchasing the put, and selling the call for a net price of $48.77 (= 53.00 + 2.51 – 6.74). On the options’ expiration date, this portfolio would have a terminal value of $50. Thus, the risk-free rate implied by this investment can be established by solving the following equation for RFR:

\[ 48.77 = 50 \left(1 + \frac{RFR}{100}\right) - 0.5 \]

or:

\[ RFR = \left[\frac{50}{48.77}\right]^2 - 1 = 5.11\% \]

If the rate of return on an actual six-month T-bill with a face value of $50 is not 5.11 percent, then an investor could exploit the difference. Suppose, for instance, that the actual T-bill rate is 6.25 percent and that there are no restrictions against using the proceeds from the short sale of any security. An investor wanting a risk-free investment would clearly choose the actual T-bill to lock in the higher return, while someone seeking a loan might attempt to secure a 5.11 percent borrowing rate by short-selling the synthetic T-bill. With an arithmetic rearrangement of Equation 20.1, such an artificial short position can be obtained as

\[(\text{Short Stock}) + (\text{Short Put}) + (\text{Long Call}) = (\text{Short T-Bill})\]

With no transaction costs, a financial arbitrage could be constructed by combining a long position in the actual T-bill with a short sale of the synthetic portfolio. Given that the current value of the actual T-bill is $48.51 \[= 50 \left(1.0625\right) - 0.5\], this set of transactions would generate the cash flows shown in Exhibit 20.17 and produce a $0.26 profit per each T-bill pair created. As the Exhibit 20.17

**B. Portfolio Value at Option Expiration (Date \( T \))**

\[ S_T \]

1. If \( S_T \leq X \):
   - Long actual T-bill at 6.25%: \( S_T \)
   - Long 1 WYZ stock: \( S_T - S_T \)
   - Short 1 put option: \( -\left(50 - S_T\right)0 \)
   - Long call option: \( 0 \) \( (S_T - 50) \)
   - Net position: \( X \)

2. If \( S_T > X \):
   - Long actual T-bill at 6.25%: \( S_T \)
   - Long 1 WYZ stock: \( S_T \)
   - Short 1 put option: \( 0 \)
   - Long call option: \( \left(S_T - X\right) \)
   - Net position: \( X \)

The proceeds generated by the sale of the call option.\(^5\) Consider also the value that this portfolio will have at the expiration date of the two options. Given that the stock’s value at Date \( T \) (i.e., \( S_T \)) is unknown when the investment is made at Date 0, two general outcomes are possible: (1) \( S_T \leq X \) and (2) \( S_T > X \). Panel B shows the value of each position as well as the net value of the whole portfolio at Date \( T \).

Whenever the Date \( T \) value of WYZ stock is less than the exercise price common to the put and call options, the investor will exercise the long position in the put and sell the WYZ share for \( X \) instead of its lower market value. In that case, it will not be rational for the holder of the call to pay \( X \) for a share that is worth less so the call will expire out of the money. On the other hand, when \( S_T \) exceeds \( X \), the holder of the call will exercise the option to purchase WYZ stock for \( X \) while the put would be out of the money. In either scenario, the net expiration date value of the portfolio is \( X \) because the combination of options guarantees that the investor will sell the share of WYZ stock at Date \( T \) for the fixed price \( X \). The investor has, in effect, a guaranteed contract to sell the share of stock when the long put and short call positions are held jointly.

The consequence of this result is that when the investor commits \( S_0 + P_{0,T} - C_{0,T} \) to acquire the position at Date 0, he knows that it will be worth \( X \) at Date \( T \). Thus, this particular portfolio has a comparable payoff structure to a U.S. Treasury bill, another risk-free, zero coupon security that can have a face value of \( X \) and a maturity date \( T \). In an arbitrage-free capital market, this means that the Date 0 value of the portfolio must be equal to that of the T-bill, which is just the face value \( X \) discounted to the present using the risk-free rate. This “no arbitrage” condition can be formalized as follows:

\[ S_0 + P_{0,T} - C_{0,T} = \frac{X}{(1 + RFR)^T} \]

where:

- \( RFR \) = the annualized risk-free rate
- \( T \) = the time to maturity (expressed in years)

Defining \( X \left(1 + RFR\right)^{-T} \) as the present value of a T-bill, this equation can be expressed on Date 0 in financial arithmetic terms as:

\[ (\text{Long Stock}) + (\text{Long Put}) + (\text{Short Call}) = (\text{Long T-Bill}) \]

---

\(^5\)In the “arithmetic” of engineering financial portfolios, a plus (+) sign can be interpreted as a long position, and a minus (−) sign represents a short position. Thus, the portfolio investment represented by \((S_0 + P_{0,T} - C_{0,T})\) can also be expressed as (long stock) + (long put) + (short call). Smith (1989a) explains this approach in more detail.
In either form, this condition—known as the put-call-spot parity condition—represents the efficient market linkages between prices for stock, T-bills, put options, and call options.

### 20.3.2 Put-Call Parity: An Example

Suppose that WYZ stock is currently valued at $53 and that call and put options on WYZ stock with an exercise price of $50 sell for $6.74 and $2.51, respectively. If both options can only be exercised in exactly six months, Equation 20.1 suggests that we can create a synthetic T-bill by purchasing the stock, purchasing the put, and selling the call for a net price of $48.77 (= 53.00 + 2.51 − 6.74). On the options’ expiration date, this portfolio would have a terminal value of $50. Thus, the risk-free rate implied by this investment can be established by solving the following equation for $RFR$:

\[
48.77 = 50 \left(1 + RFR\right)^{-0.5}
\]

or:

\[
RFR = \left(\frac{50}{48.77}\right)^{2} - 1 = 5.11\%
\]

If the rate of return on an actual six-month T-bill with a face value of $50 is not 5.11 percent, then an investor could exploit the difference. Suppose, for instance, that the actual T-bill rate is 6.25 percent and that there are no restrictions against using the proceeds from the short sale of any security. An investor wanting a risk-free investment would clearly choose the actual T-bill to lock in the higher return, while someone seeking a loan might attempt to secure a 5.11 percent borrowing rate by short-selling the synthetic T-bill. With an arithmetic rearrangement of Equation 20.1, such an artificial short position can be obtained as

\[(\text{Short Stock}) + (\text{Short Put}) + (\text{Long Call}) = (\text{Short T-Bill})\]

With no transaction costs, a financial arbitrage could be constructed by combining a long position in the actual T-bill with a short sale of the synthetic portfolio. Given that the current value of the actual T-bill is $48.51 [\(= 50 \left(1.0625\right)^{-0.5}\)], this set of transactions would generate the cash flows shown in Exhibit 20.17 and produce a $0.26 profit per each T-bill pair created. As the

arbitrage trade did not require the investor to bear any risk (i.e., both the Date 0 and the Date T values of the net position were known at inception) or commit any capital, there is nothing in this example to prevent the investor from expanding the size of the trade to increasingly larger levels. However, as additional transactions take place, the price discrepancy will disappear. In this case, the purchase of the actual T-bill and sale of the synthetic (short stock, short put, and long call) will continue until rates are equalized. This is how the markets remain efficient through arbitrage trading.

Another way of seeing this trade is:
\[ C_{0,T} - P_{0,T} = S_0 - X(1 + \text{RFR})^T \]

That is, the “no arbitrage” difference between the call and put prices should equal the difference between the stock price and the present value of the joint exercise price. The market-determined risk-free rate of 6.25 percent implies that the correct difference between the two derivatives should be $4.49 (= 53 - 48.51)$, which is $0.26$ greater than the $4.23 (= 6.74 - 2.51)$ actual difference. This discrepancy suggests that if you assume the actual T-bill is priced correctly, the call price is undervalued relative to the put option. Not surprisingly, then, the arbitrage transaction requires the purchase of the call option while shorting the put option.

### 20.3.3 Creating Synthetic Securities Using Put-Call Parity

The preceding example demonstrates that a risk-free portfolio could be created by combining three risky securities: stock, a put option, and a call option. The parity condition developed in the example can be expressed in other useful ways as well. In particular, one of the four assets represented in Equation 20.1 is always redundant because it can be defined in terms of the others. Three additional ways of expressing this result are:

**20.2**

\[ P_{0,T} = \frac{X}{(1 + \text{RFR})^T} - S_0 + C_{0,T} \]

**20.3**

\[ C_{0,T} = S_0 + P_{0,T} - \frac{X}{(1 + \text{RFR})^T} \]

**20.4**

\[ S_0 = \frac{X}{(1 + \text{RFR})^T} - P_{0,T} + C_{0,T} \]

Equation 20.2 and Equation 20.3 indicate, respectively, that (1) the payoffs to a long position in a put option can be replicated by a portfolio holding a long position in a T-bill, a short stock position, and the purchase of a call option; and (2) a synthetic call option can be mimicked by a portfolio that is long in the stock and the put option and short in the T-bill. Equation 20.4 indicates that the payoff to the stock itself can be created with its derivative securities and the T-bill.

These results are useful in two ways. First, if actual put or call options do not exist, these equations demonstrate how investors can obtain the desired, but unavailable, pattern of cash flows through the appropriate “packaging” of the other three assets. Suppose, for example, that a put option on WYZ stock did not exist but a call option does. Exhibit 20.18 shows the Date 0 and Date T cash flows associated with the portfolio replicating the terminal payoff. Combining both panels of the display, an initial investment of \([X(1 + \text{RFR})^T - S_0 + C_{0,T}]\) leads to a final cash flow that is no less than zero and as large as \(X - S_T\) whenever \(X > S_T\). Expressed in a more traditional manner, the expiration date payoff to the synthetic put is max\([0, X - S_T]\).

A second way these alternative put-call parity expressions are used in practice is the identification of arbitrage opportunities. Even when a derivative instrument does exist, if its cash flows and risks can be duplicated, this leads to the possibility that the price of the actual
lent to a T-bill, now having a face value of ($X + DT$). This allows Equation 20.1 to be adapted as follows:

$$S_0 + P_0 - C_0 = X + DT \left(1 + RFR\right)$$

which can be interpreted as:

(Long Stock) + (Long Put) + (Short Call) = (Long T-Bill) + (Long Present Value of Dividends)

Alternatively, it is often more useful to rearrange this result as follows:

$$S_0 - DT \left(1 + RFR\right) + P_0 - C_0 = X \left(1 + RFR\right)$$

This form of the equation can be compared directly with the no-dividend put-call-spot parity result and shows that the current stock price must be adjusted downward by the present value of the dividend.

With an initial stock price of $53 and an annualized risk-free rate on a six-month T-bill of 6.25 percent, a $1 dividend paid just before the expiration of a call and a put option with an exercise price of $50 would result in a theoretical price differential of:

$$C_0 - P_0 = 53 - 1 \left(1 + 0.0625\right) - 50 \left(1 + 0.0625\right) = 3.52$$

This value differs from the parity differential for options on the nondividend-paying stock, which was shown earlier to be $4.49. Thus, the payment of the dividend has reduced the price of the call relative to the put by $0.97, which is the discounted amount of the $1 cash distribution.

### 20.3.5 Put-Call-Forward Parity

Suppose that instead of buying the stock in the spot market at Date 0, we took a long position in a forward contract allowing us to purchase one share of WYZ stock at Date $T$. The price of this acquisition, $F_{0,T}$, would be established at Date 0. As before, we assume that this transaction is supplemented by the purchase of a put option and the sale of a call option, each having the same exercise price and expiration date. Exhibit 20.19 summarizes both the initial and the terminal cash flows to this position.

Panel B reveals that this is once again a risk-free portfolio. There are, however, two important differences in its cash flow patterns. First, the net initial investment of ($P_0, T - C_0, T$) is substantially smaller than when the stock was purchased in the spot market. Second, the riskless terminal payoff of ($X - F_{0,T}$) also is smaller than before as the stock now is purchased at Date $T$ rather than at Date 0. This intuition leads to the put-call-forward parity condition:

$$P_0, T - C_0, T = X - F_{0,T} \left(1 + RFR\right)$$

which says that for markets to be free from arbitrage, the difference between put and call prices must equal the discounted difference between the option exercise price and the forward contract price.

This result implies that the only time that put and call prices should be equal to one another in an efficient market is when $X = F_{0,T}$. That is, although the put-call parity result holds for any common exercise price, there is only one value of $X$ for which there would be no net cost to the option combination and that is the prevailing forward price. Recall, for example, that when WYZ stock did not pay a dividend, the theoretical difference between $C_{0,0.5}$ and $P_{0,0.5}$ was $4.49 (= 53 - 48.51)$. This meant that an investor long in the call and short in the put with a joint $50 exercise price would have what amounted to a forward contract to buy

### Exhibit 20.18 Replicating a Put Option

</tbody>
</table>

instrument and the net cost of the replicating portfolio will differ. From the previous example, the Date $T$ distribution of $\text{max}(0, 50 - S_T)$ could be acquired through the synthetic strategy at a cost of $2.25 (= 48.51 - 53 + 6.74)$ or through the purchase of the actual put for $2.51$.

This is the same $0.26 price differential we saw earlier when designing an arbitrage transaction involving the actual and synthetic T-bill. The put option arbitrage would be to short the actual put while buying the replicating portfolio (i.e., long T-bill, short stock, and long call), which is the same set of transactions we used in the T-bill arbitrage. This underscores the important point that the put-call parity model only allows us to make relative—rather than absolute—statements about security values.

Although we can change our perspective about the misvalued instrument (e.g., T-bill versus put option), the real source of the market inefficiency came from examining the difference between the put and call prices in relation to the stock and T-bill prices. Consequently, all four securities need to be included in the arbitrage trade.

### 20.3.4 Adjusting Put-Call-Spot Parity for Dividends

Another extension of the put-call-spot parity model involves the payment of dividends to the shareholders of WYZ stock. Suppose that in the basic portfolio listed in Exhibit 20.16, WYZ stock pays a dividend of $D_T$ immediately prior to the expiration of the options at Date $T$. Assume further that the amount of this distribution is known when the investment is initiated, a condition that is almost certainly met for values of $T \leq 0.25$ year because U.S.-based companies typically pay quarterly dividends. With this adjustment, the terminal value of the long stock position will be $(S_T + D_T)$, while the terminal payoffs to the put and call options remain $\text{max}(0, X - S_T)$ and $\text{max}(0, S_T - X)$, respectively, as the holders of the two derivative contracts will not participate directly in the payment of dividends to the stockholder. Thus, the net Date $T$ value of the portfolio acquired originally for $(S_0 + P_{0,T} - C_{0,T})$ is $(X + D_T)$.

With the critical assumption that the dividend payment is known at Date 0, the portfolio long in WYZ stock, long in the put, and short in the call once again can be viewed as equiva-

---

*The fact that the expiration date payoff to a call option on both a dividend- and a nondividend-paying stock can be expressed as $\text{max}(0, S_T - X)$ does not mean that the two will generate the same dollar amount of cash flow. This is because the stock's value will be reduced by the payment of the dividend in the former case but not in the latter. Thus, the call on the dividend-paying stock will be less valuable than an otherwise comparable contract on a nondividend-paying equity. We will explore this topic more fully in Chapter 22; see also Guo and Su (2006).*
lent to a T-bill, now having a face value of \( (X + D_T) \). This allows Equation 20.1 to be adapted as follows:

\[
S_0 + P_{0,T} - C_{0,T} = \frac{X + D_T}{(1 + RFR)^t} = \frac{X}{(1 + RFR)^t} + \frac{D_T}{(1 + RFR)^t}
\]

which can be interpreted as:

\[
(\text{Long Stock}) + (\text{Long Put}) + (\text{Short Call}) = (\text{Long T-Bill}) + (\text{Long Present Value of Dividends})
\]

Alternatively, it is often more useful to rearrange this result as follows:

\[
\left\{ S_0 - \frac{D_T}{(1 + RFR)^t} \right\} + P_{0,T} - C_{0,T} = \frac{X}{(1 + RFR)^t}
\]

This form of the equation can be compared directly with the no-dividend put-call-spot parity result and shows that the current stock price must be adjusted downward by the present value of the dividend. With an initial stock price of $53 and an annualized risk-free rate on a six-month T-bill of 6.25 percent, a $1 dividend paid just before the expiration of a call and a put option with an exercise price of $50 would result in a theoretical price differential of:

\[
C_{0.05} - P_{0.05} = \left\{ 53 - \frac{1}{(1 + 0.0625)^{0.5}} \right\} - \frac{50}{(1 + 0.0625)^{0.5}} = 3.52
\]

This value differs from the parity differential for options on the non-dividend-paying stock, which was shown earlier to be $4.49. Thus, the payment of the dividend has reduced the price of the call relative to the put by $0.97, which is the discounted amount of the $1 cash distribution.

### 20.3.5 Put-Call-Forward Parity

Suppose that instead of buying the stock in the spot market at Date 0, we took a long position in a forward contract allowing us to purchase one share of WYZ stock at Date \( T \). The price of this acquisition, \( F_{0,T} \), would be established at Date 0. As before, we assume that this transaction is supplemented by the purchase of a put option and the sale of a call option, each having the same exercise price and expiration date. Exhibit 20.19 summarizes both the initial and the terminal cash flows to this position.

Panel B reveals that this is once again a risk-free portfolio. There are, however, two important differences in its cash flow patterns. First, the net initial investment of \( (P_{0,T} - C_{0,T}) \) is substantially smaller than when the stock was purchased in the spot market. Second, the riskless terminal payoff of \( (X - F_{0,T}) \) also is smaller than before as the stock now is purchased at Date \( T \) rather than at Date 0. This intuition leads to the put-call-forward parity condition:

\[
P_{0,T} - C_{0,T} = \frac{X - F_{0,T}}{(1 + RFR)^t} = \frac{X}{(1 + RFR)^t} - \frac{F_{0,T}}{(1 + RFR)^t}
\]

which says that for markets to be free from arbitrage, the difference between put and call prices must equal the discounted difference between the option exercise price and the forward contract price.

This result implies that the only time that put and call prices should be equal to one another in an efficient market is when \( X = F_{0,T} \). That is, although the put-call parity result holds for any common exercise price, there is only one value of \( X \) for which there would be no net cost to the option combination and that is the prevailing forward price. Recall, for example, that when WYZ stock did not pay a dividend, the theoretical difference between \( C_{0,0.5} \) and \( P_{0,0.5} \) was $4.49 \((= 53 - 48.51)\). This meant that an investor long in the call and short in the put with a joint $50 exercise price would have what amounted to a forward contract to buy
Thus, if a $1 dividend were paid on WYZ stock just prior to the maturity of the contract in six months, the forward price would be adjusted down to

\[ F_{0,0.5} = (53)(1 + 0.0625)^{0.5} - 1 = 53.63 \]

to account for the payment to the actual shareholders but not the derivative holder.

20.4 A INTRODUCTION TO THE USE OF DERIVATIVES IN PORTFOLIO MANAGEMENT

Beyond the unique risk–reward profiles they offer as standalone investments, derivatives also are used widely to restructure existing portfolios of assets. Typically, the intent of this restructuring is to modify the portfolio’s risk. In this section, we review three prominent derivative applications in the management of equity positions: shorting forward contracts, purchasing protective puts, and purchasing equity collars.

20.4.1 Restructuring Asset Portfolios with Forward Contracts

Suppose the manager of a small corporate pension fund currently has all of her investable funds committed to a well-diversified portfolio of equity securities designed to track the Standard & Poor’s 500 Index. This investment approach is based on the manager’s belief that she cannot add value by trying to select superior individual securities. She does, however, feel that it is possible to take advantage of perceived trends at a macroeconomic level by switching her funds on a tactical basis between her current equity holding and any of several other portfolios mimicking different asset classes (e.g., fixed-income, cash equivalents).

The stock market has increased steadily over the past several months, and the pension fund has a present market value of $100 million. The manager has now become concerned about the possibility that inflationary pressures will dampen corporate earnings and drive stock prices down. She also feels confident that the uncertainty will be resolved during the coming quarter. Accordingly, she would like to shift her allocation from 100 percent equity to 100 percent T-bills for the next three months.

There are two ways she can make this change. The most direct method would be to sell her stock portfolio and buy $100 million (less the transaction costs) of 90-day T-bills. When the T-bills mature in three months, she could then repurchase her original equity holdings.

The second approach would be to maintain her current stock holdings but convert them into a synthetic risk-free position using a three-month forward contract with $100 million of the stock index as the underlying asset. This is a classic example of a hedge position, wherein the price risk of the underlying asset is offset by a supplementary derivative transaction. The following table captures the basic dynamics of this hedge.

<table>
<thead>
<tr>
<th>Economic Event</th>
<th>Actual Stock Exposure</th>
<th>Desired Forward Exposure</th>
</tr>
</thead>
<tbody>
<tr>
<td>Stock prices fall</td>
<td>Loss</td>
<td>Gain</td>
</tr>
<tr>
<td>Stock prices rise</td>
<td>Gain</td>
<td>Loss</td>
</tr>
</tbody>
</table>

To neutralize the risk of falling stock prices, the fund manager will need to adopt a forward position that benefits from that potential movement. That is, the manager requires a hedge position with payoffs that are negatively correlated with the existing exposure. As we saw in Exhibit 20.10, this requires committing to the short side of the contract. This hedging argument is identical to the point we made in the portfolio formation analysis of Chapter 7 that it is always possible to combine two perfectly negatively correlated assets to create a risk-free position.

\[ S_0 + \left\{ \frac{X}{(1 + RFR)^T} - \frac{F_{0,T}}{(1 + RFR)^T} \right\} = \frac{X}{(1 + RFR)^T} \]

which simplifies to:

\[ S_0 = \frac{F_{0,T}}{(1 + RFR)^T} \]

In the absence of dividend payments, notice that the spot price for the share of stock should simply be the discounted value of purchasing the same security in the forward market. Equivalently, this equation can be rewritten so that \( F_{0,T} = S_0(1 + RFR)^T \). In the preceding example, the market-clearing (i.e., no net initial cost) contract price for a WYZ stock forward agreement should be \( F_{0,0.5} = (53)(1 + 0.0625)^{0.5} = 54.63 \). Finally, when dividends are paid, the equation for the put-call-forward parity condition can be inserted into the dividend-adjusted spot parity condition to produce:

\[ S_0 - \left\{ \frac{D_T}{(1 + RFR)^T} \right\} = \frac{F_{0,T}}{(1 + RFR)^T} \]

7This interpretation follows by noting that the long call position will be exercised when \( S_T > 50 \) and the short put will be exercised against the investor when \( S_T \leq 50 \). Therefore, the investor’s net option position produces an identical result to holding a long position in a forward contract with a contract price of $50. Generalizing this result, any time we have a call and a put option on the same underlying stock with a common exercise price and expiration date, the following is true: (long call at \( X \)) + (short put at \( X \)) = (long forward at \( X \)). Similarly, shorting the call and buying the put produces a synthetic short forward position.
Thus, if a $1 dividend were paid on WYZ stock just prior to the maturity of the contract in six months, the forward price would be adjusted down to \( F_{0.05} = (53)(1 + 0.0625)^{0.5} - 1 = 53.63 \), to account for the payment to the actual shareholders but not the derivative holder.

### 20.4 An Introduction to the Use of Derivatives in Portfolio Management

Beyond the unique risk–reward profiles they offer as standalone investments, derivatives also are used widely to restructure existing portfolios of assets. Typically, the intent of this restructuring is to modify the portfolio’s risk. In this section, we review three prominent derivative applications in the management of equity positions: shorting forward contracts, purchasing protective puts, and purchasing equity collars.

#### 20.4.1 Restructuring Asset Portfolios with Forward Contracts

Suppose the manager of a small corporate pension fund currently has all of her investable funds committed to a well-diversified portfolio of equity securities designed to track the Standard & Poor’s 500 Index. This investment approach is based on the manager’s belief that she cannot add value by trying to select superior individual securities. She does, however, feel that it is possible to take advantage of perceived trends at a macroeconomic level by switching her funds on a tactical basis between her current equity holding and any of several other portfolios mimicking different asset classes (e.g., fixed-income, cash equivalents).

The stock market has increased steadily over the past several months, and the pension fund has a present market value of $100 million. The manager has now become concerned about the possibility that inflationary pressures will dampen corporate earnings and drive stock prices down. She also feels confident that the uncertainty will be resolved during the coming quarter. Accordingly, she would like to shift her allocation from 100 percent equity to 100 percent T-bills for the next three months.

There are two ways she can make this change. The most direct method would be to sell her stock portfolio and buy $100 million (less the transaction costs) of 90-day T-bills. When the T-bills mature in three months, she could then repurchase her original equity holdings.

The second approach would be to maintain her current stock holdings but convert them into a synthetic risk-free position using a three-month forward contract with $100 million of the stock index as the underlying asset. This is a classic example of a hedge position, wherein the price risk of the underlying asset is offset by a supplementary derivative transaction. The following table captures the basic dynamics of this hedge.

<table>
<thead>
<tr>
<th>Economic Event</th>
<th>Actual Stock Exposure</th>
<th>Desired Forward Exposure</th>
</tr>
</thead>
<tbody>
<tr>
<td>Stock prices fall</td>
<td>Loss</td>
<td>Gain</td>
</tr>
<tr>
<td>Stock prices rise</td>
<td>Gain</td>
<td>Loss</td>
</tr>
</tbody>
</table>

To neutralize the risk of falling stock prices, the fund manager will need to adopt a forward position that benefits from that potential movement. That is, the manager requires a hedge position with payoffs that are *negatively correlated* with the existing exposure. As we saw in Exhibit 20.10, this requires committing to the short side of the contract. This hedging argument is identical to the point we made in the portfolio formation analysis of Chapter 7 that it is always possible to combine two perfectly negatively correlated assets to create a risk-free position.
the manager also has surrendered the upside potential of her original holding. Suppose instead that she designed a hedge position correlated to her stock portfolio as follows:

<table>
<thead>
<tr>
<th>Economic Event</th>
<th>Actual Stock Exposure</th>
<th>Desired Forward Exposure</th>
</tr>
</thead>
<tbody>
<tr>
<td>Stock prices fall</td>
<td>Loss</td>
<td>Gain</td>
</tr>
<tr>
<td>Stock prices rise</td>
<td>Gain</td>
<td>No loss</td>
</tr>
</tbody>
</table>

In seeking an asymmetric hedge, this manager wants a derivative contract that allows her to sell stock when prices fall but keep her shares when prices rise. As we have seen, she must purchase a put option to obtain this exposure.

The purchase of a put option to hedge the downside risk of an underlying security holding is called a **protective put** position and is the most straightforward example of a more general set of derivative-based strategies known as **portfolio insurance**.

In lieu of the short forward position, suppose the manager purchased a three-month, at-the-money put option on her $100 million stock portfolio for an up-front premium of $1.324 million. The value of the protective put position (net of the initial cost of the hedge) is calculated in Exhibit 20.22 for several different expiration date prices for the underlying stock portfolio. Notice that with the exercise price set equal to the current portfolio value of $100 million, the put contract exactly offsets any expiration date share price decline while allowing the position to increase in value as stock prices increase. Thus, the put provides the manager with insurance against falling prices with no deductible.

Exhibit 20.21

| Net Position: | Long T-Bill | \( \beta_P = 0 \) | Long Stock | \( \beta_P = 1 \) |

It is far quicker and more cost-effective to convert the pension fund’s asset allocation using this approach than the physical transformations demanded by the first solution. For instance, Exhibit 20.20 shows that when all of the costs of transaction are considered (e.g., trading commissions, market impact, taxes), the average expense of actually rebalancing a U.S. equity portfolio is about 42 basis points of the position’s value, while the same trade with an equity forward contract would cost just 6 basis points. Trading expenses in other countries, though different in absolute level, reflect this same general trend.

This synthetic restructuring is best understood through the effect that it has had on the systematic risk—or beta—of the portfolio. Assume that the original stock holding had a beta of 1.0, matching the volatility of a proxy for the market portfolio. The combination of being long $100 million of stock and short a forward covering $100 million of a stock index converts the systematic portion of the portfolio into a synthetic T-bill, which by definition has a beta of 0.0. Once the contract matures in three months, however, the position will revert to its original risk profile. This is illustrated in Exhibit 20.21. More generally, the short forward position can be designed to allow for intermediate combinations of stock and T-bills as well. To see this, let \( w_S \) be the stock allocation so that \( 1 - w_S \) is the allocation to the risk-free asset created synthetically. The net beta for the converted portfolio is simply a weighted average of the systematic risks of its equity and T-bill portions or:

\[
\beta_p = (w_S)\beta_S + (1 - w_S)\beta_{FR}
\]

Thus, if the manager had wished to change the original allocation from 100 percent stock to a “60–40” mix of stock and T-bills, she would have shorted only $40 million of the index forward to leave her with an unhedged equity position totaling $60 million (i.e., \( w_S = 0.60 \) and \( 1 - w_S = 0.40 \)). This in turn would leave her with an adjusted portfolio beta of \([(0.6)(1) + (0.4)(0)] = 0.6.\]

### 20.4.2 Protecting Portfolio Value with Put Options

The manager’s concern in the previous example was to protect her stock portfolio against possible share price declines over the next three months. However, by shorting the stock index forward contract, she has effectively committed to “selling” her equity position, even if stock prices rise. That is, by using a derivative with a symmetric payoff structure to hedge her risk,
The terminal value of the combined stock and put option portfolio shown in the last column of Exhibit 20.22 resembles the payoff diagram of the long call option position illustrated earlier in Exhibit 20.11. This is shown in Exhibit 20.23, which indicates that being long in the stock and long in the put generates the same net payoff as an at-the-money long call option holding "elevated" by $100 million. Given the put-call-spot parity results of the previous section, this should come as no surprise. Indeed, the no-arbitrage equation (Equation 20.1) can be rewritten:

\[ S_0 + P_0 - X (1 + RFR) = C_0 \]

This expression says that the protective put position generates the same expiration date payoff as a long position in a call option with equivalent characteristics and a long position in a T-bill with a face value equal to the options' exercise price. It is this final term that provides the elevation to the call payoff diagram in Exhibit 20.23. Thus, the manager has two ways of

In seeking an asymmetric hedge, this manager wants a derivative contract that allows her to sell stock when prices fall but keep her shares when prices rise. As we have seen, she must purchase a put option to obtain this exposure.

The purchase of a put option to hedge the downside risk of an underlying security holding is called a protective put position and is the most straightforward example of a more general set of derivative-based strategies known as portfolio insurance. In lieu of the short forward position, suppose the manager purchased a three-month, at-the-money put option on her $100 million stock portfolio for an up-front premium of $1.324 million. The value of the protective put position (net of the initial cost of the hedge) is calculated in Exhibit 20.22 for different expiration date prices for the underlying stock portfolio. Notice that with the exercise price set equal to the current portfolio value of $100 million, the put contract exactly offsets any expiration date share price decline while allowing the position to increase in value as stock prices increase. Thus, the put provides the manager with insurance against falling prices with no deductible.\(^9\)

\(^8\)The concept and use of portfolio insurance have received a great deal of scrutiny in the research literature. See, for example, the studies by Rubinstein (1985), Basak (2002), and Pain and Rand (2008).

\(^9\)In general, the deductible portion of the portfolio insurance contract can be defined as \([S_0 − X]\). For instance, with an exercise price of only 95, the manager would not receive compensation from the hedge until the portfolio value fell below $95 million; she would effectively be self-insuring the first $5 million of losses. Naturally, the larger this deductible amount, the lower the cost of the put option.
providing price insurance for her current stock holding: (1) continue to hold her shares and purchase a put option, or (2) sell her shares and buy both a T-bill and a call option. Her choice between them will undoubtedly come down to considerations such as relative option prices and transaction costs.

20.4.3 An Alternative Way to Pay for a Protective Put

There is a third alternative for protecting against potential stock price declines, which fits between paying nothing for a hedge but surrendering future stock gains for the next three months (i.e., the short forward position) and keeping those potential gains in exchange for a considerable initial payment (i.e., the protective put position). Specifically, suppose that the manager makes two simultaneous decisions. First, she decides to purchase a three-month, out-of-the-money protective put option with an exercise price of $97 million and a commensurately lower initial cost of $0.560 million. (Notice that in purchasing an out-of-the-money contract, the manager is creating a $3 million deductible compared to her current portfolio value.) Second, she decides not to pay cash for the put option; instead, she sells to the option dealer a call option with a three-month expiration and an exercise price of $108 million that also carries an initial premium of $0.560 million. The simultaneous purchase of an out-of-the-money put and sale of an out-of-the-money call on the same underlying asset and with the same expiration date and market price is a strategy known as a collar agreement.

Exhibit 20.24 shows the expiration date outcomes of the manager’s equity collar-protected portfolio for several different terminal stock portfolio values. Like the forward contract hedge, there is no initial out-of-pocket expense associated with this derivative combination. Instead, the manager effectively pays for her desired portfolio insurance by surrendering an equivalent amount of the portfolio’s future upside potential. That is, in exchange for being “made whole” for any stock decline below $97 million, she agrees to give up any stock price appreciation beyond $108 million. Another thing to notice is that, like the protective put (and unlike the short forward position), she does retain some of the benefit of a rising stock market. However, this upside gain potential stops at the exercise price of the call option. As shown in Exhibit 20.25, the manager has placed a collar around her portfolio for the next three months—its net value will not fall below $97 million and will not rise above $108 million. At any terminal value for the stock portfolio between these extreme levels, both of the options expire out of the money and no contract settlement payment will be required of either the manager or the dealer.

D’Antonio (2008) has shown that equity collars are an effective risk management tool compared to traditional portfolio strategies.

The terminal value of the combined stock and put option portfolio shown in the last column of Exhibit 20.22 resembles the payoff diagram of the long call option position illustrated earlier in Exhibit 20.11. This is shown in Exhibit 20.23, which indicates that being long in the stock and long in the put generates the same net payoff as an at-the-money long call option holding "elevated" by $100 million. Given the put-call-spot parity results of the previous section, this should come as no surprise. Indeed, the no-arbitrage equation (Equation 20.1) can be rewritten:

\[
S_0 + P_{0,T} = C_{0,T} + \frac{X}{(1 + RFR)^t}
\]

This expression says that the protective put position generates the same expiration date payoff as a long position in a call option with equivalent characteristics and a long position in a T-bill with a face value equal to the options’ exercise price. It is this final term that provides the elevation to the call payoff diagram in Exhibit 20.23. Thus, the manager has two ways of

### Exhibit 20.23 Terminal Payoff to an Insured Stock Position
As their popularity in financial markets has increased over the past few decades, derivative securities have become an indispensable part of the investment manager’s toolkit. Although forward, futures, and option contracts play important roles as stand-alone investments, the real advantage of derivatives is their ability to modify the risk-return characteristics of a collection of existing securities in a cost-effective manner. This use of forwards and options to restructure a portfolio synthetically has two dimensions: (1) it is possible to combine derivatives with the underlying position to replicate the cash flows of another traded instrument, and (2) derivatives can be used with the original portfolio to create a payoff structure that is otherwise unavailable.

Forward and option contracts can be viewed as insurance policies that an investor can hold against adverse price movements in his underlying position. The basic difference between these contracts lies in how the investor must pay for the desired insurance. Forwards, with symmetrical terminal payoffs, typically do not require any initial payment but do obligate the investor to the possibility of an unfavorable transaction at a future date. Options provide asymmetrical terminal payoffs, but the investor must pay an up-front premium.

There are well-defined relationships that must exist in an efficient capital market between the prices of forward and option contracts. The put-call parity conditions delineate the linkages between five different securities: the underlying asset (e.g., stock), T-bills, forward contracts, call options, and put options. One of these securities is always redundant because its cash flow patterns can be replicated by the remaining instruments. This leads to another important use for derivatives: arbitrage investing. Through their ability to help create synthetic replicas of existing securities, derivatives provide investors with the possibility of providing price insurance for her current stock holding: (1) continue to hold her shares and purchase a put option, or (2) sell her shares and buy both a T-bill and a call option. Her choice between them will undoubtedly come down to considerations such as relative option prices and transaction costs.

### 20.4.3 An Alternative Way to Pay for a Protective Put

There is a third alternative for protecting against potential stock price declines, which fits between paying nothing for a hedge but surrendering future stock gains for the next three months (i.e., the short forward position) and keeping those potential gains in exchange for a considerable initial payment (i.e., the protective put position). Specifically, suppose that the manager makes two simultaneous decisions. First, she decides to purchase a three-month, out-of-the-money protective put option with an exercise price of $97 million and a commensurately lower initial cost of $0.560 million. (Notice that in purchasing an out-of-the-money contract, the manager is creating a $3 million deductible compared to her current portfolio value.) Second, she decides not to pay cash for the put option; instead, she sells to the option dealer a call option with a three-month expiration and an exercise price of $108 million that also carries an initial premium of $0.560 million. The simultaneous purchase of an out-of-the-money put and sale of an out-of-the-money call on the same underlying asset and with the same expiration date and market price is a strategy known as a collar agreement.

Exhibit 20.24 shows the expiration date outcomes of the manager’s equity collar-protected portfolio for several different terminal stock portfolio values. Like the forward contract hedge, there is no initial out-of-pocket expense associated with this derivative combination. Instead, the manager effectively pays for her desired portfolio insurance by surrendering an equivalent amount of the portfolio’s future upside potential. That is, in exchange for being “made whole” for any stock decline below $97 million, she agrees to give up any stock price appreciation beyond $108 million. Another thing to notice is that, like the protective put (and unlike the short forward position), she does retain some of the benefit of a rising stock market. However, this upside gain potential stops at the exercise price of the call option. As shown in Exhibit 20.25, the manager has placed a collar around her portfolio for the next three months—its net value will not fall below $97 million and will not rise above $108 million. At any terminal value for the stock portfolio between these extreme levels, both of the options expire out of the money and no contract settlement payment will be required of either the manager or the dealer. D’Antonio (2008) has shown that equity collars are an effective risk management tool compared to traditional portfolio strategies.

of riskless excess returns when the synthetic and actual instruments sell for different prices.

There are several issues related to the use and management of derivative securities that remain to be addressed, such as how individual positions in forwards, futures, and options are valued and the adjustments that investors need to make when using derivatives on an underlying asset other than common stock. These topics will be considered in subsequent chapters. For now, though, it is important to appreciate these instruments for their ability to assist investors in repackaging the risks and cash flows of their portfolios.

**SUGGESTED READINGS**

**QUESTIONS**

1. Explain why the difference between put and call prices depends on whether or not the underlying security pays a dividend during the life of the contracts.

2. When comparing futures and forward contracts, it has been said that futures are more liquid but forwards are more flexible. Explain what this statement means and comment on how differences in contract liquidity and design flexibility might influence an investor’s preference in choosing one instrument over the other.

3. Compare and contrast the gain and loss potential for investors holding the following positions: long forward, short forward, long call, short call, long put, and short put. Indicate what the terms symmetric and asymmetric mean in this context.

4. As the manager of a medium-sized hedge fund, the recent fluctuations in the capital markets have attracted your attention. In particular, the prices of stocks and bonds have now dropped to what you consider to be unprecedentedly attractive levels. Although you expect the prices of these investments to rise in the near future, your hedge fund is currently cash-constrained due to an unforeseen redemption wave; "fire-selling" the best holdings in your portfolio is not a practical way to generate investable funds. Further, the next round of incoming cash flows from new investor subscriptions and from the existing investments are not expected to occur for approximately three months.
   a. Briefly explain the details of two investment strategies that employ derivative instruments that would allow you to take advantage of the anticipated market rally.
   b. What are the benefits and potential risk factors for undertaking these derivative strategies in lieu of direct cash-oriented investments?

5. As the manager of a large, well-diversified school endowment fund, you are actively considering the implementation of sophisticated derivative strategies to protect your fund’s market value in the event of a substantial decline in the overall level of equity prices. Your colleagues have suggested that you acquire either (1) a short position in an S&P 500 Index futures contract, or (2) a long position in an S&P index put option contract. Explain how each of these derivative strategies would affect the risk and return of the resulting augmented endowment portfolio.

**SUMMARY**

- As their popularity in financial markets has increased over the past few decades, derivative securities have become an indispensable part of the investment manager’s toolkit. Although forward, futures, and option contracts play important roles as stand-alone investments, the real advantage of derivatives is their ability to modify the risk-return characteristics of a collection of existing securities in a cost-effective manner. This use of forwards and options to restructure a portfolio synthetically has two dimensions: (1) it is possible to combine derivatives with the underlying position to replicate the cash flows of another traded instrument, and (2) derivatives can be used with the original portfolio to create a payoff structure that is otherwise unavailable.

- Forward and option contracts can be viewed as insurance policies that an investor can hold against adverse price movements in his underlying position. The basic difference between these contracts lies in how the investor must pay for the desired insurance. Forwards, with symmetrical terminal payoffs, typically do not require any initial payment but do obligate the investor to the possibility of an unfavorable transaction at a future date. Options provide asymmetrical terminal payoffs, but the investor must pay an up-front premium.

- There are well-defined relationships that must exist in an efficient capital market between the prices of forward and option contracts. The put-call parity conditions delineate the linkages between five different securities: the underlying asset (e.g., stock), T-bills, forward contracts, call options, and put options. One of these securities is always redundant because its cash flow patterns can be replicated by the remaining instruments. This leads to another important use for derivatives: arbitrage investing. Through their ability to help create synthetic replicas of existing securities, derivatives provide investors with the possibility...
of riskless excess returns when the synthetic and actual instruments sell for different prices.

- There are several issues related to the use and management of derivative securities that remain to be addressed, such as how individual positions in forwards, futures, and options are valued and the adjustments that investors need to make when using derivatives on an underlying asset other than common stock. These topics will be considered in subsequent chapters. For now, though, it is important to appreciate these instruments for their ability to assist investors in re-packaging the risks and cash flows of their portfolios.

4. As the manager of a medium-sized hedge fund, the recent fluctuations in the capital markets have attracted your attention. In particular, the prices of stocks and bonds have now dropped to what you consider to be unprecedentedly attractive levels. Although you expect the prices of these investments to rise in the near future, your hedge fund is currently cash-constrained due to an unforeseen redemption wave; “fire-selling” the best holdings in your portfolio is not a practical way to generate investable funds. Further, the next round of incoming cash flows from new investor subscriptions and from the existing investments are not expected to occur for approximately three months.
   a. Briefly explain the details of two investment strategies that employ derivative instruments that would allow you to take advantage of the anticipated market rally.
   b. What are the benefits and potential risk factors for undertaking these derivative strategies in lieu of direct cash-oriented investments?

5. As the manager of a large, well-diversified school endowment fund, you are actively considering the implementation of sophisticated derivative strategies to protect your fund’s market value in the event of a substantial decline in the overall level of equity prices. Your colleagues have suggested that you acquire either (1) a short position in an S&P 500 Index futures contract, or (2) a long position in an S&P index put option contract. Explain how each of these derivative strategies would affect the risk and return of the resulting augmented endowment portfolio.
6. Explain how call and put options can represent a leveraged way of investing in the stock market and also enable investors to hedge their risk completely. Specifically, under what circumstances will the addition of an option increase the risk of an existing portfolio and under what circumstances will it decrease portfolio risk?

7. It has been said that, from an investor’s perspective, a long position in a call option represents the “good half” of a long position in a forward contract. Explain what is meant by this statement. Also, describe what the “bad half” of the long forward position would have to be for this statement to be true.

8. Discuss the difficulties that having options in a security portfolio create for the measurement of portfolio risk. Specifically, explain why standard deviation is a deficient statistic for capturing the essence of risk in a put-protected portfolio. How could the standard deviation statistic be modified to account for this concern?

9. If the current price of a nondividend-paying stock is $32 and a one-year futures contract on that stock has a contract price of $35, explain how an investor could create an “off-market” long position in a forward contract at an exercise price of $25. Would this synthetic contract require a cash payment from either the long or the short position? If so, explain which party would have to make the payment and how that payment should be calculated.

**PROBLEMS**

1. The common stock of Sophia Enterprises serves as the underlying asset for the following derivative securities: (1) forward contracts, (2) European-style call options, and (3) European-style put options.

   a. Assuming that all Sophia derivatives expire at the same date in the future, complete a table similar to the following for each of the following contract positions:

   (1) A long position in a forward with a contract price of $50

   (2) A long position in a call option with an exercise price of $50 and a front-end premium expense of $3.23

   (3) A short position in a call option with an exercise price of $50 and a front-end premium receipt of $5.20

   In calculating net profit, ignore the time differential between the initial derivative expense or receipt and the terminal payoff.

   b. Graph the net profit for each of the three derivative positions, using net profit on the vertical axis and Sophia’s expiration date stock price on the horizontal axis. Label the breakeven (i.e., zero profit) point(s) on each graph.
c. Briefly describe the belief about the expiration date price of Sophia stock that an investor using each of these three positions implicitly holds.

2. Refer once again to the derivative securities using Sophia common stock as an underlying asset discussed in Problem 1.
   a. Assuming that all Sophia derivatives expire at the same date in the future, complete a table similar to the following for each of the following contract positions:
      (1) A short position in a forward with a contract price of $50
      (2) A long position in a put option with an exercise price of $50 and a front-end premium expense of $3.23
      (3) A short position in a put option with an exercise price of $50 and a front-end premium receipt of $3.23

In calculating net profit, ignore the time differential between the initial derivative expense or receipt and the terminal payoff.

b. Graph the net profit for each of the three derivative positions, using net profit on the vertical axis and Sophia’s expiration date stock price on the horizontal axis. Label the break-even (i.e., zero profit) point(s) on each graph.

c. Briefly describe the belief about the expiration date price of Sophia stock that an investor using each of these three positions implicitly holds.

3. Suppose that an investor holds a share of Sophia common stock, currently valued at $50. She is concerned that over the next few months the value of her holding might decline, and she would like to hedge that risk by supplementing her holding with one of three different derivative positions, all of which expire at the same point in the future:
   (1) A short position in a forward with a contract price of $50
   (2) A long position in a put option with an exercise price of $50 and a front-end premium expense of $3.23
   (3) A short position in a call option with an exercise price of $50 and a front-end premium receipt of $5.20

a. Using a table similar to the following, calculate the expiration date value of the investor’s combined (i.e., stock and derivative) position. In calculating net portfolio value, ignore the time differential between the initial derivative expense or receipt and the terminal payoff.

b. For each of the three hedge portfolios, graph the expiration date value of her combined position on the vertical axis, with potential expiration date share prices of Sophia stock on the horizontal axis.
6. Consider Commodity Z, which has both exchange-traded futures and option contracts associated with it. As you look in today’s paper, you find the following put and call prices for options that expire exactly six months from now:

<table>
<thead>
<tr>
<th>Exercise Price</th>
<th>Put Price</th>
<th>Call Price</th>
</tr>
</thead>
<tbody>
<tr>
<td>40</td>
<td>$0.59</td>
<td>$8.73</td>
</tr>
<tr>
<td>45</td>
<td>$1.93</td>
<td>—</td>
</tr>
<tr>
<td>50</td>
<td>—</td>
<td>$2.47</td>
</tr>
</tbody>
</table>

a. Assuming that the futures price of a six-month contract on Commodity Z is $48, what must be the price of a put with an exercise price of $50 in order to avoid arbitrage across markets? Similarly, calculate the “no arbitrage” price of a call with an exercise price of $45. In both calculations, assume that the yield curve is flat and the annual risk-free rate is 6 percent.

b. What is the “no arbitrage” price differential that should exist between the put and call options having an exercise price of $40? Is this differential satisfied by current market prices? If not, demonstrate an arbitrage trade to take advantage of the mispricing.

7. Dosley Endowment Fund, which supports the activities of the Dosley Charitable Trust, is relatively new and small in terms of assets under management. The trustees of the endowment have adopted a conservative investment strategy: at the current time, all of the $700 million in assets are equally invested in an S&P 500 Index tracking fund and U.S. Treasury bonds. Right now, the annual dividend yield on the S&P 500 Index fund is 3.0 percent, whereas the annual coupon rate is 4.0 percent for the T-bonds. As the fund manager, you expect that over the next three months the market will be very volatile. Given that the priority of the trustees is to preserve the value of the endowment fund, you are required to use various derivative strategies to protect the assets under management. The current level of S&P 500 is 1,000, and the price of U.S. T-bonds is 100. Assume that the current three-month T-bill rate is 1.2 percent.

a. Using the derivative information listed below, discuss the details of two derivative strategies that could be employed to protect the endowment’s current asset value.

<table>
<thead>
<tr>
<th>Contract Size</th>
<th>Expiration Date</th>
<th>Initial Stock Price</th>
<th>Initial Derivative Payoff</th>
<th>Initial Derivative Premium</th>
</tr>
</thead>
<tbody>
<tr>
<td>S&amp;P 500 Index</td>
<td>Call option</td>

<td></td>
<td></td>
</tr>
<tr>
<td>Future</td>
<td></td>
<td>$103.00</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

b. Applying the put-call parity relationship, which derivative strategy should you recommend and why? Recall that the put and futures prices are as follows:

\[
\text{Put Price} = \text{Call Price} - \text{Security Price} + \text{Present Value of Exercise Price} + \text{Income on the Underlying Security}
\]

\[
\text{Futures Price} = \text{Underlying Security Price} + \left( \text{Treasury Bill Income} - \text{Income on the Underlying Security} \right)
\]

4. You strongly believe that the price of Breener Inc. stock will rise substantially from its current level of $137, and you are considering buying shares in the company. You currently have $13,700 to invest. As an alternative to purchasing the stock itself, you are also considering buying call options on Breener stock that expire in three months and have an exercise price of $140. These call options cost $10 each.

a. Compare and contrast the size of the potential payoff and the risk involved in each of these alternatives.

b. Calculate the three-month rate of return on both strategies assuming that at the option expiration date Breener’s stock price has (1) increased to $155 or (2) decreased to $135.

c. At what stock price level will the person who sells you the Breener call option break even? Can you determine the maximum loss that the call option seller may suffer, assuming that he does not already own Breener stock?

5. The common stock of Company XYZ is currently trading at a price of $42. Both a put and a call option are available for XYZ stock, each having an exercise price of $40 and an expiration date in exactly six months. The current market prices for the put and call are $1.45 and $3.90, respectively. The risk-free holding period return for the next six months is 4 percent, which corresponds to an 8 percent annual rate.

a. For each possible stock price in the following sequence, calculate the expiration date payoffs (net of the initial purchase price) for the following positions: (1) buy one XYZ call option, and (2) short one XYZ call option: 20, 25, 30, 35, 40, 45, 50, 55, 60

Draw a graph of these payoff relationships, using net profit on the vertical axis and potential expiration date stock price on the horizontal axis. Be sure to specify the prices at which these respective positions will break even (i.e., produce a net profit of zero).

b. Using the same potential stock prices as in Part a, calculate the expiration date payoffs and profits (net of the initial purchase price) for the following positions: (1) buy one XYZ put option, and (2) short one XYZ put option. Draw a graph of these relationships, labeling the prices at which these investments will break even.

c. Determine whether the $2.45 difference in the market prices between the call and put options is consistent with the put-call parity relationship for European-style contracts.
6. Consider Commodity Z, which has both exchange-traded futures and option contracts associated with it. As you look in today’s paper, you find the following put and call prices for options that expire exactly six months from now:

<table>
<thead>
<tr>
<th>Exercise Price</th>
<th>Put Price</th>
<th>Call Price</th>
</tr>
</thead>
<tbody>
<tr>
<td>40</td>
<td>$0.59</td>
<td>$8.73</td>
</tr>
<tr>
<td>45</td>
<td>1.93</td>
<td>—</td>
</tr>
<tr>
<td>50</td>
<td>—</td>
<td>2.47</td>
</tr>
</tbody>
</table>

a. Assuming that the futures price of a six-month contract on Commodity Z is $48, what must be the price of a put with an exercise price of $50 in order to avoid arbitrage across markets? Similarly, calculate the “no arbitrage” price of a call with an exercise price of $45. In both calculations, assume that the yield curve is flat and the annual risk-free rate is 6 percent.

b. What is the “no arbitrage” price differential that should exist between the put and call options having an exercise price of $40? Is this differential satisfied by current market prices? If not, demonstrate an arbitrage trade to take advantage of the mispricing.

7. Dosley Endowment Fund, which supports the activities of the Dosley Charitable Trust, is relatively new and small in terms of assets under management. The trustees of the endowment have adopted a conservative investment strategy: at the current time, all of the $700 million in assets are equally invested in an S&P 500 Index tracking fund and U.S. Treasury bonds. Right now, the annual dividend yield on the S&P 500 Index fund is 3.0 percent, whereas the annual coupon rate is 4.0 percent for the T-bonds. As the fund manager, you expect that over the next three months the market will be very volatile. Given that the priority of the trustees is to preserve the value of the endowment fund, you are required to use various derivative strategies to protect the assets under management. The current level of S&P 500 is 1,000, and the price of U.S. T-bonds is 100. Assume that the current three-month T-bill rate is 1.2 percent.

a. Using the derivative information listed below, discuss the details of two derivative strategies that could be employed to protect the endowment’s current asset value.

<table>

</tr>
</tbody>
</table>

b. Applying the put-call parity relationship, which derivative strategy should you recommend and why? Recall that the put and futures prices are as follows:

\[
\text{Put Price} = \text{Call Price} - \text{Security Price} + \text{Present Value of Exercise Price} + \text{Income on the Underlying Security} \\
\text{Futures Price} = \text{Underlying Security Price} + \left(\text{Treasury Bill Income} - \text{Income on the Underlying Security}\right)
\]
8. As an option trader, you are constantly looking for opportunities to make an arbitrage transaction (i.e., a trade in which you do not need to commit your own capital or take any risk but can still make a profit). Suppose you observe the following prices for options on DRKC Co. stock: $3.18 for a call with an exercise price of $60, and $3.38 for a put with an exercise price of $60. Both options expire in exactly six months, and the price of a six-month T-bill is $97.00 (for face value of $100).
   a. Using the put-call-spot parity condition, demonstrate graphically how you could synthetically recreate the payoff structure of a share of DRKC stock in six months using a combination of puts, calls, and T-bills transacted today.
   b. Given the current market prices for the two options and the T-bill, calculate the no-arbitrage price of a share of DRKC stock.
   c. If the actual market price of DRKC stock is $60, demonstrate the arbitrage transaction you could create to take advantage of the discrepancy. Be specific as to the positions you would need to take in each security and the dollar amount of your profit.

9. You are currently managing a stock portfolio worth $55 million and you are concerned that over the next four months equity values will be flat and may even fall. Consequently, you are considering two different strategies for hedging against possible stock declines: (1) buying a protective put, and (2) selling a covered call (i.e., selling a call option based on the same underlying stock position you hold). An over-the-counter derivatives dealer has expressed interest in your business and has quoted the following bid and offer prices (in millions) for at-the-money call and put options that expire in four months and match the characteristics of your portfolio:

<table>
<thead>
<tr>
<th></th>
<th>Bid</th>
<th>Ask</th>
</tr>
</thead>
<tbody>
<tr>
<td>Call</td>
<td>$2.553</td>
<td>$2.573</td>
</tr>
<tr>
<td>Put</td>
<td>1.297</td>
<td>1.317</td>
</tr>
</tbody>
</table>

   a. For each of the following expiration date values for the unhedged equity position, calculate the terminal values (net of initial expense) for a protective put strategy:
      35, 40, 45, 50, 55, 60, 65, 70, 75
   b. Draw a graph of the protective put net profit structure in Part a, and demonstrate how this position could have been constructed by using call options and T-bills, assuming a risk-free rate of 7 percent.
   c. For each of these same expiration date stock values, calculate the terminal net profit values for a covered call strategy.
   d. Draw a graph of the covered call net profit structure in Part c, and demonstrate how this position could have been constructed by using put options and T-bills, again assuming a risk-free rate of 7 percent.

10. The common stock of Company XLT and its derivative securities currently trade in the market at the following prices and contract terms:

<table>
<thead>
<tr>
<th></th>
<th>Price ($)</th>
<th>Exercise price ($)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Stock XLT</td>
<td>21.50</td>
<td>—</td>
</tr>
<tr>
<td>Call option on Stock XLT</td>
<td>5.50</td>
<td>21.00</td>
</tr>
<tr>
<td>Put option on Stock XLT</td>
<td>4.50</td>
<td>21.00</td>
</tr>
</tbody>
</table>

Both of these options will expire 91 days from now, and the annualized yield for the 91-day Treasury bill is 3.0 percent.
   a. Briefly explain how to construct a synthetic Treasury bill position.
   b. Calculate the annualized yield for the synthetic Treasury bill in Part a using the market price data provided.
c. Describe the arbitrage strategy implied by the difference in yields for the actual and synthetic T-bill positions. Show the net, riskless cash flow you could generate assuming a transaction involving 21 actual T-bills and 100 synthetic T-bills.

d. What is the net cash flow of this arbitrage strategy at the option expiration date, assuming that Stock XLT trades at $23 at expiration three months from now?

**THOMSON REUTERS**

Use the Thomson One—Business School Edition Online Database to answer the following question.

1. The put/call ratio calculates the trading volume of put contracts outstanding for a particular stock or stock index divided by trading volume for the total number of outstanding call options. The ratio is sometimes viewed as an investor sentiment indicator: When the ratio is relatively high, investors are bearish about market conditions; when the ratio is relatively low, investors are bullish.

   a. Under the “Indices” tab, download monthly data over the most recent five years for the level of the Eurex Index Option Put Call Ratio (EUXDIPC).

   b. Calculate the average value for this ratio for: (1) the full five-year period; and (2) each of the past five one-year periods. Explain what you think the trend this ratio has exhibited over time implies about investor expectations for the European stock market.

   c. Download monthly price data over the most recent five years for the Dow Jones Euro Stoxx 50 Index (DJEURST), Europe’s leading indicator of blue-chip companies. Use these price data to calculate monthly returns (i.e., price changes without dividends) for the five-year period. (Note: You will lose one month from the sample period when you convert prices to returns.)

   d. Calculate the correlation coefficient between two series: the EUXDIPC ratio and the DJEURST for the same month (i.e., both from month \( t \) for a given pair of observations).

   e. Repeat your calculation of the correlation coefficient with the following adjustment: use the EUXDIPC ratio lagged by one month (month \( t-1 \)) paired with the DJEURST from month \( t \) (i.e., you observe the put/call ratio one month before you observe the DJ Euro stock index return). You will lose another observation when you lag the put/call ratio data series.

   f. Interpret the correlation coefficients that you have calculated in Parts d and e and explain whether either of them supports the view of the put/call ratio as an effective indicator of market sentiment.
CHAPTER 21

Forward and Futures Contracts

After you read this chapter, you should be able to answer the following questions:

1. What are the historical differences in the way forward and futures contracts are structured and traded?
2. How are the margin accounts on a futures contract adjusted for daily changes in market conditions?
3. How can an investor use forward and futures contracts to hedge an existing risk exposure?
4. What is a hedge ratio, and how should it be calculated?
5. What economic functions do the forward and futures markets serve?
6. How are forward and futures contracts valued after origination?
7. What is the relationship between futures contract prices and the current and expected spot price for the underlying commodity or security?
8. How can an investor use forward and futures contracts to speculate on a particular view about changing market conditions?
9. How can forward and futures contracts be designed to hedge interest rate risk?
10. What is stock index arbitrage, and how is it related to program trading?
11. How can forward and futures contracts be designed to hedge foreign exchange rate risk?
12. What is interest rate parity, and how would you construct a covered interest arbitrage transaction?

As we saw in Chapter 20, forward and futures contracts are the most straightforward form of derivative instrument because they allow an investor to lock in the price of a transaction that will not be completed until a later date. We now continue our discussion of these contracts along several lines. First, we take a closer look at the contract terms and trading mechanics of forwards and futures. We examine important differences that exist between the two markets and describe the process by which futures contracts are marked to market on a daily basis. Further, we discuss how these contracts are used to hedge the price risk inherent in an existing or anticipated position and how hedge ratios are computed.

Second, we consider how forward and futures contracts are priced in an efficient capital market. Given how these instruments differ from stocks and bonds, the notion of traditional security valuation is not quite appropriate. Instead, valuation involves specifying the proper relationship between the forward contract price and the spot price for the underlying position. We develop the "no arbitrage" result that the forward contract price should be equal to the spot price plus the cumulative costs of transporting the underlying security or commodity from the present to the future delivery date. These carrying costs can be either positive or negative; therefore, the correct forward contract price can be either higher or lower than the spot price.
Finally, we demonstrate several applications for using forward and futures contracts. We concentrate on a class of contracts—financial forwards and futures—that are particularly useful to investors. The underlying securities in financial futures include stock indexes, Treasury bonds, bank deposits, and foreign currencies. The use of these contracts will be illustrated in a series of examples demonstrating the connections between cash and futures markets.

21.1 A NOVERVIEW OF FORWARD AND FUTURES TRADING

Historically, forward contracts are agreements negotiated directly between two parties in the OTC (i.e., nonexchange-traded) markets. A typical participant in a forward contract is a commercial or investment bank that, serving the role of the market maker, is contacted directly by the customer. Forward contracts can be tailored to the specific needs of the ultimate end user. Futures contracting, on the other hand, is somewhat more complicated. An investor wishing either to buy or to sell in the futures market gives his order to a broker (a futures commission merchant), who then passes it to a trader on the floor of an exchange (the trading pit) or through an electronic trading network. After a trade has been agreed on, details of the deal are passed to the exchange clearinghouse, which catalogs the transaction. The ultimate end users in a futures contract never deal with each other directly, but transact with the clearinghouse, which is also responsible for overseeing the delivery process, settling daily gains and losses, and guaranteeing the overall transaction. Exhibit 21.1 highlights the differences in how these contracts are created.

As an example, consider the agricultural commodity futures that have been traded for more than 160 years beginning with the creation of the Chicago Board of Trade (CBT), the world’s oldest derivatives exchange. Futures contracts based on a wide array of commodities and

As we saw in Chapter 20, forward and futures contracts are the most straightforward form of derivative instrument because they allow an investor to lock in the price of a transaction that will not be completed until a later date. We now continue our discussion of these contracts along several lines. First, we take a closer look at the contract terms and trading mechanics of forwards and futures. We examine important differences that exist between the two markets and describe the process by which futures contracts are marked to market on a daily basis. Further, we discuss how these contracts are used to hedge the price risk inherent in an existing or anticipated position and how hedge ratios are computed.

Second, we consider how forward and futures contracts are priced in an efficient capital market. Given how these instruments differ from stocks and bonds, the notion of traditional security valuation is not quite appropriate. Instead, valuation involves specifying the proper relationship between the forward contract price and the spot price for the underlying position. We develop the “no arbitrage” result that the forward contract price should be equal to the spot price plus the cumulative costs of transporting the underlying security or commodity from the present to the future delivery date. These carrying costs can be either positive or negative; therefore, the correct forward contract price can be either higher or lower than the spot price.
Finally, we demonstrate several applications for using forward and futures contracts. We concentrate on a class of contracts—financial forwards and futures—that are particularly useful to investors. The underlying securities in financial futures include stock indexes, Treasury bonds, bank deposits, and foreign currencies. The use of these contracts will be illustrated in a series of examples demonstrating the connections between cash and futures markets.

### 21.1 An Overview of Forward and Futures Trading

Historically, forward contracts are agreements negotiated directly between two parties in the OTC (i.e., nonexchange-traded) markets. A typical participant in a forward contract is a commercial or investment bank that, serving the role of the market maker, is contacted directly by the customer. Forward contracts can be tailored to the specific needs of the ultimate end user. Futures contracting, on the other hand, is somewhat more complicated. An investor wishing either to buy or to sell in the futures market gives his order to a broker (a futures commission merchant), who then passes it to a trader on the floor of an exchange (the trading pit) or through an electronic trading network. After a trade has been agreed on, details of the deal are passed to the exchange clearinghouse, which catalogs the transaction. The ultimate end users in a futures contract never deal with each other directly, but transact with the clearinghouse, which is also responsible for overseeing the delivery process, settling daily gains and losses, and guaranteeing the overall transaction. Exhibit 21.1 highlights the differences in how these contracts are created.\(^1\)

As an example, consider the agricultural commodity futures that have been traded for more than 160 years beginning with the creation of the Chicago Board of Trade (CBT), the world’s oldest derivatives exchange. Futures contracts based on a wide array of commodities and

![Exhibit 21.1 Historical Forward and Futures Trading Mechanics](image-url)

\(^1\)For a more detailed discussion of the historical futures trading process, see Clarke (1992); some of this discussion is based on his book.
securities have been created and now trade on over 100 exchanges worldwide. Exhibit 21.2 lists the leading futures exchanges in the United States and the world, ranked by trading volume. Notice that three of the top ten exchanges in the world are located in the United States. Additionally, Exhibit 21.3 shows price and trade activity data for a representative sample of commodity futures contracts; financial futures will be described in detail later in the chapter. Each of these commodity contracts is standardized in terms of the amount and type of the commodity involved and the available dates on which it can be delivered. As we will see, this standardization can lead to an important source of risk that may not exist in forward contracts.

### 21.1.1 Futures Contract Mechanics

To interpret the display in Exhibit 21.3, consider the gold futures contract traded on the Commodity Exchange (CMX), a division of the CME Group, on March 2, 2011. Each contract calls for the long position to buy, and the short position to sell, 100 troy ounces of gold in the appointed months. With commodity futures, it usually is the case that delivery can take place any time during the month at the discretion of the short position. Contracts are available with settlement dates every other month for the next five years, although only the next two contracts are shown. An investor committing on this particular date to a long position in the June 2011 contract is obligated to buy 100 ounces of gold four months later for the contract price of $1,432.10 per ounce. Open interest—the total number of outstanding contracts—was 68,083 for this expiration date.²

²New contracts are created when a new customer comes to the exchange at a time when no existing contract holder wishes to liquidate his position. On the other hand, if an existing customer wants to close out her short position and there is not a new customer to take her place, the contract price will be raised until an existing long position is enticed to sell back his agreement, thereby canceling the contract and reducing open interest by one.

Another important difference between forward and futures contracts is how the two types of agreements account for the possibility that a counterparty will fail to honor its obligation. Forward contracts may not require either counterparty to post collateral, in which case each is exposed to the potential default of the other during the entire life of the contract. In contrast, the futures exchange requires each customer to post an initial margin account in the form of cash or government securities when the contract is originated. (The futures exchange, as a well-capitalized corporation, does not post collateral to protect customers from its potential default.) This margin account is then adjusted, or marked to market, at the end of each trading day, according to that day’s price movements. All outstanding positions are adjusted to the settlement price, which is set by the exchange after trading ends to reflect the midpoint of the closing price range. The marked-to-market process effectively credits or debits each customer’s margin account for daily trading gains or losses as if the customer had closed out her position, even though the contract remains open. For example, Exhibit 21.3 indicates that the settlement price of the March 2011 gold contract increased by $21.40 per ounce from the previous trading day. This price increase benefits the holder of a long position by $2,140 (= 21.40 per ounce × 100 ounces). Specifically, if she had entered into the contract yesterday, she would have a commitment to buy gold for $1,411.30, which she could now sell for $1,432.70. Accordingly, her margin account will be increased by $2,140. Conversely, any party who is short February gold futures will have his margin account reduced by $2,140 per contract. To ensure that the exchange always has enough protection, collateral accounts are not allowed to fall below a predetermined maintenance level, typically about 75 percent of the initial level. If this $2,140 adjustment reduced the short position’s account beneath the maintenance margin, he would receive a margin call and be required to restore the account to its full initial level or face involuntary liquidation.

### 21.1.2 Comparing Forward and Futures Contracts

To summarize, the main trade-off historically between forward and futures contracts is design flexibility versus credit and liquidity risk, as highlighted by the following comparison:

<table>
<thead>
<tr>
<th></th>
<th>Futures</th>
<th>Forwards</th>
</tr>
</thead>
<tbody>
<tr>
<td>Design flexibility</td>
<td>Standardized</td>
<td>Can be customized</td>
</tr>
<tr>
<td>Credit risk</td>
<td>Clearinghouse risk</td>
<td>Counterparty risk</td>
</tr>
<tr>
<td>Liquidity risk</td>
<td>Depends on trading</td>
<td>Negotiated exit</td>
</tr>
</tbody>
</table>

These differences represent extremes; some forward contracts are quite standard and liquid, while some futures contracts now allow for greater flexibility in the terms of the agreement. Also, forwards have historically required less managerial oversight and intervention—especially on a daily basis—because of the lump-sum settlement at delivery (i.e., no margin accounts or marked-to-market settlement), a feature that is often important to unsophisticated or infrequent users of these products.

One interesting development that resulted from the global capital market decline in 2008–2009 was the increased scrutiny that OTC derivatives received from regulators. The Dodd-Frank Wall Street Reform and Consumer Protection Act, which was adopted by the U.S. Congress in 2010, contains several provisions that change the nature of the way some OTC derivatives can be created and traded. In particular, the Act (1) provides the Security Exchange Commission (SEC) and Commodity Futures Trading Commission (CFTC) with the authority to regulate OTC derivative transactions in an attempt to create more transparency in the financial system, and (2) requires central clearing and exchange trading for derivative positions that can be cleared. Thus, under these new statutes, it is likely that forward contracts will begin to look more like futures contracts in form and function, which will reduce significantly the differences implied by the preceding trade-off comparison.
Another important difference between forward and futures contracts is how the two types of agreements account for the possibility that a counterparty will fail to honor its obligation. Forward contracts may not require either counterparty to post collateral, in which case each is exposed to the potential default of the other during the entire life of the contract. In contrast, the futures exchange requires each customer to post an *initial margin account* in the form of cash or government securities when the contract is originated. (The futures exchange, as a well-capitalized corporation, does not post collateral to protect customers from its potential default.) This margin account is then adjusted, or marked to market, at the end of each trading day, according to that day’s price movements. All outstanding positions are adjusted to the *settlement price*, which is set by the exchange after trading ends to reflect the midpoint of the closing price range.

The marked-to-market process effectively credits or debits each customer’s margin account for daily trading gains or losses as if the customer had closed out her position, even though the contract remains open. For example, Exhibit 21.3 indicates that the settlement price of the March 2011 gold contract increased by $21.40 per ounce from the previous trading day. This price increase benefits the holder of a long position by $2,140 (= 21.40 per ounce × 100 ounces). Specifically, if she had entered into the contract yesterday, she would have a commitment to buy gold for $1,411.30, which she could now sell for $1,432.70. Accordingly, her margin account will be increased by $2,140. Conversely, any party who is short February gold futures will have his margin account reduced by $2,140 per contract. To ensure that the exchange always has enough protection, collateral accounts are not allowed to fall below a predetermined *maintenance level*, typically about 75 percent of the initial level. If this $2,140 adjustment reduced the short position’s account beneath the maintenance margin, he would receive a *margin call* and be required to restore the account to its full initial level or face involuntary liquidation.

### 21.1.2 Comparing Forward and Futures Contracts

To summarize, the main trade-off historically between forward and futures contracts is *design flexibility* versus *credit and liquidity risks*, as highlighted by the following comparison:

<table>
<thead>
<tr>
<th></th>
<th>Futures</th>
<th>Forwards</th>
</tr>
</thead>
<tbody>
<tr>
<td>Design flexibility:</td>
<td>Standardized</td>
<td>Can be customized</td>
</tr>
<tr>
<td>Credit risk:</td>
<td>Clearinghouse risk</td>
<td>Counterparty risk</td>
</tr>
<tr>
<td>Liquidity risk:</td>
<td>Depends on trading</td>
<td>Negotiated exit</td>
</tr>
</tbody>
</table>

These differences represent extremes; some forward contracts are quite standard and liquid, while some futures contracts now allow for greater flexibility in the terms of the agreement. Also, forwards have historically required less managerial oversight and intervention—especially on a daily basis—because of the lump-sum settlement at delivery (i.e., no margin accounts or marked-to-market settlement), a feature that is often important to unsophisticated or infrequent users of these products.

One interesting development that resulted from the global capital market decline in 2008–2009 was the increased scrutiny that OTC derivatives received from regulators. The Dodd-Frank Wall Street Reform and Consumer Protection Act, which was adopted by the U.S. Congress in 2010, contains several provisions that change the nature of the way some OTC derivatives can be created and traded. In particular, the Act (1) provides the Security Exchange Commission (SEC) and Commodity Futures Trading Commission (CFTC) with the authority to regulate OTC derivative transactions in an attempt to create more transparency in the financial system, and (2) requires central clearing and exchange trading for derivative positions that can be cleared. Thus, under these new statutes, it is likely that forward contracts will begin to look more like futures contracts in form and function, which will reduce significantly the differences implied by the preceding trade-off comparison.
21.2 Hedging with Forwards and Futures

21.2.1 Hedging and the Basis

The goal of a hedge transaction is to create a position that will offset the price risk of another, more fundamental holding. The word offset is used here rather than eliminate because the hedge transaction attempts to neutralize an exposure that remains on the balance sheet. In Chapter 20, we expressed this concept with the following chart, which assumes that the underlying exposure results from a long commodity position:

<table>
<thead>
<tr>
<th>Economic Event</th>
<th>Actual Commodity Exposure</th>
<th>Desired Hedge Exposure</th>
</tr>
</thead>
<tbody>
<tr>
<td>Commodity prices fall</td>
<td>Loss</td>
<td>Gain</td>
</tr>
<tr>
<td>Commodity prices rise</td>
<td>Gain</td>
<td>Loss</td>
</tr>
</tbody>
</table>

In this case, a short position in a forward contract based on the same commodity would provide the desired negative price correlation. By holding a short forward position against the long position in the commodity, the investor has entered into a short hedge. A long hedge is created by supplementing a short commodity holding with a long forward position.

The basic premise behind any hedge is that as the price of the underlying commodity changes, so too will the price of a forward contract based on that commodity. The hope of the hedger is that the spot and forward prices change in a predictable way relative to one another. For instance, the short hedger in the preceding example is hoping that if commodity prices fall and reduce the value of her underlying asset, the forward contract price also will fall by the same amount to create an offsetting gain on the derivative. Thus, a critical feature that affects the quality of a hedge transaction is how spot and forward prices change over time.

**Defining the Basis** To understand the relationship between spot and forward price movements, it is useful to develop the concept of the basis. At any Date \( t \), the basis is the spot price minus the forward price for a contract maturing at Date \( T \):

\[
B_{t,T} = S_t - F_{t,T}
\]

where:

- \( S_t \) = the Date \( t \) spot price
- \( F_{t,T} \) = the Date \( t \) forward price for a contract maturing at Date \( T \)

Potentially, a different level of the basis may exist on each trading Date \( t \). Two facts always are true, however. First, the initial basis at Date 0 \( (B_{0,T}) \) is known since both the current spot and the forward contract prices can be observed. Second, the maturity basis at Date \( T \) \( (B_{T,T}) \) always is zero whenever the commodity underlying the forward contract matches the asset held exactly. For this to occur, the forward price must converge to the spot price as the contract expires \( (F_{T,T} = S_T) \).

Consider again the investor who hedged her long position in a commodity by agreeing to sell it at Date \( T \) through a short position in a forward contract. The value of the combined position is \( (F_{0,T} - S_0) \). If the investor decides to liquidate her entire position (including the hedge) prior to maturity, she will have to (1) sell her commodity position on the open market for \( S_0 \), and (2) buy back her short forward position for the new contract price of \( F_{t,T} \). The profit from the short hedge liquidated at Date \( t \) is:

\[
B_{t,T} - B_{0,T} = (S_t - F_{t,T}) - (S_0 - F_{0,T})
\]

\(^3\)The mechanics of liquidating a forward or futures contract prior to maturity are described in the next section.
The term $R_{i,T}$ often is called the *cover basis* because that is when the forward contract is closed out, or covered.

### 21.2.2 Understanding Basis Risk

Equation 21.2 highlights an important fact about hedging. Once the hedge position is formed, the investor no longer is exposed to the absolute price movement of the underlying asset alone. Instead, she is exposed to *basis risk* because the terminal value of her combined position is defined as the cover basis minus the initial basis. Notice that only the cover basis is unknown at Date 0, and so her real exposure is to the *correlation* between subsequent changes in the spot and forward contract prices. If these movements are highly correlated, the basis risk will be quite small. It is usually possible to design a forward contract that reduces basis risk to zero, since $F_{T,T} = S_T$. However, basis risk is a possibility when contract terms are standardized, which is most likely to occur in the futures market.

To illustrate the concept of basis risk, suppose the investor wishes in early March to hedge a long position of 75,000 pounds of coffee she is planning to sell in April. Exhibit 21.3 shows that coffee futures contracts do exist, but with delivery months either later in March or in May. With each contract requiring the delivery of 37,500 pounds of coffee, she decides to short two of the May contracts, specifically intending to liquidate her position a month early. Suppose that on the date she initiates her short hedge, the spot coffee price was $2.5938 per pound and the May futures contract price was $2.6930 per pound. This means that her initial basis was $-0.92$ cents, which she hopes will move toward zero in a smooth and predictable manner. Suppose that when she closes out her combined position in April, coffee prices have declined so that $S_T = 2.4956$ and $F_{T,T} = 2.5070$, leaving a cover basis of $-1.14$ cents. This means the basis has increased in value, or *strengthened*, which is to the short hedger's advantage. The net April selling price for her coffee is $2.6816$ per pound, which is equal to the spot price of $2.4956$ plus the net futures profit of $0.1860 = (2.6930 - 2.5070)$. Notice that this is lower than the original futures price but considerably higher than the April spot price. Thus, the short hedger has benefited by exchanging pure price risk for basis risk.

Although it is difficult to generalize, substantial indirect evidence exists that minimizing basis risk is the primary goal of most hedgers. Brown and Smith (1995a) noted that the phenomenal growth of OTC products to manage interest rate risk—despite the existence of exchange-traded contracts—is a response to the desire to create customized solutions. A survey by Jesswein, Kwok, and Folks (1995) showed that corporate risk managers preferred to hedge their firms’ foreign exchange exposure with forward contracts rather than with futures by a ratio of about five to one. However, Bali, Hume, and Martell (2007) showed that hedging with futures does not necessarily reduce a firm’s rate of return.

### 21.2.3 Calculating the Optimal Hedge Ratio

In the preceding example, the decision to short two coffee futures contracts was simple because the investor held exactly twice as much of the same commodity as was covered by a single contract. In most cases, calculating the appropriate hedge ratio, or the number of futures contracts per unit of the spot asset, is not that straightforward. The approach suggested by Johnson (1960), Stein (1961), and Castelino (2000) is to choose the number of contracts that minimizes the variance of net profit from a hedged commodity position.

Consider the position of a short hedger who is long one unit of a particular commodity and short $N$ forward contracts on that commodity. Rewriting Equation 21.2 accordingly, the net profit ($\Pi_t$) of this position at Date $t$ can be written:

$$\Pi_t = (S_t - S_0) - (F_{i,T} - F_{0,T})(N) = (\Delta S) - (\Delta F)(N)$$
The variance of this value is then given as:

\[ \sigma_H^2 = \sigma_S^2 + (N^2)\sigma_F^2 - 2(N)\text{COV}_{S,F} \]

where:

\( \text{COV} = \) the covariance of changes in the spot and forward prices

Minimizing this expression and solving for \( N \) leaves:

\[ N^* = \frac{\text{COV}_{S,F}}{\sigma_F^2} = \left( \frac{\sigma_S}{\sigma_F} \right) \rho \]

where:

\( \rho = \) the correlation coefficient between the spot and forward price changes\(^4\)

The optimal hedge ratio \( (N^*) \) can be interpreted as the ratio of the spot and forward price standard deviations multiplied by the correlation coefficient between the two series. That is, the optimal number of contracts is determined by the ratio of total volatilities deflated by \( \rho \) to account for the systematic relationship between the spot and forward prices. (It is directly comparable to the beta coefficient of a common stock.) So, the best contract to use in hedging an underlying spot position is the one that has the highest value of \( \rho \). What if, for instance, a clothing manufacturer wanted to hedge the eventual purchase of a large quantity of wool, a commodity for which no exchange-traded futures contract exists? The expression for \( N^* \) suggests that it may be possible to form an effective cross hedge if prices for a contract based on a related commodity (e.g., cotton) are highly correlated with wool prices. The expected basis risk of such a cross hedge can be measured as \( (1 - \rho^2) \). Finally, the value for \( N^* \) also can be calculated as the slope coefficient of a regression using \( \Delta S \) and \( \Delta F \) as the dependent and independent variables, respectively.\(^5\) In the regression context, \( \rho^2 \) is called the coefficient of determination or, more commonly, \( R^2 \). Some examples of these calculations are presented in subsequent sections.

### 21.3 Forward and Futures Contracts: Basic Valuation Concepts

Forward and futures contracts are not securities but trade agreements that enable both buyers and sellers of an underlying commodity or security to lock in the eventual price of their transaction. They typically require no front-end payment from either the long or the short position, so the contract’s initial market value usually is zero. Once the terms of the agreement are set, however, any change in market conditions will likely increase the value of the contract to one of the participants. For example, an obligation made in May to purchase soybeans in September for $13.50 per bushel is surely quite valuable in July if soybean prices in the spot market are already $13.95 and no additional harvest is anticipated in the next two months. A description of the valuation of these agreements, which is different for futures and forward contracts, follows.

---

\(^4\)Given data for spot and forward prices, \( \sigma_H^2 \) in the variance equation is a function of just one variable, \( N \). Thus, differentiating this equation with respect to \( N \) leaves, \[ \frac{d\sigma_H^2}{dN} = 2(N)\sigma_F^2 - 2\text{COV}_{S,F}, \] which can be set equal to zero and solved for \( N^* \). It is easily confirmed that the second derivative of this function is positive and so \( N^* \) is a minimizing value.

\(^5\)Some have questioned whether regression-based hedge ratios are stable enough to be useful in practice. Recent researchers, however, have concluded that they are stationary; see Ferguson and Leistikow (1998), although Lien (2010) suggests that the covariance between spot and forward prices can change over time.
21.3.1 Valuing Forwards and Futures

Suppose that at Date 0 you contracted in the forward market to buy Q ounces of gold at Date T for $F_{0,T}$. At Date t, prior to the maturity Date T, you decide that this long position is no longer necessary for your portfolio, and you want to unwind your original obligation. One way to do this is to take a short position in a Date t forward contract designed to offset the terms of the first. That is, at Date t you would agree to sell Q ounces of gold at Date T for the price of $F_{t,T}$. This is shown in Panel A of Exhibit 21.4. Because you now have contracts to buy and sell Q ounces of gold, you have no exposure to gold price movements between Dates t and T. The profit or loss on this pair of forward contracts is $(Q)(F_{t,T} - F_{0,T})$, or the difference between the selling and purchase prices multiplied by the quantity involved. However, this amount would not be received (if $F_{t,T} > F_{0,T}$) or paid until Date T, meaning that the value of the original long forward position when it is sold on Date t (i.e., its unwind value) would be the present value of $(Q)(F_{t,T} - F_{0,T})$, or:

\[ V_{t,T} = (Q)(F_{t,T} - F_{0,T}) + (1 + i)^{T-t} \]

where:

- $i$ = the appropriate annualized discount rate

Equation 21.4 expresses the Date t value of a long forward contract maturing at Date t. The value $V_{t,T}$ can be positive or negative, depending on whether $F_{t,T}$ is greater or less than the original contract price, $F_{0,T}$. Also, the value of the short side of the same contract is just

\[ V_{t,T} = (Q)(F_{0,T} - F_{t,T}) + (1 + i)^{T-t} \]

For example, if you had originally agreed to a long position in a six-month gold forward at $F_{0.5} = \$1,350$, and after three months the new forward contract price is $F_{0.25} = \$1,365$, the value of your position would be $1,464.68 = (100)(1,365 - 1,300) \times (1.1)^{0.25}$, assuming a 10 percent discount rate. Conversely, the value of the original short position would then have to be $-1,464.68$. Finally, notice that as Date t approaches Date T, the value of the contract simply becomes $(Q)(F_{T,T} - F_{0,T})$.

Valuing a futures contract is conceptually similar to valuing a forward contract with one important difference. As we saw earlier, futures contracts are marked to market on a daily basis, and this settlement amount was not discounted to account for the difference between Dates t and T. That is, the Date t value of the futures contract is simply the undiscounted difference between the futures prices at the origination and unwind (or cover) dates, multiplied by the contract quantity, as shown in Panel B of Exhibit 21.4 and:

\[ V'_{t,T} = (Q)(F'_{t,T} - F'_{0,T}) \]

### Exhibit 21.4 Unwind Values for Forward and Futures Contracts

</tbody>
</table>
where:

= the possibility that forward and futures prices for the same commodity at the same point in time might be different

Cox, Ingersoll, and Ross (1981) showed that \( F_{0,T} \) and \( F_{0,T} \) would be equal if short-term interest rates (\( r \) in Equation 21.4) are known but need not be the same under other circumstances.

Typically, for commodities and securities that support both forward and futures markets, differences between \( F_{0,T} \) and \( F_{0,T} \) exist but are relatively small. Cornell and Reinganum (1981) found few economically meaningful differences between forward and futures prices in the foreign exchange market, while Park and Chen (1985) showed that certain agricultural and precious metal futures prices were significantly higher than the analogous forward prices. Grinblatt and Jegadeesh (1996) documented that differences in prices for Eurodollar forward and futures contracts are due to a mispricing of the latter, although this mispricing has been eliminated over time.

21.3.2 The Relationship between Spot and Forward Prices

The relationship between the spot and forward prices at any moment in time is often a more challenging question than how the contract is valued. We can understand the intuition for this relationship with an example: You have agreed at Date 0 to deliver 5,000 bushels of corn to your counterparty at Date T. What is a fair price \( (F_{0,T}) \) to charge? One way to look at this question is to consider how much it will cost you to fulfill your obligation. If you wait until Date T to purchase the corn on the spot market, you have a speculative position, since your purchase price \( (S_T) \) will be unknown when you commit to a selling price.

Alternatively, suppose you buy the corn now for the current cash price of \( S_0 \) per bushel and store it until you have to deliver it at Date T. Under this scheme, the forward contract price you would be willing to commit to would have to be high enough to cover (1) the present cost of the corn and (2) the cost of storing the corn until contract maturity. In general, these storage costs, denoted here as \( SC_{0,T} \), can involve several things, including commissions paid for the physical warehousing of the commodity \( (PC_{0,T}) \) and the cost of financing the initial purchase of the underlying asset \( (i_{0,T}) \) but less any cash flows received \( (D_{0,T}) \) by owning the asset between Dates 0 and T. Thus, in the absence of arbitrage opportunities, the forward contract price should be equal to the current spot price plus the cost of carry necessary to transport the asset to the future delivery date:

\[
F_{0,T} = S_0 + SC_{0,T} = S_0 + (PC_{0,T} + i_{0,T} - D_{0,T})
\]

Notice that even if the funds needed to purchase the commodity at Date 0 are not borrowed, \( i_{0,T} \) accounts for the opportunity cost of committing one’s own financial capital to the transaction.

This cost of carry model is useful in practice because it applies in a wide variety of cases. For some commodities, such as corn or cattle, physical storage is possible but the costs are enormous. Also, neither of these assets pays periodic cash flows. In such situations, it is quite likely that \( F_{0,T} > S_0 \), and the market is said to be in contango. On the other hand, common stock is costless to store but often pays a dividend. This cash flow sometimes makes it possible for the basis to be positive (i.e., \( F_{0,T} < S_0 \)), meaning that \( SC_{0,T} \) can be negative. There is another reason why \( SC_{0,T} \) might be less than zero. For certain storable commodities that do not pay a dividend, \( F_{0,T} < S_0 \) can occur when there is a premium placed on currently owning the commodity. This premium, called a convenience yield, results from a small supply of the commodity at Date 0 relative to what is expected at Date T after, say, a crop harvest.
21.4 Finance Forward and Futures Contracts

Applications and Strategies

Originally, forward and futures markets were organized largely around trading agricultural commodities, such as corn and wheat. Although markets for these products remain strong, the most significant recent developments involve the use of financial securities as the asset underlying the contract. Exhibit 21.5 shows that the top three most heavily traded derivative contracts globally are based on financial securities. In this section, we take a detailed look at three different types of financial forwards and futures: interest rate, equity index, and foreign exchange.

21.4.1 Interest Rate Forwards and Futures

Interest rate forwards and futures were among the first derivatives to specify a financial security as the underlying asset. The earliest versions of these contracts were designed to lock in the forward price of a particular fixed-coupon bond, which in turn locks in its yield. As we will see in Chapter 23, this market has progressed to where such contracts as forward rate agreements and interest rate swaps now fix the desired interest rate directly without reference to any specific underlying security. To understand the nuances of the most popular exchange-traded instruments, it is useful to separate them according to whether they involve long- or short-term rates.

21.4.2 Long-Term Interest Rate Futures

**Treasury Bond and Note Contract Mechanics** The U.S. Treasury bond and note contracts at the Chicago Board of Trade (CBT) are among the most popular of all the financial futures contracts. Delivery dates for both note and bond futures fall in March, June, September, and December. Exhibit 21.6 shows a representative set of quotes for these contracts.

Both the T-bond and the longer-term T-note contracts traded at the CBT call for the delivery of $100,000 face value of the respective instruments. For the T-bond contract, any Treasury bond that has between 15 and 25 years to the nearest call date or to maturity (if noncallable) can be used for delivery. Bonds with maturities ranging from 6.5 to 10 years and 4.17 to 5.25 years can be used to satisfy the 10-year and 5-year T-note contracts, respectively. Delivery can take place on any day during the month of maturity, with the last trading day of the contract falling seven business days prior to the end of the month.

Mechanically, the quotation process for T-bond and T-note contracts works the same way. For example, the settlement price of 120-13, for the June 2011 T-bond contract on the CBT represents 120\(\frac{13}{32}\) percent of the face amount, or $120,406.25. The contract price went up by 2 ticks from the previous day’s settlement, meaning that the long side had its margin account increased by 7\(\frac{1}{32}\) percent of $100,000—or $62.50—where each \(\frac{1}{32}\) movement in the bond’s price equals $31.25 (i.e., 1,000 \(\div\) 32).

Although T-bond and T-note futures contracts are called interest rate futures, what the long and short positions actually agree to is the price of the underlying bond. Once that price is set, however, the yield will be locked in. When a yield is quoted, it is for reference only and

Earlier in this chapter, we noted that the objective of hedging was to select a hedge ratio \( N \) such that \( \Delta S - \Delta F(N) = 0 \), where \( S \) is the current spot price of the underlying asset and \( F \) is the current futures contract price. Rewriting this leaves:

\[
N* = \frac{\Delta S}{\Delta F}
\]

Or, with the modified duration relationship:

\[
N* = \frac{\Delta S}{\Delta F} = \beta_i \times S_F
\]

where:

\( \beta_i \) = the "yield beta"

The yield beta is also called the ratio of changes in the yields applicable to the two instruments where \( n \) is the number of payment periods per year (e.g., \( n = 2 \) for semiannual coupon bonds).

Consider the following fixed-income securities making annual payments (i.e., \( n = 1 \)):

<table>
<thead>
<tr>
<th>Instrument</th>
<th>Coupon</th>
<th>Maturity</th>
<th>Yield</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>8%</td>
<td>10 years</td>
<td>10%</td>
</tr>
<tr>
<td>B</td>
<td>10%</td>
<td>15 years</td>
<td>8%</td>
</tr>
</tbody>
</table>

How much of Instrument B is necessary to hedge A? This can be answered in three steps.

First, using the method shown in Chapter 18 (and summarized in Appendix 21A), the duration statistics for each position are:

\[
D_A = 7.0439, \quad D_{mod A} = \left( \frac{7.0439}{1.10} \right) = 6.4036 \text{ years}
\]

\[
D_B = 8.8569, \quad D_{mod B} = \left( \frac{8.8569}{1.08} \right) = 8.2009 \text{ years}
\]

Second, suppose that yield beta is unity (i.e., \( \beta_i = 1 \)); this is usually calculated by observing historical yield curve movements across the 10- and 15-year maturities. Finally, current prices are easily confirmed to be 87.71 for Security A and 117.12 for Security B assuming par value of 100. Thus, the duration-based hedge ratio is:

\[
N* = \frac{D_{mod A}}{D_{mod B}} \times \beta_i \times S_F
\]

which leaves:

\[
21.7 = N* = \frac{6.4036}{8.2009} \times \frac{1}{\frac{0.0325}{(1 + 0.03)}^{31}} \times \frac{1}{\frac{0.03}{(1 + 0.03)}^{31}}
\]

or 0.5847 unit of B short for every one unit of A held long.

Treasury Futures Applications

Hedging a Future Funding Commitment

In late July, the treasurer of a U.S.-based company is arranging a 15-year, $100 million funding. The company will be ready to launch its new debt issue in late September, but he is concerned that, between July and September, interest rates may rise, thereby increasing the company’s funding cost. He decides to hedge this exposure in the T-bond futures market. In this case, he will need to take a short position in the futures market, which will appreciate in value if interest rates increase.

If the bond issue was placed today, the credit standing of the firm would lead to a funding cost of 8.25 percent for the 15-year period. He knows that a September T-bond futures contract is trading at a price of 83\text{–}16 to yield 7.62 percent and that bond yields beyond 10 years to maturity tend to move in a parallel fashion, so he is comfortable that a yield beta of 1.0 is appropriate. Further, the treasurer is aware that T-bond futures cannot hedge for changes in the firm’s risk premium over the risk-free rate; he will have to live with this source of basis risk.

Historically has assumed a coupon rate of 6 percent and 20 years to maturity. For the June 2011 bond contract, the settlement yield would be 4.449 percent, which can be established by solving for the internal rate of return in the following bond math problem:

\[
$1,204.0625 = \sum_{t=1}^{40} \frac{\$30}{(1 + i/2)^t} + \frac{\$1,000}{(1 + i/2)^{35}}
\]

This pricing formula takes into account the fact that Treasury bonds pay semiannual interest. So, a 20-year, 6 percent bond makes 40 coupon payments of 3 percent each. Thus, the long position in this contract has effectively agreed in March to buy a 20-year T-bond in June priced to yield 4.45 percent. If, in June, the actual yield on the 20-year bond is below 4.45 percent (i.e., the bond’s price is greater than $120,406.25), the long position will have made a wise decision. Thus, the long position in this contract gains as prices rise and rates decrease and loses as increasing rates lead to lower bond prices.

Because the bond and note futures contracts allow so many different instruments to qualify for delivery, the seller would naturally choose to deliver the least expensive bond if no adjustments were made for varying coupon rates and maturity dates. The CBT uses conversion factors to correct for the differences in the deliverable bonds. The conversion factor is based on the price of a given bond if its yield is 6 percent at the time of delivery and the face value is $1. For example, the March 2011 conversion factor for a 6.5 percent T-bond maturing in December 2026 would be 1.0500, calculated as:

\[
1.0500 = \sum_{t=1}^{31} \frac{0.0325}{(1 + 0.03)^t} + \frac{1}{(1 + 0.03)^{31}}
\]

The actual delivery price, or invoice price, for that Treasury bond would be the quoted futures price, $120,406.25, times the conversion factor, 1.0500, for a total of $126,426.56 (plus accrued interest). The buyer must pay more than $120,406.25 because the seller is delivering more valuable bonds, since their coupon rate exceeds 6 percent.

The conversion factors used by the CBT are technically correct only when the Treasury yield curve is flat at 6 percent. Therefore, there usually will be a cheapest to deliver bond that maximizes the difference between the invoice price (the amount received by the short) and the cash market price (the amount paid by the short to acquire the delivery bond). Market participants always know which bond is the cheapest to deliver. Therefore, the T-bond futures contract trades as if this particular security were the actual underlying delivery bond. The cheapest to deliver security usually is the T-bond with the longest duration when yields are above 6 percent, and the one with the shortest duration for yields less than 6 percent.

A Duration-Based Approach to Hedging

In Chapter 18, we stressed that the main benefit of calculating the duration statistic was its ability to link interest rate changes to bond price changes by the formula:

\[
\left( \frac{\Delta P}{P} \right) = -D \frac{\Delta (1 + i/n)}{(1 + i/n)}
\]

We also saw that a more convenient way to write this expression is:

\[
\left( \frac{\Delta P}{P} \right) = - \left( \frac{D}{(1 + i/n)} \right) \Delta (1 + i/n) = -D_{mod} \Delta (i/n)
\]

where:

\( D_{mod} \) = the bond’s modified duration
Earlier in this chapter, we noted that the objective of hedging was to select a hedge ratio (N) such that \( \Delta S - \Delta F(N) = 0 \), where \( S \) is the current spot price of the underlying asset and \( F \) is the current futures contract price. Rewriting this leaves:

\[
N^* = \frac{\Delta S}{\Delta F}
\]

or, with the modified duration relationship:

\[
N^* = \frac{\Delta S}{\Delta F} = \left( \frac{\Delta S}{S} \right) \times \frac{S}{F} = -\frac{D_{mod} \times \Delta(i_s/n)}{D_{mod} \times \Delta(i_f/n)} \times \frac{S}{F}
\]

which leaves:

\[
21.7
\]

where:

\( \beta_i \) = the “yield beta”

The yield beta is also called the ratio of changes in the yields applicable to the two instruments where \( n \) is the number of payment periods per year (e.g., \( n = 2 \) for semiannual coupon bonds). Consider the following fixed-income securities making annual payments (i.e., \( n = 1 \)):

<table>
<thead>
<tr>
<th>Instrument</th>
<th>Coupon</th>
<th>Maturity</th>
<th>Yield</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>8%</td>
<td>10 years</td>
<td>10%</td>
</tr>
<tr>
<td>B</td>
<td>10%</td>
<td>15 years</td>
<td>8%</td>
</tr>
</tbody>
</table>

How much of Instrument B is necessary to hedge A? This can be answered in three steps. First, using the method shown in Chapter 18 (and summarized in Appendix 21A), the duration statistics for each position are:

\[
D_{A} = 7.0439, \text{ so } D_{modA} = (7.0439) \times (1.10) = 6.4036 \text{ years}
\]

\[
D_{B} = 8.8569, \text{ so } D_{modB} = (8.8569) \times (1.08) = 8.2009 \text{ years}
\]

Second, suppose that yield beta is unity (i.e., \( \beta_i = 1 \)); this is usually calculated by observing historical yield curve movements across the 10- and 15-year maturities. Finally, current prices are easily confirmed to be 87.71 for Security A and 117.12 for Security B assuming par value of 100. Thus, the duration-based hedge ratio is:

\[
N^* = \frac{6.4036}{8.2009} \times \frac{1}{1} \times \frac{87.71}{117.12} = 0.5847
\]

or 0.5847 unit of B short for every one unit of A held long.

**Treasury Futures Applications**

**Hedging a Future Funding Commitment** In late July, the treasurer of a U.S.-based company is arranging a 15-year, $100 million funding. The company will be ready to launch its new debt issue in late September, but he is concerned that, between July and September, interest rates may rise, thereby increasing the company’s funding cost. He decides to hedge this exposure in the T-bond futures market. In this case, he will need to take a short position in the futures market, which will appreciate in value if interest rates increase.

If the bond issue was placed today, the credit standing of the firm would lead to a funding cost of 8.25 percent for the 15-year period. He knows that a September T-bond futures contract is trading at a price of 83–16 to yield 7.62 percent and that bond yields beyond 10 years to maturity tend to move in a parallel fashion, so he is comfortable that a yield beta of 1.0 is appropriate. Further, the treasurer is aware that T-bond futures cannot hedge for changes in the firm’s risk premium over the risk-free rate; he will have to live with this source of basis risk.
If he plans to launch his new issue at par value, how many T-bond futures contracts would he need to short today? Assuming semiannual coupons for both the Treasury and the corporate issues, their durations can be calculated using the closed-form equation shown in Appendix 21A:

\[
D_{\text{cor}} = \frac{1.04125}{0.04125} - \frac{1.04125 + [30(0.04125 - 0.04125)]}{0.04125[1.04125^{30} - 1] + 0.04125} = 17.74 \text{ periods}
\]

and

\[
D_{\text{bnd}} = \frac{1.0381}{0.0381} - \frac{1.0381 + [40(0.03 - 0.0381)]}{0.03[(1.0381)^{40} - 1] + 0.0381} = 22.22 \text{ periods}
\]

These statistics are denominated in half years so that the hedge ratio will be expressed in the same terms used to price the bonds. We can calculate the modified durations as follows: \(D_{\text{modc}} = 17.04 \approx 17.74 + 1.04125\) and \(D_{\text{modb}} = 21.40 \approx 22.22 \times 0.0381\). Finally, since each T-bond futures contract is standardized to a denomination of $100,000, the treasurer can calculate the optimal number of contracts to short as:

\[
\frac{\text{(Number of Contracts)}}{21.40} = \frac{(17.04)}{(1.0)} \times \frac{($100,000,000)}{($83,500)} = 953.6, \text{ or 954 Contracts}
\]

**A T-Bond/T-Note (NOB) Futures Spread** Frequently, speculators in the bond market have a clear view on a change in the overall shape of the yield curve but can be less certain as to the actual direction in future rate movements. Suppose you think the yield curve—which is currently upward sloping across all maturities—will flatten, but you’re not sure how this might occur:

- Short-term rates rise and long-term rates fall.
- Short- and long-term rates both rise, but short-term rates rise by more.
- Short- and long-term rates both fall, but short-term rates fall by less.

Clearly, taking a long or short position in a futures contract linked to a single point on the yield curve is too risky; you could be right about the shape shift but guess wrong about direction. One way to mitigate this unwanted risk is to go both long and short in contracts representing different points on the yield curve. This is known as the Treasury “Notes over Bond” spread (or “NOB” spread) strategy.

Suppose in mid-February you observe the following price quotes (along with their implied yields to maturity) for T-bond and T-note futures contracts maturing in June:

<table>
<thead>
<tr>
<th>Contract</th>
<th>Settle Price</th>
<th>Implied Yield</th>
</tr>
</thead>
<tbody>
<tr>
<td>20-yr, 6% T-bond</td>
<td>103–02</td>
<td>5.74%</td>
</tr>
<tr>
<td>10-yr, 6% T-note</td>
<td>104–02</td>
<td>5.47%</td>
</tr>
</tbody>
</table>

Your expectation of a flattening yield curve is identical to the view that the 27 basis point yield gap (= 0.0574 – 0.0547) between the longer- and shorter-term contracts will shrink. If you also feel this will occur by mid-June, the appropriate strategy would be:

- Go long in one Treasury bond futures.
- Go short in one Treasury note futures.

The net profit from this joint position when you close out the two contracts is calculated as the sum of the profits on the short T-note position and the long T-bond contract, or:

\[
\left[ \frac{104.0625 - \text{June T-Note Price}}{100} + \frac{\text{June T-Bond Price} - 103.0625}{100} \right] (\$100,000)
\]

To see how this combination would pay off if your view is correct, consider two scenarios in which the yield curve flattens to where there is no difference between 10- and 20-year rates in June:
1. Rates increase to 6.00 percent by June.
   In this case, both futures contracts will sell at par, and so your net profit will be:
   \[
   \text{Net Profit} = [0.040625 - 0.030625] \times \$100,000 = \$1,000
   \]
   Notice that this same calculation can be done on a “price tick” basis:
   \[
   \text{Net Profit} = \left\{ \left\{ (104-02) - (103-02) \right\} - \left\{ (100-00) - (100-00) \right\} \right\} \times (31.25) = \$1,000
   \]
   which is equivalent to the change in the number of ticks in the NOB spread multiplied by
   the dollar value of a tick (i.e., $31.25).

2. Rates decrease to 5.00 percent by June.
   In this scenario, the settlement prices on the two futures contracts will be:
   \[
   P_{T\text{-note}} = \sum_{t=1}^{20} \frac{\$3}{(1 + 0.025)^t} + \frac{\$100}{(1 + 0.025)^{20}} = \$107.79 \approx 107-25
   \]
   and
   \[
   P_{T\text{-bond}} = \sum_{t=1}^{40} \frac{\$3}{(1 + 0.025)^t} + \frac{\$100}{(1 + 0.025)^{40}} = \$112.55 \approx 112-18
   \]
   so that net profit from the NOB spread will be:
   \[
   \text{Net Profit} = \left\{ \left\{ (104-02) - (103-02) \right\} - \left\{ (107-25) - (112-18) \right\} \right\} (31.25) = \$51,781.25
   \]
   Interpreting this outcome differently, you made $9,500.00 on your long position in the T-
   bond contract (= [(112-18) - (103-02)](31.25)), but you lost $3,718.75 on your short T-note
   position (= [(104-02) - (107-25)](31.25)) for a net gain of $5,781.25.

   These results show that the futures spread allows speculators to separate their views on
   yield curve shape from an explicit forecast of a change in the curve’s position. However, the
   investor must be careful to recognize that, because the duration of the T-bond is greater than
   that of the T-note, the former will be more sensitive to a given rate change.

21.4.3 Short-Term Interest Rate Futures
Short-term interest rate futures have become a rapidly expanding segment of the exchange-
traded market. Currently, investors can hedge their exposures to several different money market
rates (e.g., T-bill, LIBOR, Banker’s Acceptance, Federal Funds) denominated in a multitude
of currencies (e.g., U.S. dollar, Japanese yen, euro). In the following analysis, we concentrate
on one of these contracts: Eurodollar futures.

Eurodollar Contract Mechanics The Eurodollar contract traded on the Chicago Mercantile
Exchange (CME) has become enormously successful since it was launched in the early 1980s.
Delivery dates occur monthly for a brief period before following the March, June, September,
December cycle and now extend 10 years into the future. The final trading and settlement date
is the second London business day before the third Wednesday of the delivery month. A repre-
sentative set of quotes is shown in Exhibit 21.7.

Hypothetically, the Eurodollar contract requires the long position to make a $1,000,000, 90-day bank deposit with the short position at the maturity date. Unlike the Treasury bond
futures just described, this contract requires all outstanding obligations to be settled in cash.
This provision is necessary because the contract nominally requires the long position to make, and the short position to receive, a 90-day euro-time deposit. However, that is something that the short position can’t legally do unless it is a bank. The underlying interest rate
Before checking futures contract price quotes, she calculates the forward rates implied by the current yield curve, using the money-market implied forward rate formula shown in Appendix 21B:

\[
IFR = \frac{0.051180 - 0.05090}{180-90} = 5.14\%
\]

She checks the quotes on the relevant Eurodollar futures contracts and finds:

<table>
<thead>
<tr>
<th>Contract Expiration</th>
<th>Settlement Price</th>
</tr>
</thead>
<tbody>
<tr>
<td>June 94.86</td>
<td>September 94.73</td>
</tr>
<tr>
<td>December 94.61</td>
<td></td>
</tr>
</tbody>
</table>

The futures settlement prices indicate LIBOR contract rates that are identical to the implied forward rates, suggesting there is no arbitrage potential between the cash and futures markets.

To lock in her receipts for the $2,000,000 loan, the banker would go long a strip of Eurodollar futures contracts by taking long positions in two June contracts, two September contracts, and two December contracts. (Recall that the long position in a Eurodollar contract gains when the price index rises with a falling LIBOR; this is the protection she is seeking.) With these positions, her quarterly interest receipts will be fixed at the following levels:

- June Receipt: \( \frac{2,000,000 \times 0.0500 \times 90}{360} = 25,000 \)
- September Receipt: \( \frac{2,000,000 \times 0.0514 \times 90}{360} = 25,700 \)
- December Receipt: \( \frac{2,000,000 \times 0.0527 \times 90}{360} = 26,350 \)
- March Receipt (Next Year): \( \frac{2,000,000 \times 0.0539 \times 90}{360} = 26,950 \)

Although these cash inflows are fixed in advance, they clearly differ in amount from quarter to quarter. The banker then asks herself the following question: What quarterly annuity payment does this sequence of receipts imply? This amount is the solution to:

\[
\sum_{i=1}^{4} \frac{2,000,000 \times 0.0500 \times 90}{360} = 5,140,000
\]

is the 3-month (i.e., 90-day) LIBOR that is quoted on a 360-day bank add-on basis. As we will see, arbitrage trading should drive the sequence of Eurodollar (or LIBOR) futures rates to equal the forward rates implied by the yield curve for interbank lending in the cash market.

In Exhibit 21.7, the quoted contract price for the June 2011 contract is 99.6450, which is not an actual purchase price but merely an index calculated as 100 minus the effective settlement yield of 0.355 percent. Eurodollar futures use this settlement price index because it conveniently preserves the inverse relation between price and yield. Thus, a long position in this contract can still be thought to “win” when prices rise—and the short position wins with falling prices—even though it is the opposite movement in the underlying interest rate that matters.

If the price index for this contract moved by one “tick” (i.e., 0.01), the contract itself would change by $25 (= $1,000,000 \times 0.0001 \times 90/360), which is called the basis point value of the position. Thus, the one tick increase in the price of the June 2011 contract means that LIBOR decreased by one basis point from the prior day’s settlement. This would benefit a person who acquired a long position at the close of the prior day, inasmuch as he would have a locked-in borrowing cost for the 90-day period from June to September 2011 that is now one basis point lower than the market level. In fact, all sellers of this contract gained $25 per contract (i.e., $25 per tick times one tick) in their margin accounts.

Finally, notice that Eurodollar open interest is spread over the various delivery dates to a greater extent than for the T-bond contract (shown in Exhibit 21.6). Brown and Smith (1988) interpreted these trading patterns as suggesting that T-bond futures are used in the market more as a speculative trading contract and that Eurodollar futures are used more frequently as a buy-and-hold hedging instrument.

**Short-Term Interest Rate Future Applications**

**Creating a Synthetic Fixed-Rate Funding with a Eurodollar Strip** Suppose that on March 15 a bank loan officer is considering an investment scheme for lending $2,000,000 to a large-cap manufacturing firm. The plan would last for one year and have the payment rate reset on a quarterly basis at LIBOR. At the planning stage, the LIBOR yield curve appears as follows:

- 90-day LIBOR 5.00%
- 180-day LIBOR 5.10%
- 270-day LIBOR 5.20%
- 360-day LIBOR 5.30%

Given the debt market convention for floating-rate deal structures, she knows that her loan receipt for the first three months would be based on the prevailing 5.00 percent rate and be receivable in 90 days. Her concern is the level of her receipts in the subsequent three quarters may fall to an unacceptable level. So, she considers using the Eurodollar futures market to hedge her exposure.
Solving this formula for annuity gives a value of $25,989.38, where the discount rates are from the prevailing cash market LIBOR curve. Finally, notice that this annuity payment, when expressed on a full 360-day percentage basis, is:

$$\frac{25,989}{1 + \left(0.050\right)\frac{90}{360}} = 5.19\%$$

Creating a TED Spread

One of the features that makes the Eurodollar futures contract such a popular hedging vehicle is the rate it is based on—three-month LIBOR. This rate can be thought of as equivalent to the three-month T-bill yield plus a risk premium (i.e., credit spread). Sometimes, bond traders will have a view on future movements in this credit spread; for example, a trader might believe the current difference between the LIBOR and T-bill yield is too narrow and that it will soon widen. The problem with using a short position in the Eurodollar contract alone is that even if the trader is right about the spread, the general level of interest rates could still decline by more than enough to offset any spread gains.

The solution is to isolate the credit spread component in LIBOR through a strategy known as the TED (Treasury/EuroDollar) spread. The TED spread is created by taking simultaneous, but opposite, positions in both a Eurodollar and a T-bill futures contract having the same maturity. In the parlance of the market, we have the following definitions:

Long TED Spread = \(\text{Long T-Bill Futures} + \text{Short Eurodollar Futures}\)

Short TED Spread = \(\text{Short T-Bill Futures} + \text{Long Eurodollar Futures}\)

Notice that a long position in a TED spread will gain when the credit spread increases; the short TED spread benefits from a narrowing of the credit spread. Exhibit 21.8 shows how volatile the three-month TED spread has been over time, particularly during the liquidity crisis of 2008–2009.

Suppose that in early August you observe the following prices in the Eurodollar and T-bill futures markets:

<table>
<thead>
<tr>
<th>Contract Expiration</th>
<th>Settlemet Price</th>
</tr>
</thead>
<tbody>
<tr>
<td>June</td>
<td>94.86</td>
</tr>
<tr>
<td>September</td>
<td>94.73</td>
</tr>
<tr>
<td>December</td>
<td>94.61</td>
</tr>
</tbody>
</table>

Recall that the difference between the T-bill and Eurodollar price indexes is the spread built into the Eurodollar contract for a particular maturity.

If you believe the economy will remain sluggish and that credit spreads currently are too narrow in the short-term contract, you would want to take a long TED spread position (i.e., short the Eurodollar futures and buy the T-bill contract). After you establish this position using the September contracts, the Federal Reserve Board tightens rates again so that by mid-September the following prices prevail when you unwind the strategy:

<table>
<thead>
<tr>
<th>New Contract Expiration</th>
<th>New Settlement Price</th>
</tr>
</thead>
<tbody>
<tr>
<td>September</td>
<td>94.55</td>
</tr>
<tr>
<td>Eurodollar Contract</td>
<td>93.95</td>
</tr>
<tr>
<td>New Spread</td>
<td>0.60</td>
</tr>
</tbody>
</table>

The futures settlement prices indicate LIBOR contract rates that are identical to the implied forward rates, suggesting there is no arbitrage potential between the cash and futures markets.

To lock in her receipts for the $2,000,000 loan, the banker would go long a strip of Eurodollar futures contracts by taking long positions in two June contracts, two September contracts, and two December contracts. (Recall that the long position in a Eurodollar contract gains when the price index rises with a falling LIBOR; this is the protection she is seeking.) With these positions, her quarterly interest receipts will be fixed at the following levels:

June Receipt = \(\frac{\left(0.0500\right)\left(90\right)}{360}\) = $25,000

September Receipt = \(\frac{\left(0.0514\right)\left(90\right)}{360}\) = $25,700

December Receipt = \(\frac{\left(0.0527\right)\left(90\right)}{360}\) = $26,350

March (Next Year) Receipt = \(\frac{\left(0.0539\right)\left(90\right)}{360}\) = $26,950

Although these cash inflows are fixed in advance, they clearly differ in amount from quarter to quarter. The banker then asks herself the following question: What quarterly annuity payment does this sequence of receipts imply? This amount is the solution to:
This new spread is more closely aligned with the December and March contracts. The profit on your transaction is calculated as:

\[
\text{Profit} = (\text{New TED Spread}) - (\text{Original TED Spread})
\]

or

\[
= (94.55 - 93.95) - (95.24 - 94.80) = 16 \text{ Basis Points}
\]

Since each basis point is worth $25, the profit per contract pair from this trade would be \((16 \times 25) = 400\). You made an 85-basis-point profit on the short position in the Eurodollar contract (= 94.80 - 93.95) but lost 69 basis points on the long T-bill contract (= 94.55 - 95.24). However, if both rates had declined, you still would have made money if the T-bill yield had fallen by more than LIBOR.

21.4.4 Stock Index Futures

In this section, we consider the basics of stock index futures trading and discuss two applications for these instruments, including a popular form of computer-assisted trading known as stock index arbitrage.

Stock Index Futures Contract Fundamentals

Like interest rate futures, stock index futures were originally intended to provide a hedge against movements in an underlying financial asset. As detailed in Chapter 5, the underlying financial asset for a stock index futures contract is a hypothetical creation that does not exist in practice and therefore cannot be delivered to settle a contract. Thus, stock index futures can only be settled in cash, similar to the Eurodollar (i.e., LIBOR) contract.

Stock index futures are intended to provide general hedges against stock market movements and can be applied to either whole (i.e., diversified) portfolios or individual stocks. Unlike using a single-stock futures contract to hedge the total risk of an individual equity position, hedging an individual stock with an index futures contract is done in an attempt to isolate the unsystematic portion of that security’s risk. Additionally, stock index futures often are used to convert entire stock portfolios into synthetic riskless positions to exploit an apparent mispricing between stock in the cash and futures markets. This strategy, commonly called

Creating a TED Spread

One of the features that makes the Eurodollar futures contract such a popular hedging vehicle is the rate it is based on—three-month LIBOR. This rate can be thought of as equivalent to the three-month T-bill yield plus a risk premium (i.e., credit spread). Sometimes, bond traders will have a view on future movements in this credit spread; for example, a trader might believe the current difference between the LIBOR and T-bill yield is too narrow and that it will soon widen. The problem with using a short position in the Eurodollar contract alone is that even if the trader is right about the spread, the general level of interest rates could still decline by more than enough to offset any spread gains.

The solution is to isolate the credit spread component in LIBOR through a strategy known as the TED (Treasury/Euro Dollar) spread. The TED spread is created by taking simultaneous, but opposite, positions in both a Eurodollar and a T-bill futures contract having the same maturity. In the parlance of the market, we have the following definitions:

Long TED Spread = (Long T-Bill Futures) + (Short Eurodollar Futures)

Short TED Spread = (Short T-Bill Futures) + (Long Eurodollar Futures)

Notice that a long position in a TED spread will gain when the credit spread increases; the short TED spread benefits from a narrowing of the credit spread. Exhibit 21.8 shows how volatile the three-month TED spread has been over time, particularly during the liquidity crisis of 2008–2009.

Suppose that in early August you observe the following prices in the Eurodollar and T-bill futures markets:

<table>
<thead>
<tr>
<th>T-Bill</th>
<th>Eurodollar</th>
<th>Spread</th>
</tr>
</thead>
<tbody>
<tr>
<td>September contracts</td>
<td>95.24</td>
<td>94.80</td>
</tr>
<tr>
<td>December contracts</td>
<td>94.68</td>
<td>94.11</td>
</tr>
<tr>
<td>March contracts</td>
<td>94.42</td>
<td>93.86</td>
</tr>
</tbody>
</table>

Recall that the difference between the T-bill and Eurodollar price indexes is the spread built into the Eurodollar contract for a particular maturity.

If you believe the economy will remain sluggish and that credit spreads currently are too narrow in the short-term contract, you would want to take a long TED spread position (i.e., short the Eurodollar futures and buy the T-bill contract). After you establish this position using the September contracts, the Federal Reserve Board tightens rates again so that by mid-September the following prices prevail when you unwind the strategy:

| New September T-bill contract | 94.55 |
| New September Eurodollar contract | 93.95 |
| New spread | 0.60 |
Stock index arbitrage, is the most prominent example of a wider class of computer-assisted trading schemes known as program trading.

Exhibit 21.9 lists quotes for futures contracts on several U.S. stock indexes, including the Dow Jones Industrial Average, Standard & Poor’s 500, NASDAQ 100, and Russell 1000. Contracts for indexes representing global markets [e.g., Nikkei 225 (Japan), DAX 30 (Germany), Euro Stoxx 50] are traded actively but not shown in the display. For example, an investor planning in March to buy stock the following June can hedge against the risk of his eventual purchase price increasing by entering into the long position in the June 2011 S&P 500 contract. Given the settlement price of 1,296.10, he has obligated himself to the theoretical purchase of 250 shares of the S&P 500 on the day before the third Friday of June for $324,025 (= 1,296.10 × 250). The minimum contract price movement is 0.10 index points, which equals $25. Thus, if the actual level of the index on the contract settlement date turned out to be 1,298.30, the long position would gain $550, or $25 times 22 ticks \[\frac{1,298.30 - 1,296.10}{0.10}\], thereby reducing the net purchase price for his desired equity position. Finally, notice that a “mini” version of the S&P 500 futures contract requiring the hypothetical purchase or sale of only 50 shares is also available.

Stock Index Futures Valuation and Index Arbitrage

To see how the concept of arbitrage works for index contracts, suppose that at Date 0 an investor (1) purchases a portfolio of stock representing the underlying stock index for \(S_0\), and (2) goes short a stock index future (with an

Exhibit 21.8 Historical TED Spread for Three-month Contracts

Implementing an Index Arbitrage Strategy

What if the parity condition between the stock index and the stock index futures price does not hold? Could you design a portfolio to take advantage of the situation? Suppose that in the preceding example the actual contract price on a six-month S&P 500 futures was 1,265.50 \[i.e., F_{0,T} > S_0 + S_0(1 + RFR_T - d_T)]\. You could then implement the following arbitrage transaction: (1) short the stock index future at a price of 1,265.50, (2) borrow money at 2.5 percent to purchase the stock index at 1,250.00, and (3) hold the position until maturity, collecting 18.75 in dividends and then selling the stock to repay your loan. Your net profit at maturity would be:

\[
1,265.50 - 1,250 - 1,250 (0.025 - 0.015) = $3.00
\]

However, since this strategy was riskless (i.e., the sales price of the stock and the dividends were known in advance) and none of your own capital was used, it is an arbitrage profit. This is stock index arbitrage, which is possible whenever the index futures price is set at a level sufficiently different from the theoretical value for \[F_{0,T} \] to account for trading costs. If the actual level of \[F_{0,T} < S_0 + S_0(1 + RFR_T - d_T)\], the previous strategy could be reversed: (1) buy the stock index future at a price of \[F_{0,T}\], (2) lend money at \[RFR_T\] and short the stock index at \[S_0\], and (3) cover the position at the expiration date of the futures contract. Indeed, index arbitrage is a popular form of trading. Exhibit 21.11 reports that about 11 percent of all computer-assisted program trading used this strategy during a recent trading period. Further program trading accounted for about 30 percent of trading volume on the New York Stock Exchange.

One important side effect of this trading activity is that stock index futures prices tend to stay close to their theoretical levels. This is because the arbitrage prescription for a futures settlement price that is too low (too high) is to go long (short) in the contract, which, when done in sufficient volume, adjusts the price in the proper direction. Panel A of Exhibit 21.12 compares the actual and theoretical levels of the nearest-term future contract for several stock indexes throughout the world, including the S&P 500, Dow Jones Industrial, and the Nikkei 225. The pricing errors on this particular day never exceeded about \[6/10\] of 1 percent for any contract and was much lower than that in most markets. Panel B of Exhibit 21.12 details the calculation of the theoretical level of the March 2011 S&P 500 futures price (SPH1). The display shows that the actual contract price (1,303.70) was very close to its theoretical value (1,305.44), which can be computed as the spot price (1,306.33) plus the net cost of carry [1,306.33 × (0.0031 − 0.0180) × (16/365)]. These values support the notion that the market for stock index futures is an efficient one.

The empirical evidence tends to support this view, particularly after transaction costs and other trading realities are considered. Cornell (1985), found that stock index futures prices tracked their model values more closely as the market matured. In response to the allegation that index arbitrage caused the worldwide stock market crash of October 1987, Roll (1988) documented that countries with the greatest level of program trading activity experienced less pronounced price declines. This finding is consistent with the notion that index arbitrage reduces volatility by stabilizing cash and futures prices. Finally, Bohl, Salm, and Schuppli (2011) demonstrate how this connection between spot and futures price facilitates the price discovery process.

A Stock Index Futures Application

Isolating the Unsystematic Risk of an Individual Stock

In Chapter 20, we demonstrated how stock index futures could alter the systematic risk of an otherwise well-diversified portfolio. When the holding is an individual stock, this process can isolate the unique attributes of the company. Recall that:

\[
\text{Total Stock Risk} = \text{Systematic Risk} + \text{Unsystematic Risk}
\]

### Exhibit 21.10 Stock Index Futures Valuation Example

</tbody>
</table>

expiration date of \(T\) for \(F_{0,T}\). Assume also that the funds for the long position are borrowed at the risk-free rate of \(RFR\). On unwinding this position at Date \(t\), the net profit \((\Pi)\) is given by:

\[
\Pi = (F_{0,T} - F_{T,t}) + (S_t - S_0 - RFR_t \times S_0 d_t) = (F_{0,T} - F_{T,t}) [S_t - S_0 (1 + RFR_t - d_t)]
\]

where:

\(d_t\) = the dividend yield accruing to the stocks comprising the index between Dates 0 and \(t\)

The profit you make on this short hedge in stock index futures will consist of two components: the net difference in the futures position and the net difference in the underlying index position (after adding borrowing costs and subtracting dividends received from the initial purchase).

Now suppose the long position in the stock portfolio is held until the expiration of the futures contract (i.e., Date \(T\)) so that the futures price and index level will converge. At Date \(T\), we will have \(F_{T,T} = S_T\), which means that the short hedge profit \((\Pi)\) equation can be written:

\[
\Pi = [F_{0,T} - S_0 - S_0 (RFR_t - d_t)]
\]

As before, \(RFR_t - d_t\) is called the net cost of carry and represents the difference between the borrowing cost paid and the dividend received.

If the dividend yield is known at Date 0, this position is riskless and requires no initial investment. Thus, buying and selling among arbitrageurs trading in both markets should ensure that \(\Pi = 0\). The futures price set at Date 0 will be:

\[
F_{0,T} = S_0 + S_0 (RFR_t - d_t)
\]

As discussed earlier, the futures price could be set below the spot level of the index (i.e., a backwardated market) if \((RFR_t - d_t) < 0\), or whenever the dividends received by holding stock exceed the borrowing cost.

To illustrate this parity relationship, assume that one share of the S&P 500 Index can be purchased for $1,250.00 and that the dividend yield and risk-free rate over the holding period are 1.5 percent and 2.5 percent, respectively. The contract price on a six-month S&P 500 futures should then be:

\[
F_{0,0.5} = 1,250 + 1,250 (0.025 - 0.015) = 1,262.50
\]

Now suppose that you construct a short hedge position by (1) purchasing the index at 1,250.00 and (2) shorting the futures at 1,262.50. If the position is held to expiration, your profit at various expiration date levels of the S&P will be as shown in Exhibit 21.10. Notice that your net profit remains constant no matter the level of the index at the expiration date. This net profit can be expressed as:

\(31.25) \div (1,250) = 2.5\) percent

which is the assumed cost of borrowing.
Implementing an Index Arbitrage Strategy What if the parity condition between the stock index and the stock index futures price does not hold? Could you design a portfolio to take advantage of the situation? Suppose that in the preceding example the actual contract price on a six-month S&P 500 futures was 1,265.50 [i.e., \( F_{0,T} > S_0 + S_0(RFR_t - d_t) \)]. You could then implement the following arbitrage transaction: (1) short the stock index future at a price of 1,265.50, (2) borrow money at 2.5 percent to purchase the stock index at 1,250.00, and (3) hold the position until maturity, collecting 18.75 in dividends and then selling the stock to repay your loan. Your net profit at maturity would be:

\[
1,265.50 - 1,250 - 1,250 (0.025 - 0.015) = $3.00
\]

However, since this strategy was riskless (i.e., the sales price of the stock and the dividends were known in advance) and none of your own capital was used, it is an arbitrage profit.

This is stock index arbitrage, which is possible whenever the index futures price is set at a level sufficiently different from the theoretical value for \( F_{0,T} \) to account for trading costs. If the actual level of \( F_{0,T} < S_0 + S_0(RFR_t - d_t) \), the previous strategy could be reversed: (1) buy the stock index future at a price of \( F_{0,T} \), (2) lend money at RFR, and short the stock index at \( S_0 \), and (3) cover the position at the expiration date of the futures contract. Indeed, index arbitrage is a popular form of trading. Exhibit 21.11 reports that about 11 percent of all computer-assisted program trading used this strategy during a recent trading period. Further program trading accounted for about 30 percent of trading volume on the New York Stock Exchange.

One important side effect of this trading activity is that stock index futures prices tend to stay close to their theoretical levels. This is because the arbitrage prescription for a futures settlement price that is too low (too high) is to go long (short) in the contract, which, when done in sufficient volume, adjusts the price in the proper direction. Panel A of Exhibit 21.12 compares the actual and theoretical levels of the nearest-term future contract for several stock indexes throughout the world, including the S&P 500, Dow Jones Industrial, and the Nikkei 225. The pricing errors on this particular day never exceeded about 0.10 of 1 percent for any contract and was much lower than that in most markets. Panel B of Exhibit 21.12 details the calculation of the theoretical level of the March 2011 S&P 500 futures price (SPH1). The display shows that the actual contract price (1,303.70) was very close to its theoretical value (1,305.44), which can be computed as the spot price (1,306.33) plus the net cost of carry \[1,306.33 \times (0.0031 - 0.0180) \times (16/365)\]. These values support the notion that the market for stock index futures is an efficient one.

The empirical evidence tends to support this view, particularly after transaction costs and other trading realities are considered. Cornell (1985), found that stock index futures prices tracked their model values more closely as the market matured. In response to the allegation that index arbitrage caused the worldwide stock market crash of October 1987, Roll (1988) documented that countries with the greatest level of program trading activity experienced less pronounced price declines. This finding is consistent with the notion that index arbitrage reduces volatility by stabilizing cash and futures prices. Finally, Bohl, Salm, and Schuppli (2011) demonstrate how this connection between spot and futures price facilitates the price discovery process.

A Stock Index Futures Application

Isolating the Unsystematic Risk of an Individual Stock In Chapter 20, we demonstrated how stock index futures could alter the systematic risk of an otherwise well-diversified portfolio. When the holding is an individual stock, this process can isolate the unique attributes of the company. Recall that:

\[
\text{Total Stock Risk} = \text{Systematic Risk} + \text{Unsystematic Risk}
\]
with the systematic component representing about 25–40 percent of the total risk for the typical firm. Thus, using stock index futures to adjust the stock’s beta to zero effectively isolates the unsystematic portion of risk.

To see how this might work, suppose that in early March you own 75,000 shares of Pharmco Inc., a multinational pharmaceutical firm. The current price of Pharmco stock is $38.90, and you calculate the company’s beta at 0.99. You like the stock as an investment because of the quality of its management, but you are concerned that over the next few months
the aggregate stock market might undergo a sizable correction that could more than offset any firm-specific gains.

To protect yourself, you decide to sell June S&P 500 futures contracts, which are currently trading at a settlement price of 1,296.10. At this price, we have seen that the implied dollar value of a single contract is $324,025. The current value of your Pharmco stock is $3,506,250. Since the stock’s beta can be defined as $\beta = \frac{\Delta S}{\Delta F}$, the optimal hedge ratio formula developed earlier leaves:

$$N^* = \frac{\text{Market Value of Spot Position}}{\text{Value Implied by Futures Contract}}$$

\[\beta = \frac{1}{2} \left( \frac{\$2,917,500}{\$324,025} \right) = 8.91\]

so you decide to short 9 contracts.

Now suppose that by mid-June when your futures position expires, the S&P 500 Index settles at a level of 1,276.10 while the price of Pharmco stock has increased to $39.65. Although you have made a modest profit on your common stock holding (i.e., $56,250, or 1.92 percent), you will also benefit from a trading profit on the futures position of $45,000 (= (9) [1,296.10 − 1,276.10](250)). Your total return is $101,250, which, expressed as a percentage of your original investment is equivalent to an unsystematic appreciation in Pharmco’s stock of 3.46 percent. Notice that the difference between this amount and the gross increase of 1.92 percent in Pharmco stock is equal to the 1.54 percent (= (1,276.10 ÷ 1,296.10) − 1) that the stock index future position fell.

the aggregate stock market might undergo a sizable correction that could more than offset any firm-specific gains.

To protect yourself, you decide to sell June S&P 500 futures contracts, which are currently trading at a settlement price of 1,296.10. At this price, we have seen that the implied dollar value of a single contract is $324,025. The current value of your Pharmco stock is $3,506,250. Since the stock’s beta can be defined as \( \rho[\sigma_{AS} + \sigma_{AF}] \), the optimal hedge ratio formula developed earlier leaves:

\[
N^* = \frac{\text{Market Value of Spot Position}}{\text{Value Implied by Futures Contract}} \beta
\]

\[
= \frac{\text{[($2,917,500) + ($324,025)]}}{0.99} = 8.91
\]

so you decide to short 9 contracts.

Now suppose that by mid-June when your futures position expires, the S&P 500 Index settles at a level of 1,276.10 while the price of Pharmco stock has increased to $39.65. Although you have made a modest profit on your common stock holding (i.e., $56,250, or 1.92 percent), you will also benefit from a trading profit on the futures position of $45,000 (= 9 [1,296.10 – 1,276.10]($250)). Your total return is $101,250, which, expressed as a percentage of your original investment is equivalent to an unsystematic appreciation in Pharmco’s stock of 3.46 percent. Notice that the difference between this amount and the gross increase of 1.92 percent in Pharmco stock is equal to the 1.54 percent (= [1,276.1 + 1,296.1] – 1) that the stock index future position fell.

### 21.4.5 Currency Forwards and Futures

Whether in the spot or forward markets, foreign exchange (FX) transactions often involve a confusing blend of unique terminology and market conventions. These conventions represent an initial barrier to understanding how FX deals work. Thus, we begin our analysis of currency derivatives with a brief overview of some of the fundamental features of these products.

**The Mechanics of Currency Transactions** The market for foreign currency is no different than any other market, in that buyer and seller negotiate for the exchange of a certain amount of a predetermined commodity at a fixed cash price. The challenge in FX transactions is that the “commodity” involved is someone else’s currency. This means that the transaction can be viewed in two ways. For example, suppose that Company A agrees to pay 100 U.S. dollars to Company B in exchange for 50 British pounds. Is Company A buying sterling (GBP) or selling dollars (USD)? Both are correct, depending on one’s point of view.

Because of this dual interpretation, the price for all FX transactions also can be quoted in two ways. Assuming that Company A is a U.S.-based firm, it would probably think of the transaction as the purchase of 50 pounds at a cost of 100 dollars, which would yield the price of USD 2.0000/GBP (= 100/50). This method of quoting FX prices is called the direct, or *American*, convention. Under this convention, the pound (i.e., the foreign currency from the U.S. firm’s perspective) is treated as the commodity, and its price per unit is expressed in terms of dollars. If Company B is a British corporation, its managers would likely think of prices in terms of the amount of sterling they have to pay to acquire dollars, or GBP 0.5000/USD. Treating the dollar as the commodity yields the *indirect*, or *European*, quotation method. The direct and indirect quotes are just reciprocals of one another, as they describe the same transaction from two different perspectives.

---

*Currency traders often use three-letter abbreviations to denote a particular currency. Some of the more common abbreviations include USD (U.S. dollars), CAD (Canadian dollars), GBP (British pounds), JPY (Japanese yen), CHF (Swiss franc), and EUR (the euro currency). For a more complete listing, see Gastineau and Kritzman (2001).*
Thus, the terms of a spot FX transaction can be structured to meet the particular needs of the counterparties involved. Another important aspect of the FX markets is that although many currencies trade in the spot market, relatively few also quote prices for forward transactions. In this list, only the British, Canadian, Japanese, and Swiss currencies have forward contracts. These contracts, which are negotiated in the over-the-counter market with a currency dealer (such as a multinational bank), carry maturities one, three, and six months into the future. For example, an investor wishing to buy Swiss francs would pay USD 1.0757 per franc if the transaction were completed immediately, 1.0760 if the transaction were negotiated now but consummated in 30 days, and USD 1.0766 or USD 1.0774 for exchanges completed in 90 or 180 days, respectively. In the situation where it costs increasingly more dollars to buy the same franc the farther out in the future it is delivered, the dollar is said to be trading at a forward discount to the franc. Conversely, the franc is at a forward premium to the dollar. This relationship depends on the currencies being compared. In this set of quotes, the U.S. dollar is trading at a forward discount to the Swiss franc and the Japanese yen, while it is at a forward premium to the Canadian dollar and the British pound. We will see shortly that whether a particular currency trades at a discount or a premium to another depends on the relative level of the investment rates in the two countries.

Exhibit 21.13 lists quotes for a sample of exchange-traded currency futures contracts. These specific instruments are traded at the CME. Each contract involving U.S. dollars follows the convention that the U.S. dollar is the native monetary unit and the foreign currency is the commodity, meaning that all prices are quoted using the direct method. These contracts are also standardized to deliver a set number of units of the foreign currency on a specific date.
in the future. For instance, the June 2011 Euro contract negotiated on that date required the long position to purchase— and the short position to deliver— 125,000 euros at the price of USD 1.3753 per euro. By convention, all currency futures on the CME mature on the third Wednesday of the stated delivery month and can be settled with a wire transfer of the foreign currency. Notice that the dollar traded at a forward premium to the euro at this time.

Interest Rate Parity and Covered Interest Arbitrage

Interest rate parity specifies the "no arbitrage" relationship between spot and forward FX rates and the level of interest rates in each currency. This connection is best seen through an example. Suppose that an institutional investor has USD 100,000 to invest for one year and is considering two different riskless alternatives. The first strategy entails the purchase of a U.S. Treasury bill. Assume that under current market conditions, the effective U.S. dollar risk-free interest rate is 4.50 percent for a one-year maturity, so that a direct T-bill investment would return USD 104,500 at the end of the 12 months.

For the second strategy, suppose that the investor also can sell the USD 100,000 in the spot market at the exchange rate of AUD 1.20/USD (or, equivalently, USD 0.8333/AUD) to obtain a total of 120,000 Australian dollars. We assume that amount can then be invested in an Australian risk-free security at a rate of 7.00 percent, returning AUD 128,400 at the end of the year. Of course, to make this return comparable to the USD-denominated proceeds from the first strategy, the Australian dollars will have to be converted back into U.S. currency. If this translation is negotiated at the end of the investment, however, the investor will be subjected to foreign exchange risk in that he will not know at Date 0 what the AUD/USD exchange rate will be at Date T. Thus, to make the second strategy riskless, the investor must enter into a forward contract to exchange AUD back into USD at the end of the year. What would the exchange rate priced into a one-year forward contract have to be at Date 0 to leave the investor indifferent between these two strategies?

These investments are depicted in Exhibit 21.15. The essence of the arbitrage argument is that the one-year forward FX rate must be such that USD 104,500 equals AUD 128,400. The forward contract rate consistent with interest rate parity is AUD 1.2287/USD (= 128,400 / 104,500) on an indirect basis, or USD 0.8139/AUD quoted directly. This is a breakeven value in the sense that it allows the 4.50 percent investment return in the United States to be equal to the 7.00 percent available in Australia when the two are converted to the same currency. That is, the Australian return must be "deflated" by 250 basis points to leave the investor indifferent between the two strategies. This reduction occurs because, to invest in the

**Interest Rate Parity and Covered Interest Arbitrage**

Interest rate parity specifies the “no arbitrage” relationship between spot and forward FX rates and the level of interest rates in each currency. This connection is best seen through an example. Suppose that an institutional investor has USD 100,000 to invest for one year and is considering two different riskless alternatives. The first strategy entails the purchase of a U.S. Treasury bill. Assume that under current market conditions, the effective U.S. dollar risk-free interest rate is 4.50 percent for a one-year maturity, so that a direct T-bill investment would return USD 104,500 at the end of the 12 months.

For the second strategy, suppose that the investor also can sell the USD 100,000 in the spot market at the exchange rate of AUD 1.20/USD (or, equivalently, USD 0.8333/AUD) to obtain a total of 120,000 Australian dollars. We assume that amount can then be invested in an Australian risk-free security at a rate of 7.00 percent, returning AUD 128,400 at the end of the year. Of course, to make this return comparable to the USD-denominated proceeds from the first strategy, the Australian dollars will have to be converted back into U.S. currency. If this translation is negotiated at the end of the investment, however, the investor will be subjected to foreign exchange risk in that he will not know at Date 0 what the AUD/USD exchange rate will be at Date T. Thus, to make the second strategy riskless, the investor must enter into a forward contract to exchange AUD back into USD at the end of the year. What would the exchange rate priced into a one-year forward contract have to be at Date 0 to leave the investor indifferent between these two strategies?

These investments are depicted in Exhibit 21.15. The essence of the arbitrage argument is that the one-year forward FX rate must be such that USD 104,500 equals AUD 128,400. The forward contract rate consistent with interest rate parity is AUD 1.2287/USD (= 128,400 ÷ 104,500) on an indirect basis, or USD 0.8139/AUD quoted directly. This is a breakeven value in the sense that it allows the 4.50 percent investment return in the United States to be equal to the 7.00 percent available in Australia when the two are converted to the same currency. That is, the Australian return must be “deflated” by 250 basis points to leave the investor indifferent between the two strategies. This reduction occurs because, to invest in the
where:

\[
\text{RFR}_{USD} = \text{the annualized risk-free rate in the United States}
\]

\[
\text{RFR}_{FC} = \text{the annualized risk-free rate in the foreign market}
\]

Equation 21.9 defines the relationship between four different Date 0 prices: spot foreign exchange rate, forward foreign exchange rate, U.S. investment rate, and foreign investment rate. If the markets are aligned properly, \( F_0, T > S_0 \) whenever \( \text{RFR}_{FC} > \text{RFR}_{USD} \), with the opposite holding when \( \text{RFR}_{FC} < \text{RFR}_{USD} \). With indirect currency quotes, \( F_0, T > S_0 \) implies that the foreign currency is at a forward discount to the dollar. In other words, the country with the lowest investment rate should see its currency trade at a forward premium. The intuition behind this is that to keep investment capital from flowing to the country with the highest returns, the high-interest country will suffer from a weaker forward value for its currency.

A Currency Futures Application

Calculating Implied World Investment Rates

Suppose that you are the cash manager for a multinational company and you have $1,000,000 in short-term balances that you can invest in sovereign-issued paper for the next several months. On July 9, you obtain the following quotes for both spot and futures exchange rates for several currencies:

<table>
<thead>
<tr>
<th>Currency</th>
<th>July Spot (USD/FC)</th>
<th>December Futures (USD/FC)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Australian dollar</td>
<td>0.8875</td>
<td>0.8802</td>
</tr>
<tr>
<td>Japanese yen</td>
<td>0.008583</td>
<td>0.008704</td>
</tr>
<tr>
<td>Swiss franc</td>
<td>0.8515</td>
<td>0.8594</td>
</tr>
<tr>
<td>Canadian dollar</td>
<td>1.0027</td>
<td>1.0045</td>
</tr>
<tr>
<td>British pound</td>
<td>2.0383</td>
<td>2.0296</td>
</tr>
<tr>
<td>Mexican peso</td>
<td>0.09190</td>
<td>0.09145</td>
</tr>
</tbody>
</table>

The futures contracts for all of the contracts mature on December 19 of the same year, which leaves a 163-day investment window.

You also observe that a U.S. Treasury bill maturing at the same time pays a bond equivalent (i.e., 365-day) yield of 3.24 percent. Before checking the actual quotes for foreign-currency-denominated government paper from these other countries, you first calculate the investment rates implied by the interest rate parity relationship as follows:

\[
\text{Implied Rate} = \frac{\text{Spot}}{\text{Futures}} \times \left( \frac{1 + (\text{Foreign Interest Rate})(T/365)}{1 + (\text{U.S. Interest Rate})(T/365)} \right)
\]

which is just the parity relationship rearranged to use direct currency quotes and to isolate the foreign interest rate. The direct parity formulation is the correct one to use because of the convention prevailing in the U.S. currency futures market. For British sterling, this calculation yields an implied 163-day annualized investment rate of:

\[
\text{21.9} \quad \frac{F_{0,T}}{S_0} = \left( \frac{1 + (\text{RFR}_{FC})(T/365)}{1 + (\text{RFR}_{USD})(T/365)} \right)
\]

\(7\)Under these conditions, the actual currency loss is calculated as \((0.8139/0.8333 - 1) = -2.33%\). This, in turn, means the dollar-denominated return to the second strategy is \((1 + 0.07) \times (1 - 0.233) - 1) = 4.50%\).
where:

\[ RFR_{\text{USD}} = \text{the annualized risk-free rate in the United States} \]
\[ RFR_{\text{FC}} = \text{the annualized risk-free rate in the foreign market} \]

Equation 21.9 defines the relationship between four different Date 0 prices: spot foreign exchange rate, forward foreign exchange rate, U.S. investment rate, and foreign investment rate. If the markets are aligned properly, \( F_{0,T} \) will be greater than \( S_0 \) whenever \( RFR_{\text{FC}} \) is greater than \( RFR_{\text{USD}} \), with the opposite holding when \( RFR_{\text{FC}} < RFR_{\text{USD}} \). With indirect currency quotes, \( F_{0,T} > S_0 \) implies that the foreign currency is at a forward discount to the dollar. In other words, the country with the lowest investment rate should see its currency trade at a forward premium. The intuition behind this is that to keep investment capital from flowing to the country with the highest returns, the high-interest country will suffer from a weaker forward value for its currency.\(^8\)

**A Currency Futures Application**

**Calculating Implied World Investment Rates** Suppose that you are the cash manager for a multinational company and you have $1,000,000 in short-term balances that you can invest in sovereign-issued paper for the next several months. On July 9, you obtain the following quotes for both spot and futures exchange rates for several currencies:

<table>
<thead>
<tr>

<td>0.09190</td>
<td>0.09145</td>
</tr>
</tbody>
</table>

The futures contracts for all of the contracts mature on December 19 of the same year, which leaves a 163-day investment window.

You also observe that a U.S. Treasury bill maturing at the same time pays a bond equivalent (i.e., 365-day) yield of 3.24 percent. Before checking the actual quotes for foreign-currency-denominated government paper from these other countries, you first calculate the investment rates implied by the interest rate parity relationship as follows:

\[
\text{Implied Rate} = \left( \frac{\text{Spot Futures}}{\text{Spot}} \right) \left( 1 + \left( \frac{\text{U.S. Interest Rate}}{365} \right) \right) - 1 \left( \frac{365}{163} \right)
\]

which is just the parity relationship rearranged to use direct currency quotes and to isolate the foreign interest rate. The direct parity formulation is the correct one to use because of the convention prevailing in the U.S. currency futures market. For British sterling, this calculation yields an implied 163-day annualized investment rate of:

\[
\left( \frac{2.0383}{2.0296} \right) \left( 1 + (0.0324) \left( \frac{163}{365} \right) \right) - 1 \left( \frac{365}{163} \right) = 4.21\%.
\]

This means that with the current spot and futures prices for exchanging dollars and pounds, you would be indifferent between receiving a 5.5-month investment rate of 3.24 percent in the United States or 4.21 percent in England.

\(^8\)When using direct quotes (i.e., USD/FC), the interest rate parity condition must be adjusted by taking the reciprocal of the ratio on the left-hand side: \( [S_0 = F_{0,T}] = [(1 + RFR_{\text{FC}} (T - 365)) - (1 + RFR_{\text{USD}} (T - 365))] \). In the example given, we have \( S_0 = \text{USD 0.8333/AUD} = \text{USD 0.8139/AUD} \times (1.071/1.045) \).
Summarizing this calculation for all of the countries leaves:

<table>
<thead>
<tr>
<th>Country</th>
<th>Implied 163-Day Rate</th>
</tr>
</thead>
<tbody>
<tr>
<td>Australia</td>
<td>5.12%</td>
</tr>
<tr>
<td>Japan</td>
<td>0.08</td>
</tr>
<tr>
<td>Switzerland</td>
<td>1.15</td>
</tr>
<tr>
<td>Canada</td>
<td>2.83</td>
</tr>
<tr>
<td>Great Britain</td>
<td>4.21</td>
</tr>
<tr>
<td>Mexico</td>
<td>4.36</td>
</tr>
</tbody>
</table>

You can now compare these figures to the actual investment rates in each of the countries to determine if a futures-based synthetic foreign bond strategy is warranted. If, for example, the actual British six-month gilt rate were 4.60 percent, you could exceed the 3.24 percent dollar-denominated T-bill return by (1) exchanging your dollars for pounds in the spot market at USD 2.0383/GBP, (2) investing for 163 days in the sterling-based security at 4.60 percent, and (3) translating your proceeds back into dollars at maturity using the futures rate of USD 2.0296/GBP.

Finally, notice that the countries with implied rates higher than 3.24 percent (i.e., Australia, Great Britain, and Mexico) are those whose currencies sold at a forward discount to the U.S. dollar over this 163-day window. Conversely, Japan, Switzerland, and Canada had currencies at a forward premium to the dollar and thus had implied investment rates less than 3.24 percent.

**SUMMARY**

- As the most fundamental type of derivative instruments available, forward and futures contracts greatly increase the alternatives that investors have to manage their portfolios and establish new trading opportunities. In this chapter, we discuss how these contracts work and the ways they are used in practice. Forwards and futures differ primarily in the areas of design flexibility and collateralization. Forward agreements generally are more flexible but carry more credit risk, while the process of marking margin accounts to market on a daily basis makes futures contracts more secure (to the exchange, at least), even as contract standardization makes them less adaptable to the end user.

- Hedging is key to understanding forward-based contracting and the basis is the most important concept in understanding hedging. The basis is the difference between spot and forward prices at any point in time. It contains the essence of a short hedge position so that the hedger effectively trades the price risk of the underlying asset for the basis risk inherent in the spot-forward combination. This leads to the calculation of an optimal hedge ratio, which specifies the appropriate number of contracts by minimizing the amount of basis (i.e., correlation) risk in the combined position.

- Although forward and futures contracts are not securities, their contract settlement prices still must follow certain regularities for these markets to remain efficient. The cost of carry model suggests that in order to avoid arbitrage, the forward price should be equal to the spot price plus the cost of transporting the underlying asset to the future delivery date. These carrying costs can include commissions for physical storage, an opportunity cost for the net amount of invested capital, and a premium for the convenience of consuming the asset now. When forward prices are set in this manner, the market value of a new contract should be zero, although this value can become either positive or negative as the contract matures under changing market conditions.

- These concepts were illustrated with examinations of three types of financial futures contracts: interest rate, equity index, and foreign exchange. In addition to describing the dynamics of each of these markets, we discussed different applications, including those involving hedging, speculation, and arbitrage. These applications produced some useful adaptations of the basic concepts, such as duration, and beta-based hedge ratios for interest rate and stock index futures as well as the currency futures version of the cost of carry model known as interest rate parity.
b. Suppose that six months after you have entered into a futures contract as suggested in Part a, interest rates increase substantially due to an unexpected change in monetary policy. Discuss how this increase in interest rates will affect the futures position you entered into.

c. Discuss whether you would have been better off (1) with the hedge position or (2) without the hedge position in this situation.

6. You own an equally weighted portfolio of 50 different stocks worth about $5,000,000. The stocks are from several different industries, and the portfolio is reasonably well diversified. Which do you think would provide you with the best overall hedge: a single position in an index futures or 50 different positions in futures contracts on the individual stocks? What are the most important factors to consider in making this decision?

7. Since their introduction, stock index futures contracts have become very popular and are now widely traded by finance professionals. Many factors, including (1) the current price of the underlying stock index, (2) the time to contract maturity, and (3) the dividends paid to the stocks in the underlying index, will affect the settlement price of a stock index futures contract. What is the fourth primary factor involved in stock index futures contract pricing, and how does this factor affect settlement prices?

8. It is often stated that a stock index arbitrage trade is easier to implement when the stock index futures contract price is above its theoretical level than when it is below that value. What institutional realities might make this statement true? Describe the steps involved in forming the arbitrage transaction in both circumstances. To the extent that the statement is valid, what does it suggest about the ability of the stock index futures market to remain efficient?

9. As the risk manager for a large pension fund, you know that the investment staff is considering a move to diversify the portfolio over the next six months by investing $900 million in Japanese government bonds. Although you like the investment profile of these securities, you are concerned that adverse foreign exchange rate fluctuations could reduce or even eliminate the expected returns from owning the bonds. Consequently, you want to consider a hedge against this exposure using currency futures contracts.

a. Describe how a currency futures contract position could be employed along with the purchase of the bond in this situation to mitigate the risk exposure the risk manager is concerned with.

b. Explain what would happen to both the currency futures position and the underlying bond holding if the USD/JPY exchange rate moved up unexpectedly after you initiated the FX hedge transaction.

10. Explain why the currency of Country A, whose interest rates are twice as great as those in Country B, must trade at a forward discount. If there were no difference between the spot and forward exchange rates in this interest rate environment, what arbitrage trade could be constructed to take advantage of the situation?

SUGGESTED READINGS

QUESTIONS

1. We have futures contracts on Treasury bonds, but we do not have futures contracts on individual corporate bonds. We have cattle and hog futures but no chicken futures. Explain why the market has developed in this manner. What do you think are the most important characteristics for the success of a new futures contract concept?

2. “Hedgers trade price risk for basis risk.” What is meant by this statement? In particular, explain the concept of the basis in a hedge transaction and how forward and futures contracts can be selected to minimize risk.

3. Suppose you are a derivatives trader specializing in creating customized commodity forward contracts for clients and then hedging your position with exchange-traded futures contracts. Your latest position is an agreement to deliver 100,000 gallons of unleaded gasoline to a client in three months.
   a. Explain how you can hedge your position using gasoline futures contracts.
   b. In calculating your hedge ratio, how must you account for the different valuation procedures used for forward and futures contracts? That is, what difference does it make that forward contracts are valued on a discounted basis while futures contracts are marked to market without discounting?
   c. If the only available gasoline futures contracts call for the delivery of 42,000 gallons and mature in either two or four months, describe the nature of the basis risk involved in your hedge.

4. A multinational corporation is about to embark on a major financial restructuring program. One critical stage will be the issuance of seven-year Eurobonds sometime within the next month. The CFO is concerned with recent instability in capital markets and with the particular event that market yields rise prior to issuance, forcing the corporation to pay a higher coupon rate on the bonds. It is decided to hedge that risk by selling 10-year Treasury note futures contracts. Notice that this is a classic cross hedge wherein 10-year Treasury notes are used to manage the risk of 7-year Eurobonds.
   Describe the nature of the basis risk in the hedge. In particular what specific events with respect to the shape of the Treasury yield curve and the Eurobond spread over Treasuries could render the hedge ineffective? In other words, under what circumstances would the hedge fail and make the corporation worse off?

5. You are the chief financial officer of a large multinational company, and six months from now you will be receiving a settlement payment of $50 million, which you plan to invest in 10-year U.S. Treasury bonds. Your interest rate forecast indicates that the yield curve will drop dramatically in the next two quarters. You are considering ways that you can guard against the possible decline in interest rates before you have the funds available to invest.
   a. Briefly describe the hedging strategy using the 10-year Treasury note futures contract that would provide the best protection against this possible decline in yields.
a. Calculate the equity value of your margin account on each settlement date, including any additional equity required to meet a margin call. Also compute the amount of cash that will be returned to you on July 9, and the gain or loss on your position, expressed as a percentage of your initial margin commitment.

b. Assuming that the underlying soybean meal investment pays no dividend and requires a storage cost of 1.5 percent (of current value), calculate the current (i.e., March 9) spot price for a ton of soybean meal and the implied May 9 price for the same ton. In your calculations, assume that an annual risk-free rate of 8 percent prevails over the entire contract life.

c. Now suppose that on March 9 you also entered into a long forward contract for the purchase of 100 tons of soybean meal on July 9. Assume further that the July forward and futures contract prices always are identical to one another at any point in time. Calculate the cash amount of your gain or loss if you unwind both positions in their respective markets on May 9 and June 9, taking into account the prevailing settlement conditions in the two markets.

You are a coffee dealer anticipating the purchase of 82,000 pounds of coffee in three months. You are concerned that the price of coffee will rise, so you take a long position in coffee futures. Each contract covers 37,500 pounds, and so, rounding to the nearest contract, you decide to go long in two contracts. The futures price at the time you initiate your hedge is 55.95 cents per pound. Three months later, the actual spot price of coffee turns out to be 58.56 cents per pound and the futures price is 59.20 cents per pound.

a. Determine the effective price at which you purchased your coffee. How do you account for the difference in amounts for the spot and hedge positions?

b. Describe the nature of the basis risk in this long hedge.

June Klein, CFA, manages a $100 million (market value) U.S. government bond portfolio for an institution. She anticipates a small parallel shift in the yield curve and wants to fully hedge the portfolio against any such change.

a. Discuss two reasons for using futures rather than selling bonds to hedge a bond portfolio. No calculations required.

b. Formulate Klein’s hedging strategy using only the futures contract shown. Calculate the number of futures contracts to implement the strategy. Show all calculations.

c. Determine how each of the following would change in value if interest rates increase by 10 basis points as anticipated. Show all calculations.

1. The original portfolio
2. The Treasury bond futures position
3. The newly hedged portfolio

d. State three reasons why Klein’s hedging strategy might not fully protect the portfolio against interest rate risk.

e. Describe a zero-duration hedging strategy using only the government bond portfolio and options on U.S. Treasury bond futures contracts. No calculations required.

PROBLEMS

1. It is March 9, and you have just entered into a short position in a soybean meal futures contract. The contract expires on July 9 and calls for the delivery of 100 tons of soybean meal. Further, because this is a futures position, it requires the posting of a $3,000 initial margin and a $1,500 maintenance margin; for simplicity, however, assume that the account is marked to market on a monthly basis. Assume the following represent the contract delivery prices (in dollars per ton) that prevail on each settlement date:

<table>
<thead>
<tr>
<th>Date</th>
<th>Price</th>
</tr>
</thead>
<tbody>
<tr>
<td>March 9 (initiation)</td>
<td>$173.00</td>
</tr>
<tr>
<td>April 9</td>
<td>179.75</td>
</tr>
<tr>
<td>May 9</td>
<td>189.00</td>
</tr>
<tr>
<td>June 9</td>
<td>182.50</td>
</tr>
<tr>
<td>July 9 (delivery)</td>
<td>174.25</td>
</tr>
</tbody>
</table>
a. Calculate the equity value of your margin account on each settlement date, including any additional equity required to meet a margin call. Also compute the amount of cash that will be returned to you on July 9, and the gain or loss on your position, expressed as a percentage of your initial margin commitment.
b. Assuming that the underlying soybean meal investment pays no dividend and requires a storage cost of 1.5 percent (of current value), calculate the current (i.e., March 9) spot price for a ton of soybean meal and the implied May 9 price for the same ton. In your calculations, assume that an annual risk-free rate of 8 percent prevails over the entire contract life.
c. Now suppose that on March 9 you also entered into a long forward contract for the purchase of 100 tons of soybean meal on July 9. Assume further that the July forward and futures contract prices always are identical to one another at any point in time. Calculate the cash amount of your gain or loss if you unwind both positions in their respective markets on May 9 and June 9, taking into account the prevailing settlement conditions in the two markets.

2. You are a coffee dealer anticipating the purchase of 82,000 pounds of coffee in three months. You are concerned that the price of coffee will rise, so you take a long position in coffee futures. Treasury bond futures (based on $100,000 face value of 20-year T-bonds having an 8 percent semi-annual coupon) with a maturity exactly six months from now are currently priced at 109–24 with a corresponding yield to maturity of 7.081 percent. The “yield betas” between the futures contract and Bonds A, B, and C are 1.13, 1.03, and 1.01, respectively. Finally, the modified duration for the T-bond underlying the futures contract is 10.355 years.

a. Calculate the modified duration (expressed in years) for each of the two bond portfolios. What will be the approximate percentage change in the value of each if all yields increase by 60 basis points on an annual basis?

b. Without performing the calculations, explain which of the portfolios will actually have its value impacted to the greatest extent (in absolute terms) by the shift yields. (Hint: This explanation requires knowledge of the concept of bond convexity.)

c. Assuming the bond speculator wants to hedge her net bond position, what is the optimal number of futures contracts that must be bought or sold? Start by calculating the optimal hedge ratio between the futures contract and the two bond portfolios separately and then combine them.

5. Arshia Hershey, a newly hired bond trader, is eager to exploit what she perceives to be an inefficiency in futures market prices. Specifically, she observes the following information concerning prices in the spot market for bonds and for the bond futures contract maturing three months from now:

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Spot price</td>
<td>$102.30</td>
</tr>
<tr>
<td>3-month futures contract price</td>
<td>$112.15</td>
</tr>
<tr>
<td>Income from the Treasury bond for 3 months</td>
<td>$2.20</td>
</tr>
<tr>
<td>Finance charge for 3 months</td>
<td>$1.10</td>
</tr>
</tbody>
</table>

a. Describe the arbitrage transaction that Arshia should undertake to take advantage of these market conditions.

b. Demonstrate the arbitrage profit that she will realize at the expiration date of the futures contract.

c. Does your answer to Part b depend on the price of the underlying bond at the maturity date of the futures contract? Explain why or why not.

6. As a relationship officer for a money-center commercial bank, one of your corporate accounts has just approached you about a one-year loan for $1,000,000. The customer would pay a quarterly interest expense based on the prevailing level of LIBOR at the beginning of each three-month period. As is the bank’s convention on all such loans, the amount of the interest payment would then be paid at the end of the quarterly cycle when the new rate for the next cycle is determined. You observe the following LIBOR yield curve in the cash market:

| 90-day LIBOR | 4.60% |
| 180-day LIBOR | 4.75  |
| 270-day LIBOR | 5.00  |
| 360-day LIBOR | 5.30  |
a. If 90-day LIBOR rises to the levels “predicted” by the implied forward rates, what will the dollar level of the bank’s interest receipt be at the end of each quarter during the one-year loan period?

b. If the bank wanted to hedge its exposure to failing LIBOR on this loan commitment, describe the sequence of transactions in the futures markets it could undertake.

c. Assuming the yields inferred from the Eurodollar futures contract prices for the next three settlement periods are equal to the implied forward rates, calculate the annuity value that would leave the bank indifferent between making the floating-rate loan and hedging it in the futures market and making a one-year fixed-rate loan. Express this annuity value in both dollar and annual (360-day) percentage terms.

7. Suppose that one day in early April, you observe the following prices on futures contracts maturing in June: 93.35 for Eurodollar and 94.07 for T-bill. These prices imply three-month LIBOR and T-bill settlement yields of 6.65 percent and 5.93, respectively. You think that over the next quarter the general level of interest rates will rise while the credit spread built into LIBOR will narrow. Demonstrate how you can use a TED (Treasury/Eurodollar) spread, which is a simultaneous long (short) position in a Eurodollar contract and short (long) position in the T-bill contract, to create a position that will benefit from these views.

8. An investment bank engages in stock index arbitrage for its own and customer accounts. On a particular day, the S&P Index at the New York Stock Exchange is 602.25 when the futures contract for delivery in 90 days is 614.75. If the annualized 90-day interest rate is 8.00 percent and the (annualized) dividend yield is 3 percent, would program trading involving stock index arbitrage possibly take place? If so, describe the transactions that should be undertaken, and calculate the profit that would be made per each “share” of the S&P 500 Index used in the trade.

9. Alex Andrew, who manages a $95 million large-capitalization U.S. equity portfolio, currently forecasts that equity markets will decline soon. Andrew prefers to avoid the transaction costs of making sales but wants to hedge $15 million of the portfolio’s current value using S&P 500 futures.

Because Andrew realizes that his portfolio will not track the S&P 500 Index exactly, he performs a regression analysis on his actual portfolio returns versus the S&P futures returns over the past year. The regression analysis indicates a risk-minimizing beta of 0.88 with an $R^2$ of 0.92.

<table>
<thead>

<td>S&amp;P 500 futures price</td>
</tr>
<tr>
<td>S&amp;P 500 index</td>
</tr>
<tr>
<td>S&amp;P 500 index multiplier</td>
</tr>
</tbody>
</table>

a. Calculate the number of futures contracts required to hedge $15 million of Andrew’s portfolio, using the data shown. State whether the hedge is long or short. Show all calculations.

b. Identify two alternative methods (other than selling securities from the portfolio or using futures) that replicate the strategy in Part a. Contract each of these methods with the futures strategy.

10. The treasurer of a middle market, import-export company has approached you for advice on how to best invest some of the firm’s short-term cash balances. The company, which has been a client of the bank that employs you for a few years, has $250,000 that it is able to commit for a one-year holding period. The treasurer is currently considering two alternatives: (1) invest all the funds in a one-year U.S. Treasury bill offering a bond equivalent yield of 4.25 percent, and (2) invest all the funds in a Swiss government security over the same horizon, locking in the spot and forward currency exchanges in the FX market. A
A Closed-Form Equation for Calculating Duration

To calculate the duration statistic, it helps to think of a bond that pays a fixed coupon for a finite maturity as being just a portfolio of zero coupon cash flows. Duration is then the weighted average of the payment (i.e., maturity) dates of those zero coupon cash flows, its zero coupon equivalent maturity.

Consider a nonamortizing, five-year bond with a face value of $1,000 making annual coupon payments of $120 (i.e., 12 percent). Assuming a yield to maturity of 10 percent, this bond will trade at a premium and its weighted average payment date (i.e., duration) is 4.0740 years, as shown in Exhibit 21A.1. The duration of 4.0740 years is the weighted average maturity of that portfolio, where the weights are the respective shares of market value (e.g., the one-year zero coupon cash flow is 10.14 percent of the value of the portfolio; the five-year zero is 64.64 percent).

This five-year coupon bond with a duration of 4.0740 years is equivalent in terms of price risk to a zero coupon bond having a maturity of 4.0740 years. When the interest rate increases by 1 percent above its original level (i.e., \[ Δ \left(1 + \frac{i}{n}\right) = 0.01\] ), then the price of this bond will decline by about 4.074 percent.

The Macaulay duration can be calculated with the following formula:

\[
D = \frac{1}{1 + \frac{Y}{n}} - \frac{1}{1 + \frac{Y}{n} + \left(n \times T\right)} \frac{C/F - \frac{Y}{n}}{m} \frac{C/F + \frac{Y}{n}}{m + \left(n \times T\right)}
\]

where:
- \(C\) = the periodic coupon payment
- \(F\) = the face value at maturity
- \(T\) = the number of years until maturity
- \(n\) = the payments per year
- \(Y\) = the yield to maturity

In the preceding numerical example, \(Y = 0.10\), \(n = 1\), \(T = 5\), \(C/F = 0.12\), and \(Y/n = 0.10\). The bond’s duration can therefore be solved as:

\[
D = \frac{1}{1 + 0.10} - \frac{1}{1 + 0.10 + \left(5 \times 1\right)} \frac{0.12 - 0.10}{1 + 0.10} = 4.0740
\]

As a second example, what is the duration of a 30-year Treasury bond with a 7 5/8 percent coupon and a stated yield to maturity of 7.72 percent? Recall that T-bonds pay semiannual interest and so the appropriate definitions of the variables are \(C/F = 0.38125\), \(T = 30\), \(n = 2\), and \(Y/n = 0.0386\). Therefore:

\[
D = \frac{1}{1 + 0.0386} - \frac{1}{1 + 0.0386 + \left(60 \times 2\right)} \frac{0.38125 - 0.0386}{1 + 0.0386} = 24.18\text{ or }12.09\text{ years.}
\]

819

11. Bonita Singer is a hedge fund manager specializing in futures arbitrage involving stock index contracts. She is investigating potential trading opportunities in S&P 500 stock index futures to see if there are any inefficiencies that she can exploit. She knows that the S&P 500 stock index is currently trading at 1,100.

a. Assume that the Treasury yield curve is flat at 3.2 percent and the annualized dividend yield on the S&P index is 1.8 percent. Using the cost of carry model, demonstrate what the theoretical contract price should be for a futures position expiring six months from now.

b. Describe the set of transactions that Bonita would have to undertake to take advantage of an actual futures contract price that was (1) substantially higher or (2) substantially lower than the theoretical value you established in Part a.

c. Assuming that total round-trip arbitrage transaction costs are $20 for the set trades described in Part b, calculate the upper and lower bounds for the theoretical contract price such that arbitrage trading would not be profitable.
A. Calculating Money Market Implied Forward Rates

Implied forward rates are an essential factor in understanding how short-term interest rate futures contracts are priced. In Chapter 18, we discussed that implied forward rates represented the sequence of future short-term rates that were built into the yield to maturity of a longer-term security. However, implied forward rates can have another interpretation. Consider an investor who is deciding between the following strategies for making a two-year investment: (1) buy a single two-year, zero coupon bond yielding 6 percent per annum; or (2) buy a one-year, zero coupon bond with a 5 percent yield and replace it at maturity with another one-year instrument. An implied forward rate is the answer to the following question: At what rate must the investor be able to reinvest the interim proceeds from the second strategy to exactly equal the total return from the first investment? In other words, the implied forward rate is a breakeven reinvestment rate. In the notation of Chapter 18, we want to solve for $r_1^2$ in the following equation:

$$\left(1 + \frac{0.06}{2}\right)^2 = \left(1 + \frac{0.05}{2}\right)\left(1 + 2r_1\right)$$

or

$$2r_1 = \frac{\left(1 + \frac{0.06}{2}\right)^2}{\left(1 + \frac{0.05}{2}\right)} - 1 = 7\%$$

Implied forward money market rates can be interpreted in the same way as bond yields, but they must be calculated differently because of differences in the quotation methods for the various rates. We have seen that LIBOR is a bank add-on yield (AY) that is used to figure out how much money, $F$, an investor will have at maturity in $T$ days given an initial investment of $P$ (i.e., interest is “added on”):

$$F = P + P \times A.Y. \times \frac{T}{360}$$

LIBOR is based on a presumed 360-day year, the standard U.S. money market practice. Smith (1989) has shown that the implied forward rate between two money market instruments quoted on an add-on basis (e.g., LIBOR) can be calculated as:

$$A.Y. _B - A.Y. _A = \frac{B \times A.Y. _B - A \times A.Y. _A}{B - A - 1} - \frac{A + A.Y. _A}{360}$$

where

- $A.Y. _B$ and $A.Y. _A$ are add-on yields for $A$ and $B$ days from settlement to maturity, with $B > A$.
- The implied forward rate ($A.Y. _B - A.Y. _A$) also is on an add-on basis and has maturity of $(B - A)$ days.

Consider the following short-term yield curve for LIBOR:

<table>
<thead>
<tr>
<th>Maturity</th>
<th>LIBOR</th>
</tr>
</thead>
<tbody>
<tr>
<td>30 days</td>
<td>4.15%</td>
</tr>
<tr>
<td>60 days</td>
<td>4.25%</td>
</tr>
<tr>
<td>90 days</td>
<td>4.35%</td>
</tr>
</tbody>
</table>

What is the implied forward LIBOR between Days 60 and 90? Using $A.Y. _A = 0.0425$, $A.Y. _B = 0.0435$, $A = 60$ days, and $B = 90$ days for LIBOR, we have:

$$A.Y. _{90} - A.Y. _{60} = \frac{90 \times 0.0435 - 60 \times 0.0425}{90 - 60 - 1} - \frac{60 + 0.0425}{360} = 4.52\%$$

So, investing in a 60-day bank deposit at 4.25 percent and then a 30-day deposit at 4.52 percent would have the same total return as the 90-day deposit at 4.35 percent.

A. A Closed-Form Equation for Calculating Duration

To calculate the duration statistic, it helps to think of a bond that pays a fixed coupon for a finite maturity as being just a portfolio of zero coupon cash flows. Duration is then the weighted average of the payment (i.e., maturity) dates of those zero coupon cash flows, its zero coupon equivalent maturity.

Consider a nonamortizing, five-year bond with a face value of $1,000 making annual coupon payments of $120 (i.e., 12 percent). Assuming a yield to maturity of 10 percent, this bond will trade at a premium and its weighted average payment date (i.e., duration) is 4.0740 years, as shown in Exhibit 21A.1. The duration of 4.0740 years is the weighted average maturity of that portfolio, where the weights are the respective shares of market value (e.g., the one-year zero coupon cash flow is 10.14 percent of the value of the portfolio; the five-year zero is 64.64 percent).

This five-year coupon bond with a duration of 4.0740 years is equivalent in terms of price risk to a zero coupon bond having a maturity of 4.0740 years. When the interest rate increases by 1 percent above its original level (i.e., $\Delta (1 + i) + (1 + i) = 0.01$), then the price of this bond will decline by about 4.074 percent.

The Macaulay duration can be calculated with the following formula:

$$D = \frac{1 + \frac{Y}{n}}{Y} - \frac{1 + \frac{Y}{n} + \left[\frac{C}{F} - \frac{Y}{n}\right]}{F}$$

where:

- $C$ = the periodic coupon payment
- $F$ = the face value at maturity
- $T$ = the number of years until maturity
- $n$ = the payments per year
- $Y$ = the yield to maturity

In the preceding numerical example, $Y = 0.10$, $n = 1$, $T = 5$, $C/F = 0.12$, and $Y/n = 0.10$. The bond’s duration can therefore be solved as:

$$D = \frac{1 + 0.10}{0.10} - \frac{1 + 0.10 + 5(0.12 - 0.10)}{(0.12)(1 + 0.10)^5 - 1} + 0.10 = 4.0740$$

As a second example, what is the duration of a 30-year Treasury bond with a 7% percent coupon and a stated yield to maturity of 7.72 percent? Recall that T-bonds pay semiannual interest and so the appropriate definitions of the variables are $C/F = 0.38125$, $T = 30$, $n = 2$, and $Y/n = 0.0386$. Therefore:

$$D = \frac{1 + 0.0386}{0.0386} - \frac{1 + 0.0386 + 60(0.038125 + 0.0386)}{(0.038125)(1 + 0.0386)^{60} - 1} + 0.0386 = 24.18$$

or 12.09 years.

Price = $1,075.82 Duration = 4.0740 years
B. Calculating Money Market Implied Forward Rates

Implied forward rates are an essential factor in understanding how short-term interest rate futures contracts are priced. In Chapter 18, we discussed that implied forward rates represented the sequence of future short-term rates that were built into the yield to maturity of a longer-term security. However, implied forward rates can have another interpretation. Consider an investor who is deciding between the following strategies for making a two-year investment: (1) buy a single two-year, zero coupon bond yielding 6 percent per annum; or (2) buy a one-year, zero coupon bond with a 5 percent yield and replace it at maturity with another one-year instrument. An implied forward rate is the answer to the following question: At what rate must the investor be able to reinvest the interim proceeds from the second strategy to exactly equal the total return from the first investment? In other words, the implied forward rate is a breakeven reinvestment rate. In the notation of Chapter 18, we want to solve for $x_r$ in the following equation:

$$(1 + 0.06)^2 = (1 + 0.05)(1 + x_r)$$

or

$$x_r = [(1 + 0.06)^2 - (1 + 0.05)] - 1 = 7\%$$

Implied forward money market rates can be interpreted in the same way as bond yields, but they must be calculated differently because of differences in the quotation methods for the various rates. We have seen that LIBOR is a bank add-on yield (AY) that is used to figure out how much money, $F$, an investor will have at maturity in $T$ days given an initial investment of $P$ (i.e., interest is "added on"): 

$$F = P + \left(P \times AY \times \frac{T}{360}\right) = P \left(1 \times AY \times \frac{T}{360}\right)$$

LIBOR is based on a presumed 360-day year, the standard U.S. money market practice. Smith (1989) has shown that the implied forward rate between two money market instruments quoted on an add-on basis (e.g., LIBOR) can be calculated as:

$$\beta AY_A = \left[\frac{(B \times AY_B) - (A \times AY_A)}{B - A}\right] \left[\frac{1}{1 + \left(\frac{A \times AY_A}{360}\right)}\right]$$

where $AY_A$ and $AY_B$ are add-on yields for $A$ and $B$ days from settlement to maturity, with $B > A$. The implied forward rate ($\beta AY_A$) also is on an add-on basis and has maturity of $(B - A)$ days.

Consider the following short-term yield curve for LIBOR:

<table>
<thead>
<tr>
<th>Maturity</th>
<th>LIBOR</th>
</tr>
</thead>
<tbody>
<tr>
<td>30 days</td>
<td>4.15%</td>
</tr>
<tr>
<td>60 days</td>
<td>4.25</td>
</tr>
<tr>
<td>90 days</td>
<td>4.35</td>
</tr>
</tbody>
</table>

What is the implied forward LIBOR between Days 60 and 90? Using $AY_A = 0.0425$, $AY_B = 0.0435$, $A = 60$ days, and $B = 90$ days for LIBOR, we have:

$$90 AY_{90} = \left[\frac{(90 \times 0.0435) - (60 \times 0.0425)}{90 - 60}\right] \left[\frac{1}{1 + \left(\frac{60 \times 0.0425}{360}\right)}\right] = 4.52\%$$

So, investing in a 60-day bank deposit at 4.25 percent and then a 30-day deposit at 4.52 percent would have the same total return as the 90-day deposit at 4.35 percent.
CHAPTER 22
Option Contracts

After you read this chapter, you should be able to answer the following questions:

- How are options traded on exchanges and in OTC markets?
- How are options for stock, stock indexes, ETFs, foreign currency, and futures contracts quoted in the financial press?
- How can investors use option contracts to hedge an existing risk exposure?
- What are the three steps in establishing the fundamental no-arbitrage value of an option contract?
- What is the binomial (or two-state) option pricing model, and in what way is it an extension of the basic valuation approach?
- What is the Black-Scholes option pricing model, and how does it extend the binomial valuation approach?
- What is the relationship between the Black-Scholes and put-call parity valuation models?
- How can models for valuing stock options be adapted to other underlying assets such as stock indexes, foreign currency, and futures contracts?
- How do American- and European-style options differ from one another?
- What is implied volatility, and what is its role in the contract valuation process?
- How do investors use options with the underlying security or in combination with one another to create payoff structures tailored to a particular need or view of future market conditions?
- What differentiates a spread from a straddle, a strangle, or a range forward?

At the most basic level, only two kinds of derivative contracts exist: forwards, which fix the price or rate of an underlying asset, and options, which allow holders to decide at a later date whether such a fixing is in their best interest. This chapter focuses on the trading and valuation of option contracts. We develop the discussion in four parts. First, we consider the contract terms and trading mechanics for both call and put options. Options trade on exchanges as well as in the OTC dealer markets. To focus this discussion, we concentrate on options that have financial instruments as underlying securities, including options on individual stocks, stock indexes and ETFs, foreign currency, and futures contracts.

The second topic we explore is how option contracts are valued in an efficient capital market. We show that this can be viewed as a simple, three-step process: (1) creating a riskless hedge portfolio combining options with the underlying security, (2) invoking a no-arbitrage assumption about the rate of return that such a portfolio should earn, and (3) solving for the option value consistent with the first two steps. We also show that several of the most widely used valuation models, including the binomial and Black-Scholes models, are consistent with this approach. In this analysis, it is important to keep in mind that we will be valuing options and not pricing
them. Prices are established through the actions of buyers and sellers; investors and analysts use valuation models to estimate what those prices should be.

Third, we consider several extensions in option valuation. We show how the Black-Scholes model for call options on stock can be adapted to value put options, as well as the other financial assets commonly used as underlying assets. We describe how the payment of dividends affects an option’s value and how the model can be adjusted accordingly. We discuss the practical differences between the European and American styles of contracting, and we also examine price or return volatility—the role it plays in the valuation process and the ways an investor can estimate it in practice.

Finally, several option-based investment and hedging strategies are examined. After describing protective put and covered call strategies, we demonstrate how options can be used in combination with one another to create risk-reward trade-offs that do not otherwise exist in financial markets. We consider three broad classes of option combination strategies: straddles, which involve the purchase and sale of both puts and calls; spreads, in which the investor simultaneously buys one call (or put) while selling another; and range forwards (or collars), which require the purchase of a call and the concurrent sale of a put, or vice versa.

22.1 An Overview of Option Markets and Contracts

In Chapter 21, we discussed the primary difference between forward and futures contracts: Futures are standardized and trade on exchanges, while forward contracts have negotiable terms and therefore must be arranged in the OTC market. Option contracts offer investors similar trading alternatives. The most important features of how these contracts are traded and quoted in the financial press are highlighted in the following sections.

22.1.1 Option Market Conventions

Option contracts have been traded for centuries in the form of separate agreements or embedded in other securities. Malkiel (2011), for example, tells the story of how call options were used to speculate on flower prices during the tulip bulb frenzy in 17th-century Holland. Then, and for most of the time until now, options were arranged and executed in private transactions. Collectively, these private transactions represent the OTC market for options, and agreements can be structured around any terms or underlying asset to which two parties can agree. This has been a particularly useful mechanism when the underlying asset is too illiquid to support a widely traded contract. Also, credit risk is a paramount concern in this market if OTC agreements are not collateralized. This credit risk is one-sided with an option agreement because the buyer worries about the seller’s ability to honor his obligations, but the seller has received everything he will get up front and is not concerned about the buyer’s creditworthiness.

OTC options ultimately are created in response to the needs and desires of the corporations and individual investors who use them. Financial institutions, such as money-center banks and investment banks, serve as market makers by facilitating the arrangement and execution of these deals. Over the years, various trade associations of broker-dealers in OTC options have emerged (and, in some cases, faded), including the Put and Call Brokers and Dealers Association, which helped arrange private stock option transactions, and the International Swap and Derivatives Association, which monitors the activities of market makers for interest rate and foreign exchange derivatives. These trade groups create a common set of standards and language to govern industry transactions. More recently, the enactment of the Dodd-Frank Act in 2011 created a new level of regulatory oversight for OTC options.
In April 1973, the Chicago Board of Trade opened the Chicago Board Options Exchange (CBOE). Specializing in stock and stock index options, the CBOE has introduced two important aspects of market uniformity. Foremost, contracts offered by the CBOE are standardized in terms of the underlying common stock, the number of shares covered, the delivery dates, and the range of available exercise prices. This standardization helped develop a secondary market for the contracts. The rapid increase in trading volume on the CBOE and other options exchanges suggests that this feature is desirable compared to OTC contracts that must often be held to maturity due to a lack of liquidity.

The centralization of the trading function also necessitated the creation of the Options Clearing Corporation (OCC), which acts as the guarantor of each CBOE-traded contract. Therefore, end users in option transactions ultimately bear the credit risk of the OCC. For this reason, even though the OCC is independent of the exchange, it demands that the option seller post margin to guarantee future performance. The option buyer will not have a margin account because a future obligation to the seller is nonexistent. Finally, this central market structure makes monitoring, regulation, and price reporting much easier than in the decentralized OTC markets.

### 22.1.2 Price Quotations for Exchange-Traded Options

**Equity Options** Options on the common stock of individual companies have traded on the CBOE since 1973. Several other markets, including the American (AMEX), Philadelphia (PHLX), and International Securities (ISE) Exchanges, began trading their own contracts soon afterward. By early 2011, the CBOE remains the largest exchange in terms of option market volume with a market share of about 27 percent; PHLX is second at around 22 percent. Options on each of these exchanges are traded similarly, with a typical contract for 100 shares of stock. Because exchange-traded contracts are not issued by the company whose common stock serves as the underlying asset, they require secondary transactions in the equity if exercised.\(^1\)

Panel A of Exhibit 22.1 displays price and volume statistics for a sample of the most actively traded individual equity options on March 21, 2011. Some of the names represented—General Electric (GE), Bank of America (BAC), Sprint Nextel (S), and Citigroup (C)—also rank among the most actively traded stocks. To interpret this exhibit, suppose that an investor wanted to buy an option on Bank of America common stock. The ninth entry on the left side of the display indicates that the BAC call with an exercise price of $14 and an expiration date one month later in April 2011 traded at a price of $0.45 per share of the underlying stock. By convention, stock options expire on the Saturday following the third Friday of the designated month. Panel B of Exhibit 22.1 provides more details for this contract and many other available BAC options.

To consider a specific option transaction in more detail, assume that on this date in March 2011, the investor did indeed buy the April 2011 BAC 14 call. Based on the last reported price, her contract would cost a total of $45.00, calculated as the stated per-share price of 0.45 multiplied by 100 shares. In exchange for that payment, the holder of this American-style call would then be able to exercise the option at expiration in mid-April—or any time before then—by paying $1,400 (= 14 x 100) and would receive 100 Bank of America shares from the option seller. Such an action will only be rational if the mid-April price of BAC stock is greater than $14. If that price closes below $14, the investor will simply let the call expire without acting on the option. Finally, notice that with the prevailing BAC share price being $14.05 (which is shown in Panel B), the investor could immediately recover $0.05 of the $0.45 she

---

\(^1\)Call options issued directly by the firm whose common stock is the underlying asset are called *warrants*. We discuss the use and valuation of these contracts in Chapter 23.
paid for the contract. Her time premium of $0.40 (= 0.45 − 0.05) preserves her right to buy BAC stock at a price of $14 for the next month, even if the market value of those shares moves higher.

Consider another investor who sells the April 14 Bank of America put, the details of which are shown in the fourth row on the right side of Panel B of Exhibit 22.1. In return for an up-front receipt of $42 (= 0.42 × 100), he must stand ready to buy 100 shares of stock in mid-April for $1,400 if the put holder chooses to exercise his option to sell. Of course, the stock price will have to fall from its current level before this will occur. The investor in this case has sold an out-of-the-money contract and hopes that it will stay out of the money through expiration. As we saw earlier, the front-end premium is all that sellers of put or call options ever receive, and they hope to retain as much of it possible. Like the long position in the call, the short put position benefits from an increase in BAC share prices.

Notice that most of the options listed in both panels of Exhibit 22.1 expire within a few months of the quotation date. In fact, the expiration dates available for most of these exchange-traded contracts are the two nearest term months (April and May for Bank of America) and up to three additional months from a quarterly cycle beginning in either January, February, or March. In the case of BAC options, April 2011 and May 2011 (which is part of the quarterly cycle beginning in February) are the additional months most frequently listed. For high-volume stocks like BAC, additional expiration months can also be added (June 2011 and July 2011, in this case). Finally, for investors with a very short-term perspective, the CBOE recently created **Weeklys**, which are option contracts that are created on a Thursday morning and expire on Friday afternoon of the following week.

Exhibit 22.2 gives quotations for Long-Term Equity Anticipation Securities (LEAPS), which are simply regular call and put options with longer expiration dates. Like the contracts just described, LEAPS are also traded on the CBOE and have comparable terms. The LEAPS quotes allow us to see the effect that time to expiration has on the value of an option. The highlighted entries in the display show prices for two different calls and two different puts for BAC. Each highlighted contract has an exercise price of 15, but the expiration dates are either 0.83 years (January 2012) or 1.83 years (January 2013) in the future. For both calls and puts, the value of the contract increases as the expiration date is pushed further out (e.g., $1.22 for the January 2012 call versus $2.22 for the January 2013). Of course, since these contracts have the same exercise price and underlying stock, the intrinsic value is the same for both. Thus, the difference in the contract prices is purely because of additional time premium.

**Stock Index and Index ETF Options**

As we saw in Chapter 20, options on stock indexes, such as the Standard and Poor’s 500, are patterned closely after equity options. However, they differ in one important way: Index options can only be settled in cash. This is because the underlying index is a hypothetical portfolio. First traded on the CBOE in 1983, index options are popular with investors for the same reason as stock index futures: They provide a relatively inexpensive and convenient way to take an investment or hedge position in a broad-based indicator of market performance. Index puts are particularly useful in portfolio insurance applications, such as the protective put strategy described earlier and again at the end of this chapter.

Prices for a representative sample of S&P 500 (SPX) Index options are listed in Panel A of Exhibit 22.3. They are interpreted the same way as individual equity option prices, with each contract specifying the transfer of 100 "shares" of the underlying index. For example, the June 2011 call is for 100 contracts, each with an exercise price of 140.50 and an expiration date of June 21, 2011. The call is in the money because its strike price of 140.50 is below the current index level of 140.75. The intrinsic value of the call is $2.25, which is the difference between the current index level and the strike price. The time premium is the difference between the call price and the intrinsic value, which is $2.50. The put is out of the money because its strike price of 140.50 is above the current index level of 140.75. The intrinsic value of the put is zero, and the time premium is the difference between the put price and the intrinsic value, which is $3.25.
paid for the contract. Her time premium of $0.40 (= 0.45 – 0.05) preserves her right to buy BAC stock at a price of $14 for the next month, even if the market value of those shares moves higher.  

Consider another investor who sells the April 14 Bank of America put, the details of which are shown in the fourth row on the right side of Panel B of Exhibit 22.1. In return for an upfront receipt of $42 (= 0.42 × 100), he must stand ready to buy 100 shares of stock in mid-April for $1,400 if the put holder chooses to exercise his option to sell. Of course, the stock price will have to fall from its current level before this will occur. The investor in this case has sold an out-of-the-money contract and hopes that it will stay out of the money through expiration. As we saw earlier, the front-end premium is all that sellers of put or call options ever receive, and they hope to retain as much of it possible. Like the long position in the call, the short put position benefits from an increase in BAC share prices.

Notice that most of the options listed in both panels of Exhibit 22.1 expire within a few months of the quotation date. In fact, the expiration dates available for most of these exchange-traded contracts are the two nearest term months (April and May for Bank of America) and up to three additional months from a quarterly cycle beginning in either January, February, or March. In the case of BAC options, April 2011 and May 2011 (which is part of the quarterly cycle beginning in February) are the additional months most frequently listed. For high-volume stocks like BAC, additional expiration months can also be added (June 2011 and July 2011, in this case). Finally, for investors with a very short-term perspective, the CBOE recently created *Weeklys*, which are option contracts that are created on a Thursday morning and expire on Friday afternoon of the following week.

Exhibit 22.2 gives quotations for Long-Term Equity Anticipation Securities (LEAPS), which are simply regular call and put options with longer expiration dates. Like the contracts just described, LEAPS are also traded on the CBOE and have comparable terms. The LEAPS quotes allow us to see the effect that time to expiration has on the value of an option. The highlighted entries in the display show prices for two different calls and two different puts for BAC. Each highlighted contract has an exercise price of 15, but the expiration dates are either 0.83 years (January 2012) or 1.83 years (January 2013) in the future. For both calls and puts, the value of the contract increases as the expiration date is pushed further out (e.g., $1.22 for the January 2012 call versus $2.22 for the January 2013). Of course, since these contracts have the same exercise price and underlying stock, the intrinsic value is the same for both. Thus, the difference in the contract prices is purely because of additional time premium.

**Stock Index and Index ETF Options** As we saw in Chapter 20, options on stock indexes, such as the Standard and Poor’s 500, are patterned closely after equity options. However, they differ in one important way: Index options can only be settled in cash. This is because the underlying index is a hypothetical portfolio. First traded on the CBOE in 1983, index options are popular with investors for the same reason as stock index futures: They provide a relatively inexpensive and convenient way to take an investment or hedge position in a broad-based indicator of market performance. Index puts are particularly useful in portfolio insurance applications, such as the protective put strategy described earlier and again at the end of this chapter.

Prices for a representative sample of S&P 500 (SPX) Index options are listed in Panel A of Exhibit 22.3. They are interpreted the same way as individual equity option prices, with each contract specifying the transfer of 100 “shares” of the underlying index. For example, the June

---

2Recall from Chapter 20 that a call option’s value can be divided into two components: the intrinsic value, which is the greater of either zero or the stock price minus the exercise price, and the time premium. In this example, the BAC call is said to be in the money because it has positive intrinsic value, whereas an option with no intrinsic value is out of the money.

Source: Chicago Board Options Exchange (www.cboe.com), March 22, 2011. Provided as a courtesy by Chicago Board Options Exchange, Inc.
2011 SPX Index call option with an exercise price of 1,300 is out of the money, given that the index level on this day in March 2011 was 1,293.77. This contract could be purchased at the ask price for $4,100 (= 41.00 × 100) and would only be exercised to acquire $130,000 worth of the index if the S&P rises above 1,300 by the expiration date.

Chapter 16 introduced us to exchange-traded funds (ETFs) as an effective way to make an investment in a stock index. Given the popularity of these products, it is not surprising that the derivatives market now offers options based on them as well. Panel B of Exhibit 22.3 lists a price and volume data for SPDR S&P 500 ETF (SPY) options, which are traded on the CBOE. Since the underlying ETF is a security (unlike the index itself), these options are designed like regular stock options and permit physical delivery. For example, the June 2011 SPY Index put option with an exercise price of 132 is in the money, since SPY traded at 129.29. In exchange for an upfront payment of $636 (= 6.36 × 100), the owner of this put contract would find it advantageous to sell $13,200 worth of the index ETF, assuming it remained below 132 at the expiration date.

Foreign Currency Options

In our analysis of currency futures contracts in Chapter 21, we saw that those agreements are generally designed from the viewpoint of a U.S. dollar–based investor who thinks of the foreign (i.e., non-U.S. dollar) currency as the underlying asset in the transaction. Foreign currency options traded on U.S. exchanges are similar in that each contract allows for the sale or purchase of a set amount of foreign currency at a fixed exchange (FX) rate. A currency call option permits, but does not obligate, the contract holder to buy the currency at a later date, while a put allows the holder to sell the foreign currency if she so desires. FX option contracts exist for several major currencies, including the euro, Australian dollars, Japanese yen, Canadian dollars, British pounds, and Swiss francs. Although the majority of currency options trade in OTC markets, exchange-traded versions have also existed since being launched by the PHLX in 1982. Exhibit 22.4 shows the prevailing USD/GBP spot rate as well as quotes for some of the British pound contracts that were available on March 22, 2011.

Consider an investor in New York who holds British pound–denominated government bonds in her portfolio. It is March, and, when the bonds mature in three months, she will need to convert the proceeds back into U.S. dollars. This exposes the investor to the risk that the British currency will weaken (i.e., will be exchangeable for fewer dollars) by June. To hedge this risk, she buys the June put on the British pound with an exercise price of USD 163/GBP, which is expressed in U.S. cents per pound. Thus, her initial cost to acquire a put option allowing her to sell 10,000 pounds is USD 286 (= 0.0286 × 10,000), using the ask price (second entry under the "Puts—Jun11" block) and delivery amount associated with the contract. This option would allow the investor to exchange the GBP 10,000 that will come from the maturing British bond in June for USD 16,300 (= 10,000 × 1.63). She will only exercise the contract if the spot USD/GBP rate prevailing in June weakens to a level less than 1.63, which was her original concern. Finally, because the spot rate at the time the put is acquired in March is USD 1.6367/GBP, this contract is out of the money and the entire purchase price represents a time premium.

Options on Futures Contracts

Although long a staple of OTC markets, options on futures contracts have only been exchange-traded since 1982. Also known as futures options, they give the holder the right, but not the obligation, to enter into a futures contract on an underlying security or commodity at a later date and at a predetermined price. Purchasing a call on a futures contract allows for the acquisition of a long position in the futures market, while exercising a put would create a short futures position. The seller of the call would be obligated to enter into the short side of the futures contract if the option holder decided to exercise the contract, while the seller of the put might be forced into a long futures position. Futures options exist for several major futures contracts, including those for Soybeans, Sugar, Coffee, Cotton, and Light Sweet Crude Oil.
2011 SPX Index call option with an exercise price of $1,300 is out of the money, given that the index level on this day in March 2011 was $1,293.77. This contract could be purchased at the ask price for $4,100 (= $4.10 × 1,000) and would only be exercised to acquire $130,000 worth of the index if the S&P rises above $1,300 by the expiration date.

Chapter 16 introduced us to exchange-traded funds (ETFs) as an effective way to make an investment in a stock index. Given the popularity of these products, it is not surprising that the derivatives market now offers options based on them as well. Panel B of Exhibit 22.3 lists a price and volume data for SPDR S&P 500 ETF (SPY) options, which are traded on the CBOE. Since the underlying ETF is a security (unlike the index itself), these options are designed like regular stock options and permit physical delivery. For example, the June 2011 SPY Index put option with an exercise price of $132 is in the money, since SPY traded at $129.29. In exchange for an upfront payment of $636 (= $6.36 × 100), the owner of this put contract would find it advantageous to sell $13,200 worth of the index ETF, assuming it remained below $132 at the expiration date.

**Foreign Currency Options** In our analysis of currency futures contracts in Chapter 21, we saw that those agreements are generally designed from the viewpoint of a U.S. dollar-based investor who thinks of the foreign (i.e., non-U.S. dollar) currency as the underlying asset in the transaction. Foreign currency options traded on U.S. exchanges are similar in that each contract allows for the sale or purchase of a set amount of foreign currency at a fixed exchange (FX) rate. A currency call option permits, but does not obligate, the contract holder to buy the currency at a later date, while a put allows the holder to sell the foreign currency if she so desires. FX option contracts exist for several major currencies, including the euro, Australian dollars, Japanese yen, Canadian dollars, British pounds, and Swiss francs. Although the majority of currency options trade in OTC markets, exchange-traded versions have also existed since being launched by the PHX in 1982. Exhibit 22.4 shows the prevailing USD/GBP spot rate as well as quotes for some of the British pound contracts that were available on March 22, 2011.

Consider an investor in New York who holds British pound–denominated government bonds in her portfolio. It is March, and, when the bonds mature in three months, she will need to convert the proceeds back into U.S. dollars. This exposes the investor to the risk that the British currency will weaken (i.e., will be exchangeable for fewer dollars) by June. To hedge this risk, she buys the June put on the British pound with an exercise price of USD 163/GBP, which is expressed in U.S. cents per pound. Thus, her initial cost to acquire a put option allowing her to sell 10,000 pounds is USD 286 (= 0.0286 × 10,000), using the ask price (second entry under the “Puts—Jun11” block) and delivery amount associated with the contract. This option would allow the investor to exchange the GBP 10,000 that will come from the maturing British bond in June for USD 16,300 (= 10,000 × 1.63). She will only exercise the contract if the spot USD/GBP rate prevailing in June weakens to a level less than 1.63, which was her original concern. Finally, because the spot rate at the time the put is acquired in March is USD 1.6367/GBP, this contract is out of the money and the entire purchase price represents a time premium.

**Options on Futures Contracts** Although long a staple of OTC markets, options on futures contracts have only been exchange-traded since 1982. Also known as futures options, they give the holder the right, but not the obligation, to enter into a futures contract on an underlying security or commodity at a later date and at a predetermined price. Purchasing a call on a futures contract allows for the acquisition of a long position in the futures market, while exercising a put would create a short futures position. The seller of the call would be obligated to enter into the short side of the futures contract if the option holder decided to exercise the contract, while the seller of the put might be forced into a long futures position. Futures options exist for
a wide variety of underlying assets, including commodities, Treasury bonds, foreign currencies, and stock indexes. Exhibit 22.5 lists prices quotes for a representative set of contracts.

To understand how these contracts work, consider the June 2011 call option on copper with an exercise price of $4.32 (i.e., 432 cents) per pound. This contract would cost the buyer 20.40 cents per pound of copper covered by the futures position. As each copper futures contract on the Commodity Exchange (COMX) specifies 25,000 pounds of the metal, the total purchase price for this futures call is $5,100 (25,000 × 0.2040). Because the June copper futures price on this day in March 2011 settled at $4.3185, this option was out of the money.

As with any call option, the holder will only exercise at the expiration date if the prevailing price of the underlying asset exceeds the exercise price. This arrangement might fit the needs of an electronics manufacturer exposed to higher copper prices or a speculator bullish on copper prices. Suppose that on the expiration date, the contract price of the June futures has risen to $4.40. The holder will exercise her option and assume a long position in the June futures with a contract price of $4.32 per pound. Her new position will immediately be marked to market and $2,000 (4.40 – 4.32) × 25,000 will be added to her margin account. Alternatively, she may decide to unwind her below-market futures contract and take the $2,000 in cash.

Leverage is the primary attraction of this derivative. The call buyer has been able to control 25,000 pounds of copper for two months for an investment of $5,100. Had she purchased the
That is, it always is theoretically possible to use the option as a perfect hedge against fluctuations in the value of the asset on which it is based. This was essentially the same approach we used in Chapter 20 to establish the put-call parity relationships. The primary differences between put-call parity and what follows are twofold. First, the hedge portfolio implied by the put-call parity transaction did not require special adjustment; it simply consisted of one stock long, one put long, and one call short held until the expiration date. However, hedging an underlying asset position’s risk with a single option position—whether it is a put or a call—often involves using multiple contracts and frequent changes in the requisite number to maintain the riskless portfolio. Second, put-call parity did not demand a forecast of the underlying asset’s future price level, whereas the following analysis will. We will see that forecasting the volatility of future asset prices is the most important input the investor must provide in determining option values.

### 22.2.1 The Basic Approach

While the mathematics associated with option valuation can be complex, the fundamental intuition behind the process is straightforward and can be illustrated quite simply. Suppose you have just purchased a share of stock in WYZ Corp. for $50. The stock is not expected to pay a dividend during the time you plan to hold it, and you have forecast that in one year the stock price will either rise to $65 or fall to $40. This can be summarized as follows:

<table>
<thead>
<tr>
<th></th>
<th>Calls</th>
<th>Puts</th>
</tr>
</thead>
<tbody>
<tr>
<td>Today</td>
<td>50</td>
<td></td>
</tr>
<tr>
<td>One Year</td>
<td>65</td>
<td>40</td>
</tr>
</tbody>
</table>

Suppose further that you can either buy or sell a call option on WYZ stock with an exercise price of $52.50. If this is a European-style contract that expires in exactly one year, it will have the following possible expiration date values:

<table>
<thead>
<tr>
<th></th>
<th>Calls</th>
<th>Puts</th>
</tr>
</thead>
<tbody>
<tr>
<td>Today</td>
<td>8.50</td>
<td></td>
</tr>
<tr>
<td>One Year</td>
<td>16.95</td>
<td>7.95</td>
</tr>
</tbody>
</table>

Given your forecast of future WYZ stock prices, you know what the option is worth at expiration. The dilemma is establishing what the contract should sell for today (i.e., \( C_0 \)). This question can be answered in three steps. First, design a hedge portfolio consisting of one share of WYZ stock held long and some number of call options (i.e., \( h \)), so that the combined position will be riskless. The number of call options needed can be established by ensuring that the portfolio has the same value at expiration no matter which of the two forecasted stock values occurs, or:

\[
65 + (h)(12.50) = 40 + (h)(0)
\]

leaving:

\[
h = \frac{65 - 40}{12.50} = -2.00
\]

There are both direction and magnitude dimensions to this number. The negative sign indicates that, in order to create negative correlation between two assets that are naturally positively correlated, call options must be sold to hedge a long stock position. Further, given that copper outright, it would have cost her $107,962.50 (\( = 25,000 \times 4.3185 \)), assuming that spot and futures prices were the same on this date. Further, the cost of the futures call is less than margin required for a direct long position in the June copper futures contract, which was set by the exchange at $6,413 for nonmember customers. Because leverage—and not actually acquiring the futures position—is the driving force behind this market, in most cases the option expires at virtually the same time as the futures contract.

### 22.2 The Fundamentals of Option Valuation

Although options can be used by investors to anticipate future security prices, the key to understanding how they are valued is that they also are risk-reduction tools. An option’s theoretical value depends on combining it with its underlying security to create a synthetic risk-free
portfolio. That is, it always is theoretically possible to use the option as a perfect hedge against fluctuations in the value of the asset on which it is based.

This was essentially the same approach we used in Chapter 20 to establish the put-call parity relationships. The primary differences between put-call parity and what follows are twofold. First, the hedge portfolio implied by the put-call parity transaction did not require special adjustment; it simply consisted of one stock long, one put long, and one call short held until the expiration date. However, hedging an underlying asset position’s risk with a single option position—whether it is a put or a call—often involves using multiple contracts and frequent changes in the requisite number to maintain the riskless portfolio. Second, put-call parity did not demand a forecast of the underlying asset’s future price level, whereas the following analysis will. We will see that forecasting the volatility of future asset prices is the most important input the investor must provide in determining option values.

### 22.2.1 The Basic Approach

While the mathematics associated with option valuation can be complex, the fundamental intuition behind the process is straightforward and can be illustrated quite simply. Suppose you have just purchased a share of stock in WYZ Corp. for $50. The stock is not expected to pay a dividend during the time you plan to hold it, and you have forecast that in one year the stock price will either rise to $65 or fall to $40. This can be summarized as follows:

<table>
<thead>
<tr>
<th>Today</th>
<th>One Year</th>
</tr>
</thead>
<tbody>
<tr>
<td>50</td>
<td>65</td>
</tr>
<tr>
<td></td>
<td>40</td>
</tr>
</tbody>
</table>

Suppose further that you can either buy or sell a call option on WYZ stock with an exercise price of $52.50. If this is a European-style contract that expires in exactly one year, it will have the following possible expiration date values:

<table>
<thead>
<tr>
<th>Today</th>
<th>One Year</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>max[0, 65 − 52.5] = 12.50</td>
</tr>
<tr>
<td>$C_0$</td>
<td>max[0, 40 − 52.5] = 0</td>
</tr>
</tbody>
</table>

Given your forecast of future WYZ stock prices, you know what the option is worth at expiration. The dilemma is establishing what the contract should sell for today (i.e., $C_0$).

This question can be answered in three steps. First, design a hedge portfolio consisting of one share of WYZ stock held long and some number of call options (i.e., $h$), so that the combined position will be riskless. The number of call options needed can be established by ensuring that the portfolio has the same value at expiration no matter which of the two forecasted stock values occurs, or:

\[ 65 + (h)(12.50) = 40 + (h)(0) \]

leaving:

\[ h = \frac{(65 - 40)}{(0 - 12.5)} = -2.00 \]

There are both direction and magnitude dimensions to this number. The negative sign indicates that, in order to create negative correlation between two assets that are naturally positively correlated, call options must be sold to hedge a long stock position. Further, given that
the range of possible expiration date option outcomes (i.e., 12.5 – 0) is only half as large as the range for WYZ stock (i.e., 65 – 40), twice as many options must be sold as there is stock in the hedge portfolio. The value \( h \) is known as the hedge ratio.\(^3\) Thus, the risk-free hedge portfolio can be created by purchasing one share of stock and selling two call options.

The second step assumes capital markets that are free from arbitrage, so that all riskless investments are priced to earn the risk-free rate over the time until expiration. The hedge portfolio costing \([50 − (2)(C_0)]\) today would grow to the certain value of \$40 by the following formula:

\[
[50 − (2.00)(C_0)](1 + RFR)^T = 40
\]

where:

\( RFR \) = the annualized risk-free rate

\( T \) = the time to expiration (i.e., one year)

Two unknown values exist in this formula: \( C_0 \) and \( RFR \). Finding a suitable estimate for \( RFR \) seldom is a problem because the investor can use as a proxy the yield to maturity on a U.S. Treasury security of appropriate length. For example, if the one-year T-bill yield is 8 percent, the formula for \( C_0 \) can be solved as follows:

\[
C_0 = \frac{50 − 40}{2.00} = \frac{10}{2.00} = 6.48
\]

This calculation is the third and final step in establishing the call’s fair market value. That is, \$6.48 represents the fundamental value of a one-year call option on WYZ stock, given both the prevailing market prices for two other securities (i.e., stock and T-bills) and the investor’s forecast of future share values, which becomes the critical element in determining if this present value is a reasonable estimate. Finally, because the call option is currently out of the money, this amount is purely a time premium.

### 22.2.2 Improving Forecast Accuracy

Because it is unrealistic to assume only two possible outcomes for future WYZ share prices, the expiration date forecast of stock prices can be expanded to allow for numerous possibilities. To see the consequences of this expansion in the simplest terms possible, consider a revised forecast that includes only one additional potential price falling between the previous values:

<table>
<thead>
<tr>
<th>Today</th>
<th>One Year</th>
</tr>
</thead>
<tbody>
<tr>
<td>50</td>
<td>65.00</td>
</tr>
<tr>
<td></td>
<td>50.99</td>
</tr>
<tr>
<td></td>
<td>40.00</td>
</tr>
</tbody>
</table>

The three-step riskless hedge approach to calculating \( C_0 \) is still conceptually valid, but it must be modified because it is now impossible to calculate a single hedge ratio that simultaneously accounts for all three Date \( T \) possibilities.

**Creating a Stock Price Tree** The solution to this problem involves dividing the time to expiration into as many subintervals as necessary so that at any point in time the subsequent price can

---

\(^3\)In some valuation models (e.g., Black-Scholes), the hedge ratio is expressed as the option’s potential volatility divided by that of the stock. In this example, that would be \( (0 − 12.5) + (65 − 40) = 0.5 \), meaning that the option is half as volatile in dollar terms as the share of stock. Of course, this alternative calculation is just the reciprocal of the value of \( h = −2.00 \).
only move up or down. In this example, only one additional subinterval is needed. Exhibit 22.6 shows how the WYZ stock price forecast might be embellished. This illustration, which is sometimes called a *stock price tree*, indicates that for the stock price to reach, say, $65 in one year, it must first move up to $57.01 in Subperiod S1 before moving up a second time to its final value. Similarly, the lower extreme of $40 can only be reached by two consecutive “down” price changes. There are two different paths to the terminal outcome in the middle: (1) one “up” followed by one “down,” or (2) a down movement followed by an up movement—both reach $50.99.

Once the investor fills in this price tree, the call option’s value can be solved by working backward on each pair of possible outcomes from the future. If, for instance, an initial up movement left the price of WYZ stock at $57.01, a price change over the remaining subperiod could be characterized as:

<table>
<thead>
<tr>
<th>S1</th>
<th>One Year</th>
</tr>
</thead>
<tbody>
<tr>
<td>57.01</td>
<td>65.00</td>
</tr>
<tr>
<td></td>
<td>50.99</td>
</tr>
</tbody>
</table>

The corresponding change in the value of the call option (i.e., $C_{11}$) can then be shown as:

<table>
<thead>
<tr>
<th>S1</th>
<th>One Year</th>
</tr>
</thead>
<tbody>
<tr>
<td>$C_{11}$</td>
<td>12.50</td>
</tr>
<tr>
<td></td>
<td>0.00</td>
</tr>
</tbody>
</table>

With $X = 52.50$, the call option will be in the money at expiration only if WYZ stock moves up in price again. This suggests a hedge ratio of:

\[
h = \frac{(65.00 - 50.99)}{(0.00 - 12.50)} = -1.12
\]

meaning that the riskless hedge portfolio at this point would contain one share of stock long and 1.12 calls short. The intermediate option value is then found by solving:

\[
[57.01 - (1.12)(C_{11})]/(1.08)^{0.5} = [65 - (1.12)(12.50)] = 50.99
\]

or

\[
C_{11} = \frac{57.01 - 50.99/1.0392}{1.12} = 7.09
\]

Here the factor $1.0392 = (1.08)^{0.5}$ is roughly one-half the annual risk-free rate (plus one) since the original holding period was divided into two six-month subintervals.
Valuing in Other Subintervals Having established the value for \( C_{11} \), the value for the option corresponding to an S1 share price of $44.72 (i.e., \( C_{12} \)) can be established by the same three-step procedure with the stock and option price trees truncated as follows:

<table>
<thead>
<tr>
<th>S1</th>
<th>One Year</th>
</tr>
</thead>
<tbody>

</tr>
</thead>
<tbody>
<tr>
<td>( C_{12} )</td>
<td></td>
</tr>
<tr>
<td>0.00</td>
<td>0.00</td>
</tr>
</tbody>
</table>

In this case, the call option is certain to be out of the money at the expiration date one subinterval hence since even a subsequent increase to $50.99 (i.e., an up move in the second subperiod) would leave the share price below the $52.50 exercise price. Thus, it is clear that \( C_{12} \) must be $0.00. Further, the concept of forming a riskless hedge portfolio under such circumstances is meaningless.

These intermediate calculations have little importance to the investor who only cares about the current value of the option. They are a necessary evil as \( C_0 \) cannot be established before determining \( C_{11} \) and \( C_{12} \). With these values in hand, the relevant part of the stock price tree is:

<table>
<thead>
<tr>
<th>Today</th>
<th>S1</th>
</tr>
</thead>
<tbody>
<tr>
<td>50.00</td>
<td></td>
</tr>
<tr>
<td>57.01</td>
<td>44.72</td>
</tr>
</tbody>
</table>

with the corresponding call option tree being given by:

<table>
<thead>
<tr>
<th>Today</th>
<th>S1</th>
</tr>
</thead>
<tbody>
<tr>
<td>( C_0 )</td>
<td></td>
</tr>
<tr>
<td>7.09</td>
<td>0.00</td>
</tr>
</tbody>
</table>

Once again applying the three-step valuation process, the initial (i.e., Date 0) hedge ratio is:

\[
h = \frac{(57.01 - 44.72)}{(0.00 - 7.09)} = -1.73
\]

so that the riskless hedge portfolio at inception would short 1.73 calls for every share held long. The current option value is then found by solving:

\[
[50.00 - (1.73)(C_0)](1.08)^{0.5} = [44.72 - (1.73)(0.00)] = 44.72
\]

or

\[
C_{11} = \frac{50.00 - 44.72}{1.73} = \$4.02
\]

These initial, intermediate, and terminal option values are summarized in Exhibit 22.7.

Two interesting things resulted from this expansion of possible stock price outcomes. First, the addition of a third potential terminal stock price had the effect of reducing the Date 0 option value from $6.48 to $4.02. Although this reduction was a consequence of choosing a third stock price (i.e., $50.99) that caused the option to be out of the money—selecting a value closer to $65.00 would have increased \( C_0 \)—it does underscore that the option valuation process critically depends on the investor’s stock price forecast. Second, the hedge ratio changes with
Given its exercise price of $52.50, the call option would be certain to be in the money for both expiration date stock values. This suggests a hedge ratio of:

\[
h = \frac{65}{55} - \frac{29}{12} = -1.00
\]

so that the riskless hedge portfolio at this point would contain one share of stock long and one call short.\[C_{21}\] can then be found by solving:

\[
[59.56 - (1.00)(C_{21})](1.08)^{0.33} = [65 - (1.00)(12.50)] = 52.50
\]

or

\[
C_{21} = 59.56 - 52.50 = 1.06
\]

The discount factor of \(1.026 = (1.08)^{0.33}\) is now based on roughly one-third of the annual risk-free rate since the one-year option expiration period was adjusted to accommodate three subintervals. Solving for the remaining values leaves the option value tree shown in Exhibit 22.9. Once again, the net effect of these particular forecast improvements has been to change the current value of the derivative to $3.60.

---

**Exhibit 22.7 Tree of Calculated Option Values (Three Terminal Outcomes)**

<table>
<thead>
<tr>

<th>One Year</th>
</tr>
</thead>
<tbody>
<tr>
<td>4.02</td>
<td>7.09</td>
<td>12.50</td>
</tr>
</tbody>
</table>

stock price changes prior to the expiration date. That is, the composition of the riskless hedge portfolio must be rebalanced after each share price movement. From the initial position of being short 1.73 calls against one share held long, an upward movement in WYZ stock from $50.00 to $57.01 would require buying back 0.61 \((= 1.73 - 1.12)\) options. Thus, replicating a risk-free position with stock and call options is a *dynamic* process.

**Expanding the Stock Price Tree** This valuation process can become even more precise as more terminal share price outcomes are included in the forecast. As this happens, the number of pairwise calculations and the number of necessary subperiods will also increase. Consequently, there is a trade-off between realism and the volume of required calculations. To see how even seemingly minor expansions of the stock price forecast can dramatically increase the computational burden, consider the implications of including four potential expiration date stock prices:

<table>
<thead>
<tr>
<th>Today</th>
<th>One Year</th>
</tr>
</thead>
<tbody>
<tr>
<td>65.00</td>
<td>55.29</td>
</tr>
<tr>
<td>50</td>
<td>47.03</td>
</tr>
<tr>
<td>40.00</td>
<td>0.00</td>
</tr>
</tbody>
</table>

Valuing the option in this case will require the creation of two subintervals (S1 and S2) and five intermediate stock price forecasts. These are illustrated in Exhibit 22.8.

To compute \(C_0\), the investor must now work recursively backward through calculations for the five intermediate option values: \(C_{22}, C_{23}\) and \(C_{23}\) in Subperiod S2 and \(C_{11}\) and \(C_{12}\) in Subperiod 1. Each of these calculations applies the same three-step riskless hedge process outlined earlier, appropriately modified for the new length of a subperiod (i.e., one-third of a year instead of six months). If, for instance, two consecutive up movements took the price of WYZ stock from $50.00 to $54.57 to $59.56, a price change over the remaining subperiod could be characterized as:

<table>
<thead>
<tr>
<th>S2</th>
<th>One Year</th>
</tr>
</thead>
<tbody>
<tr>
<td>59.56</td>
<td>65.00</td>
</tr>
<tr>
<td>59.56</td>
<td>55.29</td>
</tr>
</tbody>
</table>

The change in the value of the call option from this uppermost state of Subinterval S2 (i.e., \(C_{22}\)) can then be shown as:

<table>
<thead>
<tr>

</table>
22.2.3 The Binomial Option Pricing Model

A crucial element of this approach to option valuation is that future changes in the underlying asset’s price always can be simplified to one of two possibilities: an up movement or a down movement. As shown by Rendleman and Bartter (1979) and Cox, Ross, and Rubinstein (1979), this analytical development is part of a more general valuation methodology known as the two-state option pricing model. The preceding examples required the investor to specify cash amounts for each of the future potential stock prices in all the subperiods demanded by the forecast, a daunting task as the number of terminal outcomes is allowed to grow larger with the time to expiration of the contract.

Forecasting Price Changes

To simplify this process, suppose an investor focuses her estimates on how stock prices change between subperiods, rather than on the dollar levels. Beginning with today’s known stock price, for the next subperiod she forecasts: (1) one plus the percentage change for an up ($u$) movement, and (2) one plus the percentage change for a down ($d$) movement. Further, to limit the number of required forecasts, suppose she also assumes that the same values for $u$ and $d$ apply to every up and down price change in all subsequent subperiods. With these assumptions, the investor need only forecast three things: $u$, $d$, and $N$ — the total number of subperiods.

Exhibit 22.10 shows the effect that these modifications — which represent the essence of the binomial option pricing model — have on the forecasted stock price and option value trees.

Given its exercise price of $52.50, the call option would be certain to be in the money for both expiration date stock values. This suggests a hedge ratio of:

$$h = \frac{65.00 - 55.29}{2.79 - 12.50} = -1.00$$

so that the riskless hedge portfolio at this point would contain one share of stock long and one call short. $C_{21}$ can then be found by solving:

$$[59.56 - (1.00)(C_{21})](1.08)^{0.33} = [65 - (1.00)(12.50)] = 52.50$$

or

$$C_{21} = \frac{59.56 - 52.50/1.026}{1.00} = 8.39$$

The discount factor of 1.026 ($= (1.08)^{0.33}$) is now based on roughly one-third of the annual risk-free rate since the one-year option expiration period was adjusted to accommodate three subintervals. Solving for the remaining values leaves the option value tree shown in Exhibit 22.9. Once again, the net effect of these particular forecast improvements has been to change the current value of the derivative to $3.60.
22.2.3 The Binomial Option Pricing Model

A crucial element of this approach to option valuation is that future changes in the underlying asset’s price always can be simplified to one of two possibilities: an up movement or a down movement. As shown by Rendleman and Barter (1979) and Cox, Ross, and Rubinstein (1979), this analytical development is part of a more general valuation methodology known as the two-state option pricing model. The preceding examples required the investor to specify cash amounts for each of the future potential stock prices in all the subperiods demanded by the forecast, a daunting task as the number of terminal outcomes is allowed to grow larger with the time to expiration of the contract.

Forecasting Price Changes To simplify this process, suppose an investor focuses her estimates on how stock prices change between subperiods, rather than on the dollar levels. Beginning with today’s known stock price, for the next subperiod she forecasts: (1) one plus the percentage change for an up (u) movement, and (2) one plus the percentage change for a down (d) movement. Further, to limit the number of required forecasts, suppose she also assumes that the same values for u and d apply to every up and down price change in all subsequent subperiods. With these assumptions, the investor need only forecast three things: u, d, and N—the total number of subperiods.

Exhibit 22.10 shows the effect that these modifications—which represent the essence of the binomial option pricing model—have on the forecasted stock price and option value trees. Consistent with the four-outcome version of the preceding example, this illustration allows

</table>
forecasts are 1.026 \[= (1.08)^0.33\] and 0.599 \[= (1.026 - 0.92832) ÷ (1.09139 - 0.92832)\]. By Equation 22.3, which ignores the two terminal option outcomes that are equal to zero, the value of a one-year European-style call option with an exercise price of $52.50 is:

\[C_0 = \left( \frac{3}{0.599} \right)^2 \left( 0.401 \right)^2 \left( 12.50 \right) + \left( 1 \right)^2 (0.599)^3 \left( 12.50 \right) = 3.60\]

This is the same value the three-step approach produced in the previous example because the forecasted stock price tree in Exhibit 22.8 was generated with these same values of \(u\) and \(d\) (e.g., \((uu)S = (1.09139)^2(50) = 59.56\)). Thus, the tree of forecasted option values illustrated in Exhibit 22.9 may be replicated through repeatedly calculating the "State \(j\)" equation. With this notation, the hedge ratio for any state \(j\) becomes:

\[h_j = \frac{u - d}{S_j (C_{jd} - C_{ju})}\]

So, a share of stock held long could be hedged initially by shorting 1.78 call options \[= (1.09139 - 0.92832)(50) ÷ (0.95 - 5.53)\], a position that would be rebalanced to 1.32 calls after one subperiod if the first price change was positive.

22.2.4 The Black-Scholes Valuation Model

The binomial model is a discrete method for valuing options because it allows security price changes to occur in distinct upward or downward movements. Prices can also be assumed to change continuously over time. This was the approach taken by Black and Scholes (1973) in developing their method for valuing European-style options. This is not a more realistic assumption because it presumes that security prices change when markets are closed (e.g., at night or on weekends). The advantage of the Black-Scholes approach—identical in spirit to the basic three-step, riskless hedge method outlined earlier—is that it leads to a relatively simple, closed-form equation capable of valuing options accurately under a wide array of circumstances.

The Black-Scholes model assumes that stock price movements can be described by a statistical process known as geometric Brownian motion. This process is summarized by a volatility factor, \(\sigma\), which is analogous to the investor’s stock price forecasts in the previous models. Formally, the stock price process assumed by Black and Scholes is:

\[\Delta S = \mu \Delta T + \sigma \varepsilon \sqrt{\Delta T}\]

so that a stock’s return \((\Delta S / S)\) from the present through any future Period \(T\) has both an expected component \((\mu \Delta T)\) and a "noise" component \((\sigma \varepsilon \sqrt{\Delta T})\), where \(\mu\) is the mean return and \(\varepsilon\) is the standard normally distributed random error term. Assuming the continuously compounded risk-free rate and the stock’s variance (i.e., \((\sigma^2)\)) remain constant until the expiration date \(T\), Black and Scholes used the riskless hedge intuition to derive the following formula for valuing a call option on a nondividend-paying stock:

\[C_0 = \text{SN}(d_1) - X \left( e^{-\left(\frac{RFR^T}{100}\right)} \right) \text{SN}(d_2)\]

where:

\[d_1 = \left[ \ln \left( \frac{S}{X} \right) + \left( \frac{RFR}{2} + \frac{\sigma^2}{2} \right) \right] \div \left(\sigma \sqrt{T}\right)\]

For example, \(C_{uu} = \left[ (0.599)(12.50) + (0.401)(2.79) \right] ÷ (1.026) = 8.39\).

For a detailed analysis of the mathematics underlying the Black-Scholes model, see Hull (2009).
forecasts are 1.026 \[= (1.08)^{0.33}\] and 0.599 \[= (1.026 - 0.92832) \div (1.09139 - 0.92832)\]. By Equation 22.3, which ignores the two terminal option outcomes that are equal to zero, the value of a one-year European-style call option with an exercise price of $52.50 is:

\[
C_0 = \left(\frac{3(0.599)^2(0.401)(2.79) + (1)(0.599)^3(12.50)}{(1.026)^3}\right) = \$3.60
\]

This is the same value the three-step approach produced in the previous example because the forecasted stock price tree in Exhibit 22.8 was generated with these same values of \(u\) and \(d\) (e.g., \((uu)S = (1.09139)^2(50) = $59.56\)). Thus, the tree of forecasted option values illustrated in Exhibit 22.9 may be replicated through repeatedly calculating the "State j" equation.\(^4\) With this notation, the hedge ratio for any state \(j\) becomes:

\[
h_j = \frac{(u - d)S_j}{C_{u} - C_{d}}
\]

So, a share of stock held long could be hedged initially by shorting 1.78 call options \[= (1.09139 - 0.92832)(50) \div (0.95 - 5.53)\], a position that would be rebalanced to 1.32 calls after one subperiod if the first price change was positive.

### 22.2.4 The Black-Scholes Valuation Model

The binomial model is a \textit{discrete} method for valuing options because it allows security price changes to occur in distinct upward or downward movements. Prices can also be assumed to change \textit{continuously} over time. This was the approach taken by Black and Scholes (1973) in developing their method for valuing European-style options. This is not a more realistic assumption because it presumes that security prices change when markets are closed (e.g., at night or on weekends). The advantage of the Black-Scholes approach—identical in spirit to the basic three-step, riskless hedge method outlined earlier—is that it leads to a relatively simple, closed-form equation capable of valuing options accurately under a wide array of circumstances.

The Black-Scholes model assumes that stock price movements can be described by a statistical process known as \textit{geometric Brownian motion}. This process is summarized by a volatility factor, \(\sigma\), which is analogous to the investor’s stock price forecasts in the previous models. Formally, the stock price process assumed by Black and Scholes is:

\[
\frac{\Delta S}{S} = \mu[\Delta T] + \sigma \varepsilon[\Delta T]^{1/2}
\]

so that a stock’s return (\(\Delta S/S\)) from the present through any future Period \(T\) has both an expected component (\(\mu[\Delta T]\)) and a “noise” component (\(\sigma \varepsilon[\Delta T]^{1/2}\)), where \(\mu\) is the mean return and \(\varepsilon\) is the standard normally distributed random error term.\(^5\)

Assuming the continuously compounded risk-free rate and the stock’s variance (i.e., \((\sigma^2)\)) remain constant until the expiration date \(T\), Black and Scholes used the riskless hedge intuition to derive the following formula for valuing a call option on a nondividend-paying stock:

\[
C_0 = SN(d_1) - Xe^{-RFRT}N(d_2)
\]

where \(e^{-RFRT}\) is the discount function for continuously compounded variables,

\[
d_1 = \left[\ln(S/X) + (RFR + 0.5\sigma^2)[T]\right] + (\sigma[T]^{1/2})
\]

\(^4\)For example, \(C_{uw} = [(0.599)(12.50) + (0.401)(2.79)] \div (1.026) = \$8.39.\)

\(^5\)For a detailed analysis of the mathematics underlying the Black-Scholes model, see Hull (2009).
and

\[ d_2 = d_1 - \sigma \sqrt{T} \]

with \( \ln() \) being the natural logarithm function. The variable \( N(d) \) represents the cumulative probability of observing a value drawn from the standard normal distribution (i.e., one with a mean of zero and a standard deviation of one) equal to or less than \( d \). As the standard normal distribution is symmetric around zero, a value of \( d = 0 \) would lead to \( N(d) = 0.5000 \); positive values of \( d \) would then have cumulative probabilities greater than 50 percent, with negative values of \( d \) leading to cumulative probabilities of less than one-half.

Values for \( N(d) \) can be established in two ways. First, an investor can use a table of calculated values for the standard normal distribution, as in Appendix D at the end of the book. For example, if the value of \( d_1 \) is 0.65, \( N(d_1) \) could be established by finding the entry corresponding to the 0.6 row and the 0.05 column, or 0.7422. This means that 74.22 percent of the observations in the standard normal distribution have a value of 0.65 or less. If \( d_1 \) had been \(-0.65 \), the value of \( N(-d_1) = 1 - N(d_1) = 1 - 0.7422 = 0.2578 \), which must be the case since the distribution is symmetric.

A second approach to calculating cumulative normal probabilities is approximating them with the following formula shown by Carr (1988):

\[
N(d) = \begin{cases} 
0.5e^{-(d^2)/2 - 281/(83 - 351/d)} & \text{if } d < 0 \\
1 - 0.5e^{-(d^2)/2 - 281/(83 + 351/d)} & \text{if } d \geq 0
\end{cases}
\]

For example, with \( d = 0.65 \), we have an approximate probability of:

\[
N(0.65) = 1 - 0.5e^{-(0.65^2)/2 - 281/(83 + 351/0.65)} = 0.7422
\]

**Properties of the Model** The Black-Scholes valuation model reveals that the option’s value is a function of five variables:

1. Current security price
2. Exercise price
3. Time to expiration
4. Risk-free rate
5. Security price volatility

so that \( C = f(S, X, T, RFR, \sigma) \). The first and fourth factors are observable market prices, and the second and third variables are defined by the contract itself. Thus, the only variable an investor must provide is the volatility factor, which embeds the investor’s forecast of future stock prices.

The value of the call option will rise with increases in each of the five factors except the exercise price. Exhibit 22.11 summarizes these relationships. The middle column of the exhibit shows what will happen to the value of the call when one of the five factors increases. The

22.2.5 Estimating Volatility

Just as the growth rate of dividends (i.e., $g$) was a crucial element in establishing the fundamental value of common stock using the dividend discount model, option valuation depends critically on an accurate forecast of the underlying asset’s future price level. In the Black-Scholes framework, this means selecting the proper $\sigma$, which is equivalent to the standard deviation of returns to the underlying asset. This value can be estimated in two ways. First, it can be calculated in the traditional manner using historical returns. Specifically, calculate the Day $t$ price relative as $R_t = \ln(P_t / P_{t-1})$. If a series of price relatives are calculated for a sequence of $N$ days in the recent past, the mean and standard deviation of this series can be established as:

$$\frac{1}{N} \sum_{t=1}^{N} R_t$$

and

$$\sigma^2 = \frac{1}{N-1} \sum_{t=1}^{N} (R_t - \bar{R})^2$$

The factor $\sigma$ is expressed in terms of daily price movements. To annualize this value, $\sigma$ can be multiplied by the square root of the number of trading days in the year (usually assumed to be 250). The advantage of historical volatility is that it is easy to compute and requires no prior assumption about stock market efficiency; its disadvantage is its presumption that stock price behavior in the future will continue as it has in the past, a sometimes dubious assumption.

Another useful facet of the Black-Scholes model is that the hedge ratio at any moment is simply $N(d_1)$, the partial derivative of the call’s value with respect to the stock price (i.e., $\partial C / \partial S$). $N(d_1)$ is the change in the option’s value given a one dollar change in the underlying security’s price. For this reason, $N(d_1)$ often is called the option’s delta, and it indicates the number of stock shares that can be hedged by a single call—the exact reciprocal of the previous interpretation of the hedge ratio, $h$. Finally, the Black-Scholes model is actually an extension of the binomial model. As the number of subperiods (i.e., $N$) approaches infinity, the up or down price movements begin to occur on a continuous basis. If the values of $u$ and $d$ are then set equal to $e^{\mu \Delta T^{1/2}}$ and $e^{-\sigma \Delta T^{1/2}}$, respectively, the binomial model collapses to become the Black-Scholes formula.

**An Example** Consider the following values for the five input variables: $S = 40$, $X = 40$, $T = 1$ year, $RFR = 9$ percent, and $\sigma = 0.30$. To calculate the Black-Scholes value of a European-style call option under these conditions, first calculate:

$$d_1 = (\ln(40/40) + (0.09 + 0.5(0.3)^2)[1]) / (0.3[1]^{1/2}) = 0.45$$

and

$$d_2 = 0.45 - 0.3[1]^{1/2} = 0.15$$

so that:

$$N(d_1) = 1 - 0.5e^{-(0.45^2)/2} - 281/(83 + 351/0.45) = 0.6736$$

and

$$N(d_2) = 1 - 0.5e^{-(0.15^2)/2} - 281/(83 + 351/0.15) = 0.5596$$

Thus:

$$C_0 = (40)(0.6736) - 40(e^{-0.09})(0.5596) = 6.49$$

$N(d_1)$ says that the call option will change in value by about 67 cents for every dollar of a change in the underlying asset, which suggests a hedge ratio of one-and-a-half calls short for every stock share held long. Exhibit 22.12 shows how both the option’s value and $N(d_1)$ change as the security’s value changes—with the other factors held constant. Notably, the hedge ratios range in value from 0 to 1, and increase as stock prices increase. Therefore, the deeper in the money the option is, the closer its price movements will come to duplicating those of the stock itself. The relationship between stock prices and call option prices for this example is shown in Exhibit 22.13. The delta, or hedge ratio, associated with a given stock price is simply the slope of a line tangent to the call option price curve.

---

*In more technical terms, these relationships can be summarized as $\delta C/\delta S > 0$, $\delta C/\delta RFR > 0$, $\delta C/\delta T > 0$, $\delta C/\delta \sigma > 0$, and $\delta C/\delta X < 0$.\*
Exhibit 22.14 lists annualized 30-day historical volatilities for a representative sample of optionable stocks during May 2007 and December 2010.

An alternative to relying on historical price movements is a second volatility estimation approach that involves the Black-Scholes equation. Recall that if we know all five input factors — \( S, X, T, RFR, \) and \( \sigma \) — we can solve for the value of the call option. However, if we know the current price of the option (call it \( C^* \)) and the four other variables, we can calculate the level of \( \sigma \) that forces the Black-Scholes value to equal \( C^* \). That is, the volatility implied by current market prices is established by finding \( \sigma^* \) such that \( C^* = f(S, X, T, RFR, \sigma^*) \); the value \( \sigma^* \) is known as the implied volatility. No simple closed-form solution exists for performing this calculation; it must be done using a search routine.

Implied volatility is advantageous because it calculates the same volatility forecast investors use to set option prices. The disadvantage of implied volatility is its presumption that markets are efficient in that the option price set in the market corresponds directly to that generated by the Black-Scholes equation. Beckers (1981) has shown that implied volatilities do a better job than historical volatilities of predicting future stock price movements; however, Figlewski (1989b) and Shiu, Pan, Lin, and Wu (2010) caution that \( \sigma^* \) can be "noisy" because it picks up not only the true level of volatility but also any misestimate inherent in the valuation or trading process.

Brown, Harlow, and Tinic (1989) estimated the volatilities implied by the S&P 500 Index call option contract for the 121-day period surrounding the stock market crash on October 19, 1987. These calculations are reproduced in Exhibit 22.15. The time variable is denominated relative to "Black Monday" (i.e., Day 0). To see how much market risk changed with the crash, the average implied volatility measure for the period Day \( -60 \) to Day \( -5 \) (i.e., the period beginning approximately two and a half months before the crash) was 18.9 percent. The comparable statistic for the period from Day +5 to Day +60 was 43.3 percent. Moreover, on Black Monday itself, the implied volatility rose to 145 percent, more than seven and a half times its precrash level!

**22.2.5 Estimating Volatility**

Just as the growth rate of dividends (i.e., \( g \)) was a crucial element in establishing the fundamental value of common stock using the dividend discount model, option valuation depends critically on an accurate forecast of the underlying asset’s future price level. In the Black-Scholes framework, this means selecting the proper \( \sigma \), which is equivalent to the standard deviation of returns to the underlying asset. This value can be estimated in two ways. First, it can be calculated in the traditional manner using historical returns. Specifically, calculate the Day \( t \) price relative as \( R_t = \ln(P_t/P_{t-1}) \). If a series of price relatives are calculated for a sequence of \( N \) days in the recent past, the mean and standard deviation of this series can be established as:

\[
\overline{R} = \left( \frac{1}{N} \right) \sum_{i=1}^{N} R_i \quad \text{and} \quad \sigma^2 = \left( \frac{1}{N-1} \right) \sum_{i=1}^{N} (R_i - \overline{R})^2
\]

The factor \( \sigma \) is expressed in terms of daily price movements. To annualize this value, \( \sigma \) can be multiplied by the square root of the number of trading days in the year (usually assumed to be 250). The advantage of historical volatility is that it is easy to compute and requires no prior assumption about stock market efficiency; its disadvantage is its presumption that stock price behavior in the future will continue as it has in the past, a sometimes dubious assumption.
The concept of implied volatility is also the foundation of a popular measure of stock market sentiment. Introduced by Whaley (1993), the Volatility Index (VIX) is calculated as a weighted average of the implied volatility estimates from options on the Standard & Poor’s 500 Index using a wide range of exercise prices. VIX purports to measure investor expectations of near-term (i.e., 30-day) volatility in the stock market, with higher levels of the index indicating greater investor wariness about future economic conditions. In a typical year, the VIX can range between 10.00 and 45.00 percent. Futures and option contracts using the VIX as the underlying asset have traded on the CBOE since 2004 and 2006, respectively, and a S&P 500 VIX ETF began trading in 2010.

22.2.6 Problems with Black-Scholes Valuation

The Black-Scholes option valuation model is popular with investors for at least two reasons: It is computationally convenient, and it produces reasonable values under a wide variety of conditions. There are, however, circumstances in which the model is less than desirable. In an empirical test of the Black-Scholes equation, MacBeth and Merville (1979) showed that implied volatilities tended to be overly large when the associated call options were in the money and too small for out-of-the-money contracts. Given the assumption that at-the-money options are priced fairly by the market, this suggested that in-the-money options were priced higher by investors than their Black-Scholes values, with the opposite being true for the out-of-the-money contracts. Thus, for the authors’ sample of stocks, the Black-Scholes model overvalued out-of-the-money call options and undervalued in-the-money contracts. Interestingly, in two different studies, Rubinstein (1985b, 1994) found evidence that both supported and contradicted these results.

In general, any violation of the assumptions upon which the Black-Scholes model is based could lead to a misvaluation of the option contract. For instance, because stock prices do not change continuously, less actively traded stocks might have options that are priced differently in the market than those stocks that trade frequently. Figlewski (1989a) noted how market imperfections (brokerage fees, bid-ask spreads, and inflexible position sizes) can create arbitrageable differences between option values and prices. He cautioned that Black-Scholes values should be viewed as approximations, best suited for comparing prices of different contracts. Black (1989a) has observed that other conditions of the model are almost certain to be violated in practice, such as the assumption that the risk-free rate and volatility level remain constant until the expiration date. Cornell (2010) notes that misestimations of future stock price dynamics due to inappropriate historical volatilities can lead to option misvaluations.

Exhibit 22.14 lists annualized 30-day historical volatilities for a representative sample of optionable stocks during May 2007 and December 2010.

An alternative to relying on historical price movements is a second volatility estimation approach that involves the Black-Scholes equation. Recall that if we know all five input factors—$S$, $X$, $T$, $RFR$, and $\sigma$—we can solve for the value of the call option. However, if we know the current price of the option (call it $C^*$) and the four other variables, we can calculate the level of $\sigma$ that forces the Black-Scholes value to equal $C^*$. That is, the volatility implied by current market prices is established by finding $\sigma^*$ such that $C^* = f(S, X, T, RFR, \sigma^*)$; the value $\sigma^*$ is known as the implied volatility. No simple closed-form solution exists for performing this calculation; it must be done using a search routine.

Implied volatility is advantageous because it calculates the same volatility forecast investors use to set option prices. The disadvantage of implied volatility is its presumption that markets are efficient in that the option price set in the market corresponds directly to that generated by the Black-Scholes equation. Beckers (1981) has shown that implied volatilities do a better job than historical volatilities of predicting future stock price movements; however, Figlewski (1989b) and Shiu, Pan, Lin, and Wu (2010) caution that $\sigma^*$ can be “noisy” because it picks up not only the true level of volatility but also any misestimate inherent in the valuation or trading process.

Brown, Harlow, and Tinic (1989) estimated the volatilities implied by the S&P 500 Index call option contract for the 121-day period surrounding the stock market crash on October 19, 1987. The preceding discussion has concentrated on the valuation of European-style call options having a nondividend-paying stock as the underlying asset. Many other conditions and underlying assets exist for which options need to be valued. This section explores several extensions of the basic approach.

### 22.3.1 Valuing European-Style Put Options

The put-call-spot parity model of Chapter 20 held that, in an efficient market, the value of a European-style put on a nondividend-paying security should be equivalent to a portfolio short in the security while long in both a call option and a Treasury bill having a face value equal to the common exercise price $X$. With continuous discounting for the T-bill, this relationship can be expressed:

$$P_0 = C_0 + X(e^{-RFT_T}) - S$$

so, if we know the prices of the security, the call option, and the T-bill, we can solve for the value of the put option. Inserting the Black-Scholes value for $C_0$ into this expression, we have:

$$P_0 = \left[SN(d_1) - X(e^{-RFT_T})N(d_2)\right] + X(e^{-RFT_T}) - S$$

which can be manipulated to equal:

$$P_0 = X(e^{-RFT_T})N(-d_2) - SN(-d_1)$$

where all the notation is the same as before. Equation 22.5 is the Black-Scholes put option valuation model.

The comparative statics of put option valuation were shown in the final column of Exhibit 22.11. The value of the put will increase with higher levels of $X$ but decline with an increase in $S$ because of the effect these movements have on the contract’s intrinsic value. Like the call option, the put’s value benefits from an increase in $\sigma$ since this increases the likelihood that the contract will finish in the money. Also, an increase in the risk-free rate reduces the present value of $X$, which hurts the holder of the put who receives the exercise price if the contract is executed. Finally, the sign of $\delta P / \delta T$ could be either positive or negative, depending on the trade-off between the longer time over which the security price could move in the desired direction and the reduced present value of the exercise price received by the seller at expiration.

In the preceding valuation example, we had the following inputs: $S = 40$, $X = 40$, $T = \text{one year}$, $RFR = 9$ percent, and $\sigma = 0.30$. With these assumptions, $d_1$ and $d_2$ still are 0.45 and 0.15, respectively, but now we need to compute $N(-0.45) = 1 - 0.6736 = 0.3264$ and $N(-0.15) = 1 - 0.5596 = 0.4404$. Thus:

$$P_0 = 40(e^{-0.09})(0.4404) - 40(0.3264) = $3.04$$

Finally, the hedge ratio for the put option in this model is $N(d_1) - 1$, which in this case is $-0.3264$ and indicates that the put option’s value will decrease by approximately 33 cents for every dollar increase in $S$.

### 22.3.2 Valuing Options on Dividend-Bearing Securities

We learned earlier that the put-call parity relationship required an adjustment when the underlying asset common to the put and call options paid a dividend. This adjustment is needed because the payment of the dividend reduces the asset’s market value. Other than the tax implications, the underlying asset’s owner should not lose any overall net worth with the payment of the dividend. However, the prospective call option owner will not receive the

**Exhibit 22.15 Implied Volatilities and the Stock Market Crash of 1987**

The concept of implied volatility is also the foundation of a popular measure of stock market sentiment. Introduced by Whaley (1993), the Volatility Index (VIX) is calculated as a weighted average of the implied volatility estimates from options on the Standard & Poor’s 500 Index using a wide range of exercise prices. VIX purports to measure investor expectations of near-term (i.e., 30-day) volatility in the stock market, with higher levels of the index indicating greater investor wariness about future economic conditions. In a typical year, the VIX can range between 10.00 and 45.00 percent. Futures and option contracts using the VIX as the underlying asset have traded on the CBOE since 2004 and 2006, respectively, and a S&P 500 VIX ETF began trading in 2010.

### 22.2.6 Problems with Black-Scholes Valuation

The Black-Scholes option valuation model is popular with investors for at least two reasons: It is computationally convenient, and it produces reasonable values under a wide variety of conditions. There are, however, circumstances in which the model is less than desirable. In an empirical test of the Black-Scholes equation, MacBeth and Merville (1979) showed that implied volatilities tended to be overly large when the associated call options were in the money and too small for out-of-the-money contracts. Given the assumption that at-the-money options are priced fairly by the market, this suggested that in-the-money options were priced higher by investors than their Black-Scholes values, with the opposite being true for the out-of-the-money contracts. Thus, for the authors’ sample of stocks, the Black-Scholes model overvalued out-of-the-money call options and undervalued in-the-money contracts. Interestingly, in two different studies, Rubinstein (1985b, 1994) found evidence that both supported and contradicted these results.

In general, any violation of the assumptions upon which the Black-Scholes model is based could lead to a misvaluation of the option contract. For instance, because stock prices do not change continuously, less actively traded stocks might have options that are priced differently in the market than those stocks that trade frequently. Figlewski (1989a) noted how market imperfections (brokerage fees, bid-ask spreads, and inflexible position sizes) can create arbitrageable differences between option values and prices. He cautioned that Black-Scholes values should be viewed as approximations, best suited for comparing prices of different contracts. Black (1989a) has observed that other conditions of the model are almost certain to be violated in practice, such as the assumption that the risk-free rate and volatility level remain constant until the expiration date. Cornell (2010) notes that misestimations of future stock price dynamics due to inappropriate historical volatilities can lead to option misvaluations.
22.3 Option Valuation: Extensions and Advanced Topics
The preceding discussion has concentrated on the valuation of European-style call options having a nondondividend-paying stock as the underlying asset. Many other conditions and underlying assets exist for which options need to be valued. This section explores several extensions of the basic approach.

22.3.1 Valuing European-Style Put Options
The put-call-spot parity model of Chapter 20 held that, in an efficient market, the value of a European-style put on a nondondividend-paying security should be equivalent to a portfolio short in the security while long in both a call option and a Treasury bill having a face value equal to the common exercise price X. With continuous discounting for the T-bill, this relationship can be expressed:

\[ P_0 = C_0 + X(e^{-(RFR)T}) - S \]

so, if we know the prices of the security, the call option, and the T-bill, we can solve for the value of the put option. Inserting the Black-Scholes value for C into this expression, we have:

\[ P_0 = [SN(d_1) - X(e^{-(RFR)T})N(d_2)] + X(e^{-(RFR)T}) - S \]

which can be manipulated to equal:

\[ P_0 = X(e^{-(RFR)T})N(-d_2) - SN(-d_1) \]

where all the notation is the same as before. Equation 22.5 is the Black-Scholes put option valuation model.

The comparative statics of put option valuation were shown in the final column of Exhibit 22.11. The value of the put will increase with higher levels of X but decline with an increase in S because of the effect these movements have on the contract’s intrinsic value. Like the call option, the put’s value benefits from an increase in \( \sigma \) since this increases the likelihood that the contract will finish in the money. Also, an increase in the risk-free rate reduces the present value of \( X \), which hurts the holder of the put who receives the exercise price if the contract is executed. Finally, the sign of \( \delta P/\delta T \) could be either positive or negative, depending on the trade-off between the longer time over which the security price could move in the desired direction and the reduced present value of the exercise price received by the seller at expiration.

In the preceding valuation example, we had the following inputs: \( S = 40 \), \( X = 40 \), \( T = \) one year, \( RFR = 9 \) percent, and \( \sigma = 0.30 \). With these assumptions, \( d_1 \) and \( d_2 \) still are 0.45 and 0.15, respectively, but now we need to compute \( N(-0.45) = 1 - 0.6736 = 0.3264 \) and \( N(-0.15) = 1 - 0.5596 = 0.4404 \). Thus:

\[ P_0 = 40(e^{-0.09})(0.4404) - 40(0.3264) = 3.04 \]

Finally, the hedge ratio for the put option in this model is \( [N(d_1) - 1] \), which in this case is -0.3264 and indicates that the put option’s value will decrease by approximately 33 cents for every dollar increase in \( S \).

22.3.2 Valuing Options on Dividend-Bearing Securities
We learned earlier that the put-call parity relationship required an adjustment when the underlying asset common to the put and call options paid a dividend. This adjustment is needed because the payment of the dividend reduces the asset’s market value. Other than the tax implications, the underlying asset’s owner should not lose any overall net worth with the payment of the dividend. However, the prospective call option owner will not receive the
However, modifying the model’s structure is often much more convenient than adjusting the stock input level for a specific payment structure.

22.3.3 Valuing American-Style Options

The preceding discussion considered European-style options. If the contract had been American style—that is, its exercise is not limited to the expiration date—how would the valuation process change? The possibility of early exercise makes the derivation of an exact closed-form analog to the Black-Scholes equation an elusive goal. Instead, Roll (1977b), Geske (1979), and Whaley (1981) have designed elaborate approximation procedures for estimating the value of American-style calls. Further, Johnson (1983) and Barone-Adesi and Whaley (1986), among others, have taken different approaches to address the issue of American put valuation.

We can consider several fundamental properties of these models. Most important is that an American put or call has to be at least as valuable as its European-style counterpart because, by definition, the American option gives the holder more choices than the simpler contract. The American contract holder can exercise at the same time as the European option owner (i.e., at expiration) as well as any point prior to that terminal date. Since we have seen that an option’s value ultimately derives from the choice to exercise, superior terms for that decision mean a more valuable contract. Letting \( C_a \) and \( C_e \) represent the values of American and European calls, this relationship can be expressed as:

\[
S ≥ C_a(S,T,X) ≥ C_e(S,T,X) ≥ \max[0,S - Xe - (RFR)T] ≥ 0
\]

This expression says that (1) the American call is at least as valuable as the European contract, (2) neither call can be more valuable than the underlying stock, and (3) both contracts are at least as valuable as their intrinsic values, expressed on both a nominal and a discounted basis.

For puts, a similar boundary condition would be:

\[
X ≥ P_a(S,T,X) ≥ P_e(S,T,X) ≥ \max[0,Xe - (RFR)T - S] ≥ 0
\]

For a stock that does not pay dividends, \( C_a \) and \( C_e \) will be equal to one another. At any point prior to expiration, the preceding relationship shows that

\[
C_a(S,T,X) - \max[0,S - X] > 0,
\]

with \( \max[0,S - X] \) being the value the investor would extract from the option’s exercise. Therefore, without the reduction in the stock’s price caused by the dividend payment, an investor wishing to liquidate his American call position would sell it rather than exercise it so as not to surrender the contract’s time premium. Thus, the Black-Scholes model for \( C_e \) can be used to value \( C_a \) as well.

When the stock pays dividends, this situation changes. Suppose an investor holds an American call option on a stock just prior to its ex-dividend date. On the ex-date—call it Date \( t \)—the value of the stock will decline by about the dividend amount, leaving \( S_t = S_{t-1} - (\text{dividend}) \) assuming no other new information impacted the share’s value from the previous day. The value of the option will decline as well, from \( C(S_{t-1}) \) to \( C(S_t) \). Selling the contract on the day prior to the ex-date will not be possible since rational buyers know what will happen the following day. Therefore, the investor must decide on Date \( t-1 \) whether he should exercise his contract and receive only the intrinsic value of \( \max[0,S_t - X] \). This is the proper choice if the loss of the option’s time premium is less than \( C(S_{t-1}) - C(S_t) \), which will likely occur when the option is (1) close to maturity (and, hence, the time premium is low) and (2) the stock’s dividend is large. Because the American option allows the investor the possibility of preserving value when the European contract cannot, we must have \( C_a > C_e \) for almost all cases. Deciding to exercise a put prior to maturity does not depend on the presence of dividends. Indeed, dividend payments increase a put’s value because they reduce the underlying common stock’s value without an offset in the exercise price. Instead, the relevant issue is the limited

For a complete development of these boundary conditions, see Chance and Brooks (2010).
However, modifying the model’s structure is often much more convenient than adjusting the stock input level for a specific payment structure.

22.3.3 Valuing American-Style Options

The preceding discussion considered European-style options. If the contract had been American style—that is, its exercise is not limited to the expiration date—how would the valuation process change? The possibility of early exercise makes the derivation of an exact closed-form analog to the Black-Scholes equation an elusive goal. Instead, Roll (1977b), Geske (1979), and Whaley (1981) have designed elaborate approximation procedures for estimating the value of American-style calls. Further, Johnson (1983) and Barone-Adesi and Whaley (1986), among others, have taken different approaches to address the issue of American put valuation.

We can consider several fundamental properties of these models. Most important is that an American put or call has to be at least as valuable as its European-style counterpart because, by definition, the American option gives the holder more choices than the simpler contract. The American contract holder can exercise at the same time as the European option owner (i.e., at expiration) as well as any point prior to that terminal date. Since we have seen that an option’s value ultimately derives from the choice to exercise, superior terms for that decision mean a more valuable contract. Letting \( C_a \) and \( C_e \) represent the values of American and European calls, this relationship can be expressed as:

\[
S \geq C_a(S,T,X) \geq C_e(S,T,X) \geq \max[0, S - X e^{-(RFR)T}] \geq \max[0, S - X] \geq 0
\]

This expression says that (1) the American call is at least as valuable as the European contract, (2) neither call can be more valuable than the underlying stock, and (3) both contracts are at least as valuable as their intrinsic values, expressed on both a nominal and a discounted basis. For puts, a similar boundary condition would be:

\[
X \geq P_a(S,T,X) \geq P_e(S,T,X) \geq \max[0, X e^{-(RFR)T} - S] \geq 0
\]

For a stock that does not pay dividends, \( C_a \) and \( C_e \) will be equal to one another. At any point prior to expiration, the preceding relationship shows that \( C_a(S,T,X) - \max[0, S - X] > 0 \), with \( \max[0, S - X] \) being the value the investor would extract from the option’s exercise. Therefore, without the reduction in the stock’s price caused by the dividend payment, an investor wishing to liquidate his American call position would sell it rather than exercise it so as not to surrender the contract’s time premium. Thus, the Black-Scholes model for \( C_e \) can be used to value \( C_a \) as well.7

When the stock pays dividends, this situation changes. Suppose an investor holds an American call option on a stock just prior to its ex-dividend date. On the ex-date—call it Date \( t \)—the value of the stock will decline by about the dividend amount, leaving \( S_t = S_{t-1} - \text{dividend} \), assuming no other new information impacted the share’s value from the previous day. The value of the option will decline as well, from \( C(S_{t-1}) \) to \( C(S_t) \). Selling the contract on the day prior to the ex-date will not be possible since rational buyers know what will happen the following day. Therefore, the investor must decide on Date \( t - 1 \) whether he should exercise his contract and receive only the intrinsic value of \( \max[0, S_{t-1} - X] \). This is the proper choice if the loss of the option’s time premium is less than \( C(S_{t-1}) - C(S_t) \), which will likely occur when the option is (1) close to maturity (and, hence, the time premium is low) and (2) the stock’s dividend is large. Because the American option allows the investor the possibility of preserving value when the European contract cannot, we must have \( C_a > C_e \) for almost all cases.

Deciding to exercise a put prior to maturity does not depend on the presence of dividends. Indeed, dividend payments increase a put’s value because they reduce the underlying common stock’s value without an offset in the exercise price. Instead, the relevant issue is the limited

---

7For a complete development of these boundary conditions, see Chance and Brooks (2010).
The dividend yield on the S&P 100 is 2.00 percent, and the annualized yield on a 61-day Treasury bill is 5.70 percent. The investor forecasts the index’s volatility to be 18 percent, and establishes that:

\[ d_1 = \left( \ln\left(\frac{601.40}{e^{-(0.02)0.1671}}\right) + (0.057 + 0.5(0.18)^2) \right)^{0.1671} \frac{1}{(0.18^{0.1671})^{1/2}} = 0.1525 \]

and

\[ d_2 = 0.1525 - 0.18^{0.1671}^{1/2} = 0.0789 \]

leading to

\[ N(d_1) = 0.5607 \]

and

\[ N(d_2) = 0.5315 \]

Thus, she estimates the call’s value to be:

\[ C_0 = (599.39)(0.5607) - (600)(e^{-(0.057)0.1671})(0.5315) = $20.20 \]

Since this is higher than the market price of the option (i.e., $17.75), the contract appears undervalued. This is not necessarily an arbitrage opportunity, however, as the investor’s valuation was based on two assumptions that may not match the consensus view of other market participants: (1) the Black-Scholes framework is appropriate, and (2) the index’s volatility is 18 percent and not something lower.

Foreign Currency Options
Recall that prices for exchange-traded currency options are quoted in U.S. cents per unit of foreign currency, reflecting that a call option is the right to buy a fixed amount of foreign currency with U.S. dollars. Let \( RFR_f \) and \( RFR_d \) be the risk-free rates in the foreign and U.S. domestic markets, respectively. Further, let \( \sigma \) be the volatility of the exchange rate between the United States and the foreign country, denominated in USD per unit of FC. Garman and Kohlhagen (1983) and Biger and Hull (1983) showed that the Black-Scholes model for European-style calls and puts under these conditions can be written as:

\[
C_0 = e^{-RFR_f T} SN(d_1) - X e^{-RFR_d T}N(-d_2)
\]

\[
P_0 = X e^{-RFR_d T}N(d_2) - e^{-RFR_f T}SN(-d_1)
\]

where:

\[ d_1 = \frac{\ln(e^{-(RFR_f T)}/S) + (RFR_d + 0.5 \cdot \sigma^2)^{1/2}T}{\sigma^{1/2}} \]

\[ d_2 = d_1 - \sigma^{1/2} = \frac{1}{2} \]

\[ S = \text{the spot exchange rate quoted on a direct basis (i.e., USD}/\text{FC}) \]

Again, this formula is equivalent to the dividend-adjusted Black-Scholes model for stock options when \( RFR_f \) is interpreted as the "dividend yield" on the foreign currency. As an example, suppose the spot exchange rate between the U.S. dollar and the British pound is USD 1.50/GBP. The risk-free rates in the United States and England are 4.5 percent and 9 percent, respectively, so interest rate parity holds that the dollar should trade at a forward premium to the pound, suggesting that the dollar price of sterling will fall. Thus, an at-the-money put option should be more valuable to an investor than an at-the-money sterling call. To see if this is the case, consider the valuation of six-month contracts where \( S = 1.50, X = 1.50, RFR_d = 4.5 \text{ percent}, RFR_f = 9 \text{ percent}, \sigma = 13 \text{ percent}, \) and \( T = 0.5 \). With these inputs, \( S_0 = S e^{-(0.09)0.5} = 1.434 \) so that:

\[ d_1 = \frac{\ln(1.434/1.50) + (0.045 + 0.5(0.13)^2)\cdot0.5}{0.13^{0.5}} = -0.20 \]

and

\[ d_2 = -0.20 - 0.13^{0.5}^{1/2} = -0.29 \]

22.3.4 Other Extensions of the Black-Scholes Model
The dividend-adjusted Black-Scholes model is also quite useful in valuing options for underlying assets other than common stock. Three important applications along these lines follow.

Stock Index Options
Stock index options are fundamentally no different than regular stock options. However, the stock index cannot be delivered to settle the contract, and so it must be settled in cash. Beyond that, as a well-diversified portfolio, the volatility of the stock index’s price usually is quite a bit lower than the typical stock. Finally, the applicable dividend yield is the average annualized yield on the index during the option’s life, which is likely to be known to investors at least one calendar quarter into the future.

Suppose the Standard & Poor’s 100 currently is at 601.40 and a call option on the index with an exercise price of 600 is being offered at a price of $17.75. Is this the fair value of this contract? The option is set to expire in exactly 61 days, which translates to 0.1671 (= 61/365)
Therefore, the option values are as expected at:

\[ C_0 = (1.434)(0.4207) - (1.50)(e^{-0.0450.5})(0.3859) = \$0.037 \]

and

\[ P_0 = (1.50)(e^{-0.0450.5})(0.6141) - (1.434)(0.5793) = \$0.070 \]

Futures Options

In the preceding chapter, we showed that in the absence of physical storage costs or dividends, the futures contract price (\( F \)) should simply be the spot price (\( S \)) of the underlying asset carried forward to date at the risk-free rate. With continuous yields, this can be written as:

\[ F = S e^{(RFR)T} \]

Black (1976) showed that substituting \( F \) for \( S \) in the Black-Scholes formula for call options leaves:

\[ C_0 = \frac{1}{2} e^{-0.5(RFR)T} \frac{F}{C138} N(d_1) - (e^{-0.5(RFR)T}) \frac{X}{C138} N(d_2) = \]

\[ (e^{-0.5(RFR)T}) \frac{F}{C138} N(d_1) - (e^{-0.5(RFR)T}) \frac{X}{C138} N(d_2) \]

where:

\[ d_1 = \frac{\ln(F/S) + (0.5\sigma^2)T}{\sigma\sqrt{T}} \]

\[ d_2 = d_1 - \sigma\sqrt{T} \]

\( S \) = the spot exchange rate quoted on a direct (i.e., USD/FC) basis

Again, this formula is equivalent to the dividend-adjusted Black-Scholes model for stock options when \( RFR_f \) is interpreted as the “dividend yield” on the foreign currency. As an example, suppose the spot exchange rate between the U.S. dollar and the British pound is USD 1.50/GBP. The risk-free rates in the United States and England are 4.5 percent and 9 percent, respectively, so interest rate parity holds that the dollar should trade at a forward premium to the pound, suggesting that the dollar price of sterling will fall. Thus, an at-the-money put option should be more valuable to an investor than an at-the-money sterling call. To see if this is the case, consider the valuation of six-month contracts where \( S = 1.50, X = 1.50, RFR_d = 4.5 \) percent, \( RFR_f = 9 \) percent, \( \sigma = 13 \) percent, and \( T = 0.5 \). With these inputs, \( S = S(e^{-0.090.5}) = 1.434 \) so that:

\[ d_1 = \frac{\ln(1.434/1.50) + (0.045 + 0.5(0.13)^2)(0.5)}{(0.13)(0.5)} = -0.20 \]

and

\[ d_2 = -0.20 - 0.13(0.5)^{1/2} = -0.29 \]
Therefore, the option values are as expected at:

\[
C_0 = (1.434)(0.4207) - (1.50)(e^{-(0.045)0.5})(0.3859) = 0.037
\]

and

\[
P_0 = (1.50)(e^{-(0.045)0.5})(0.6141) - (1.434)(0.5793) = 0.070
\]

**Futures Options** In the preceding chapter, we showed that in the absence of physical storage costs or dividends, the futures contract price \(F\) should simply be the spot price \(S\) of the underlying asset carried forward to date \(T\) at the risk-free rate. With continuous yields, this can be written as \(F = Se^{(RFR)T}\). Black (1976) showed that substituting \(F\) for \(S\) in the Black-Scholes formula for call options leaves:

\[
C_0 = [e^{-(RFR)T}F]N(d_1) - (e^{-(RFR)T})XN(d_2)
\]

\[
= (e^{-(RFR)T})[FN(d_1) - XN(d_2)]
\]

where:

\[
d_1 = (\ln(F/X) + 0.5\sigma^2[T]^{1/2})
\]

\[
d_2 = d_1 - \sigma[T]^{1/2}
\]

In the expressions for \(d_1\) and \(d_2\), the risk-free rate factor drops out because a risk-free hedge portfolio with futures and call options requires no initial investment since futures contracts require no front-end payment. Also, here \(\sigma\) represents the futures price volatility, which normally is assumed to be equal to the underlying asset volatility.

### 22.4 Option Trading Strategies

Chapter 20 highlighted two ways in which investors use options. First, we saw that the asymmetrical payoff structures they possess as stand-alone positions allow investors to isolate the benefits of an anticipated change in the value of an underlying security while limiting the downside risk of an adverse price movement. Second, we also saw that put options could be used in conjunction with an existing portfolio to limit the portfolio’s loss potential. After revisiting this protective put application for individual stock holdings, we will now consider a **covered call** option strategy as another method for modifying the risk or enhancing the return of an existing equity position.

This section also emphasizes a third way in which options are used: in combination with one another to create customized payoff distributions that do not exist in more fundamental securities, like stocks or bonds. The equity collar application that concluded Chapter 20 is a good example of this type of option strategy. In designing such combinations, the investor usually attempts to exploit a very specific view about future economic conditions. For example, he may feel that a company’s stock returns will be extraordinarily volatile but have no clear impression about the price movement direction. Or, he may feel that another firm’s shares will trade within a very narrow range around their current price during the next few months. In developing all these strategies, we will return to the hypothetical example of SAS Corporation, which has exchange-traded common stock, as well as call and put options. Current prices for SAS stock and six different derivatives, all of which expire at the same time, are reproduced in Exhibit 22.17.

### 22.4.1 Protective Put Options

Although the protective put strategy is most often used to provide insurance for price declines in entire portfolios, Brown and Statman (1987) have noted that the technique can also be employed with individual equity positions. To see how this “insured stock” concept works, consider an investor who holds SAS stock in her portfolio but is concerned that an unexpected downturn in
the company’s product sales may lead to a decline in the value of her position. To hedge against this firm-specific exposure, she decides to purchase an at-the-money put option on SAS shares, meaning that she would spend $3.67 to buy Put #2 with an exercise price of $40. If at expiration the price of SAS had declined below $40, the put option would pay her the difference.

The effect of this acquisition is shown in Exhibit 22.18, which lists the expiration date value of the combined protective put position for a range of possible SAS prices. As noted earlier, the primary benefit of the insured stock strategy is that it preserves the investor’s upside potential from rising share prices but limits her losses when share prices fall. In this case, the at-the-money put insures her against any losses beyond the $3.67 initial put premium. This is the same outcome the investor would have if, instead of the put-protected SAS shares, she had held an at-the-money SAS call option and a T-bill; the risk-free security provides the safety and the call option provides the potential for price appreciation. Recall from the put-call parity model of Chapter 20 that this result was shown as $S_0 + P_{0,T} = C_{0,T} + PV(X)$ or:

$\text{(Long Stock)} + (\text{Long Put}) = (\text{Long Call}) + (\text{Long T-bill})$

To extend the insurance interpretation of the protective put, Exhibit 22.19 shows the expiration date profits (net of the initial $40 purchase price for the investor’s SAS shares) for using each of three put options. To interpret this display, if SAS shares are priced at $40 on the expiration date, for Protective Put #2 (i.e., the at-the-money contract), the investor’s combined position will be worth $36.33, giving her a net loss of $3.67. The main thing about this illustration is the trade-off it shows between the risk and reward potential of the various positions. Put #1 has the smallest front-end expense, but its $35 exercise price forces the investor to bear the first $5 of SAS stock price declines; this $5 “deductible” leads to the largest potential loss of

<td>0</td>
<td>-3.67</td>
<td>(60 + 0) – 3.67 = 56.33</td>
</tr>
</tbody>
</table>
There are two dimensions to the price risk inherent in this strategy. First, if by the option expiration date, SAS stock has risen above $40, the investor will be forced to sell her shares for less than they are actually worth. However, this will represent a lost opportunity only at prices above $45.24, or the exercise price plus the initial call premium. Second, if SAS stock experiences a decline in value, her potential loss is not hedged beyond the $5.24 in premium income that she received for selling the call; after prices fall beyond $31.09 (= 40 − 5.24 − 3.67), she would have been better off purchasing the at-the-money protective put option. Thus, to be profitable, the covered call strategy requires that the investor guess correctly that share values remain reasonably close to their present levels.

22.4.3 Straddles, Strips, and Straps

A **straddle** is the simultaneous purchase (or sale) of a call and a put option with the same underlying asset, exercise price, and expiration date. A long straddle requires the purchase of the put and the call, while a short straddle sells both contracts. The long straddle gives the investor a

**Exhibit 22.19 Terminal Net Profits to Three Protective Put Positions**

three positions at $6.70 (= 1.70 + 5.00). However, for this degree of self-insuring on the part of the investor, Protective Put #1 has, at $41.70 (= 35.00 + 6.70), the smallest breakeven price. Conversely, Put #3, with an exercise price above the current share value, does not break even until SAS prices reach $46.47 but has a maximum possible loss of only $1.47 and therefore provides the best downside protection.

**22.4.2 Covered Call Options**

Another popular way to alter the payoff structure of an equity position involves the sale of call options. When investors sell call options based on an underlying position they own, they are said to be **writing** covered calls. Usually, the purpose of this strategy is to generate additional income for a stock holding that is not expected to change in value much over the near term. By selling a call, an investor receives the premium from the option contract to bolster an otherwise small (or negative) return. The danger is that the value of the stock position rises above the exercise price by the end of the contract’s life causing the shares to be called away.

Suppose now that our investor believes that over the next few months the value of her SAS stock will neither rise nor fall by an appreciable amount. She decides not to insure her position against losses but, instead, to increase the cash flow of the investment by selling an at-the-money call option (Call #2). In exchange for granting the contract buyer the right to purchase her stock for $40 at the expiration date, she receives an immediate payment of $5.24. The expiration date values for the covered call position are listed in Exhibit 22.20. The construction of the terminal profit diagram—once again net of the current SAS share price—is depicted in Exhibit 22.21.

Both of these displays indicate that the expiration date payoff to the covered call position is comparable in form to that of a short position in a put option. Once again, this can be seen directly by adjusting the put-call parity condition as follows:

\[(\text{Long Stock}) + (\text{Short Call}) = (\text{Long T-bill}) + (\text{Short Put})\]
A straddle is the simultaneous purchase (or sale) of a call and a put option with the same underlying asset, exercise price, and expiration date. A long straddle requires the purchase of the put and the call, while a short straddle sells both contracts. The long straddle gives the investor a combination that will appreciate in value whether stock prices rise or fall in the future. Buying two options increases the initial cost, meaning that stock price movements must be more pronounced than if the investor had predicted changes in a single direction. In this sense, a straddle is a volatility play; the buyer expects stock prices to move strongly one way or the other, while the seller hopes for lower-than-normal volatility.

Assume that an investor who does not hold SAS stock purchases a put and a call, each with an exercise price of $40. The cost of this purchase will be the combined prices of Call #2 and Put #2, or $8.91 (= 5.24 + 3.67). Because the terminal values of the options are \( \max(0, S - 40) \) and \( \max(0, 40 - S) \), respectively, the potential expiration date profits to the straddle position (net of the initial cost, unadjusted for the time value differential) are shown in Exhibit 22.22. These are illustrated in Exhibit 22.23, which also depicts the profit to the seller of the straddle. The break-even points on this graph occur at $31.09 (= 40 - 8.91) and $48.91 (= 40 + 8.91). The expiration date values to the long and short positions are mirror images of each other.

There are two dimensions to the price risk inherent in this strategy. First, if by the option expiration date, SAS stock has risen above $40, the investor will be forced to sell her shares for less than they are actually worth. However, this will represent a lost opportunity only at prices above $45.24, or the exercise price plus the initial call premium. Second, if SAS stock experiences a decline in value, her potential loss is not hedged beyond the $5.24 in premium income that she received for selling the call; after prices fall beyond $31.09 (= 40 - 5.24 - 3.67), she would have been better off purchasing the at-the-money protective put option. Thus, to be profitable, the covered call strategy requires that the investor guess correctly that share values remain reasonably close to their present levels.

### Exhibit 22.21 Terminal Net Profit to a Covered Call Position

Terminal Net Profit

**Long stock plus short call:**

- Terminal Net Profit = Long Stock + Short Call - 5.24
- Expiration Date Stock Value = 40
- Value of Call Option = 5.24

Terminal Net Profit

**Covered Call Position**

- Terminal Net Profit = Covered Call Position + Long Stock - 5.24
- Expiration Date Stock Value = 40
- Value of Call Option = 5.24
combination that will appreciate in value whether stock prices rise or fall in the future. Buying two options increases the initial cost, meaning that stock price movements must be more pronounced than if the investor had predicted changes in a single direction. In this sense, a straddle is a volatility play; the buyer expects stock prices to move strongly one way or the other, while the seller hopes for lower-than-normal volatility.

Assume that an investor who does not hold SAS stock purchases a put and a call, each with an exercise price of $40. The cost of this purchase will be the combined prices of Call #2 and Put #2, or $8.91 ( = 5.24 + 3.67). Because the terminal values of the options are \(\max[0, S_T - 40]\) and \(\max[0, 40 - S_T]\), respectively, the potential expiration date profits to the straddle position (net of the initial cost, unadjusted for the time value differential) are shown in Exhibit 22.22. These are illustrated in Exhibit 22.23, which also depicts the profit to the seller of the straddle. The break-even points on this graph occur at $31.09 ( = 40 - 8.91) and $48.91 ( = 40 + 8.91).

The expiration date values to the long and short positions are mirror images of each other. The buyer of the straddle is hoping for a dramatic event—such as a company-specific technological breakthrough or the impending judgment in a major lawsuit—that will either increase or decrease the stock price from its present $40 by at least $8.91. Conversely, the best result for the straddle seller is for SAS stock to continue to trade at its current price through the expiration

price; instead, they are selected so that both are out of the money. By buying two out-of-the-money contracts, the investor reduces the original straddle position’s initial cost. Offsetting this reduced cost, though, is that stock prices will have to change by a greater amount before the strangle becomes profitable. Thus, the strangle offers a more modest risk-reward structure than the straddle.

Suppose the investor purchased Call #3 and Put #1 for a combined price of $4.94 (= 3.24 + 1.70). If the stock price remained between the put exercise price of $35 and the call exercise price of $45, both contracts would expire worthless and the investor would lose his entire investment. Prices would have to decline to $30.06 (= 35 − 4.94) or increase to $49.94 (= 45 + 4.94) before the investor would break even on the position. Exhibit 22.25 shows that these breakeven points for the strangle are outside those for the straddle, described earlier. Thus, among the set of “volatility bets,” the strangle costs less to implement than the straddle but requires greater stock price movement before it generates a positive return. Finally, by varying the exercise prices on the two options, the investor can create a strangle position with the exact trade-off between initial cost and future expected profit that he desires.

22.4.5 Chooser Options

The straddle is a special case of a wider class of option contracts called chooser options. With a chooser option, the investor selects an exercise price and expiration date but doesn’t have to decide if the option should be a put or a call until after the contract is purchased. That is, the straddle is just a chooser option for which the decision can be deferred until the expiration date. Rubinstein (1992) has shown that the value of a chooser option will depend on when the investor has to make that choice.

At one extreme, if the decision has to be made immediately, the buyer will select the option most likely to be in the money at expiration. In the previous example, with \( X = 40 \), we have seen that this will be the call. Thus, a chooser option in this case is worth $5.24. At the other extreme, a chooser option that allows the holder to defer the decision until expiration is, as already noted, equivalent to holding both a put and a call for the entire time to expiration. Consequently, the straddle price of $8.91 is the upper bound of the chooser option value struck at $40. The usual design for the chooser contract requires the holder to make a choice after the initial purchase but before expiration, which would create a position worth somewhere between $5.24 and $8.91.

date (i.e., no volatility at all) so that both options expire worthless. The seller’s position demonstrates that it is possible to make money in the stock market even when prices do not change.

The long straddle position assumes implicitly that the investor has no intuition about the likely direction of future stock price movements. A slight modification is overweighting either the put or the call holding to emphasize a directional belief while maintaining a contract that would profit from a price movement the other way. A long strap position is the purchase of two calls and one put with the same exercise price, suggesting an investor who thinks stock prices are more likely to increase. An investor with a more bearish view could create a long strip position by purchasing two puts and only one call. The terminal profits to both of these combinations are listed in Exhibit 22.24, which again assumes the use of the two at-the-money SAS contracts.

Panel A of the exhibit shows that for the higher up-front payment of $14.15 \([= (2 \times 5.24) + 3.67]\), the strap will accelerate the profit in a rising market relative to the straddle. The settlement payment when SAS stock is above $40 on the expiration date is twice as great because the strap has doubled the investor’s number of calls. The gross payoff when the price falls below $40 remains the same; however, the net amount received is considerably lower because the extra contract the investor purchased would then be out of the money. The net terminal value of the strap position tells a similar story, only with the acceleration of the profit generated by falling stock prices.

22.4.4 Strangles

One final variation on the straddle is an option combination known as a strangle, which also involves the simultaneous purchase or sale of a call and a put on the same underlying security with the same expiration date. The options used in the strangle do not have the same exercise
22.4.6 Spreads

As described by Black (1975), option spreads are the purchase of one contract and the sale of another, where the options are alike in all respects except for one distinguishing characteristic. In a 

money spread, the investor would sell an out-of-the-money call and purchase an in-the-money call on the same stock and expiration date. Alternatively, a 

calendar (or time) spread requires the purchase and sale of two calls— or two puts—with the same exercise price but different expiration dates. Option spreads are often used when one contract is perceived to be misvalued relative to the other. For instance, if an investor determines that a call option with an exercise price of $X_1$ and an expiration date $T$ is selling at too high a price, he can short it, thereby speculating on an eventual correction. However, if a broad-based increase in the stock market occurs before this contract-specific correction, he stands to lose a great deal because the short call position has unlimited liability. Thus, when he sells the first option, he can hedge some or all of the risk by buying a call with an exercise price of $X_2$ expiring at $T$.

Returning to the data for SAS options, assume the investor purchases the in-the-money call (Call #1) and sells the contract that is out of the money (Call #3). This requires a net cash outlay of $4.83 (= 8.07 − 3.24). At the common expiration date, three price ranges should be considered. If SAS stock settles below $35, both options will expire worthless. With an SAS price above $45, both contracts will be exercised, meaning that the investor must sell at $45 the share he bought for $35, leaving a $10 gross payoff. Finally, if SAS prices fall between the two exercise prices, the option the investor owns will be in the money while the contract he sold will not. This situation is summarized by the net profit calculations shown in Exhibit 22.26.

This combination is sometimes called a 

bull money spread because it will be profitable when stock prices rise. With the initial cost of $4.83, the investor’s breakeven point occurs when the stock price rises to $39.83 (= 35 + 4.83). His benefit stops increasing if SAS shares reach $45, or where the short position in Call #3 becomes a liability. Exhibit 22.27 contrasts this situation with the outright purchase of the in-the-money call. This contract costs $8.07 initially, leading to the higher breakeven price of $43.07. It would not have a constraint on the upside profit potential, however, so once a share price of $48.24 is reached [= 45 + (8.07 − 4.83)], it would become the preferable alternative. Thus, in exchange for a lower initial purchase price, the bull spread investor is giving up the benefits of rising SAS prices after some point — as strategy makes sense only if he expects the share price to settle within a fairly narrow range.

22.4.5 Chooser Options

The straddle is a special case of a wider class of option contracts called chooser options. With a chooser option, the investor selects an exercise price and expiration date but doesn’t have to decide if the option should be a put or a call until after the contract is purchased. That is, the straddle is just a chooser option for which the decision can be deferred until the expiration date. Rubinstein (1992) has shown that the value of a chooser option will depend on when the investor has to make that choice.

At one extreme, if the decision has to be made immediately, the buyer will select the option most likely to be in the money at expiration. In the previous example, with $X = 40$, we have seen that this will be the call. Thus, a chooser option in this case is worth $5.24. At the other extreme, a chooser option that allows the holder to defer the decision until expiration is, as already noted, equivalent to holding both a put and a call for the entire time to expiration. Consequently, the straddle price of $8.91 is the upper bound of the chooser option value struck at $40. The usual design for the chooser contract requires the holder to make a choice after the initial purchase but before expiration, which would create a position worth somewhere between $5.24 and $8.91.
22.4.6 Spreads

As described by Black (1975), option spreads are the purchase of one contract and the sale of another, where the options are alike in all respects except for one distinguishing characteristic. In a money spread, the investor would sell an out-of-the-money call and purchase an in-the-money call on the same stock and expiration date. Alternatively, a calendar (or time) spread requires the purchase and sale of two calls—or two puts—with the same exercise price but different expiration dates. Option spreads are often used when one contract is perceived to be misvalued relative to the other. For instance, if an investor determines that a call option with an exercise price of $X_1$ and an expiration date $T$ is selling at too high a price, he can short it, thereby speculating on an eventual correction. However, if a broad-based increase in the stock market occurs before this contract-specific correction, he stands to lose a great deal because the short call position has unlimited liability. Thus, when he sells the first option, he can hedge some or all of the risk by buying a call with an exercise price of $X_2$ expiring at $T$.

Returning to the data for SAS options, assume the investor purchases the in-the-money call (Call #1) and sells the contract that is out of the money (Call #3). This requires a net cash outlay of $4.83 (= 8.07 – 3.24). At the common expiration date, three price ranges should be considered. If SAS stock settles below $35, both options will expire worthless. With an SAS price above $45, both contracts will be exercised, meaning that the investor must sell at $45 the share he bought for $35, leaving a $10 gross payoff. Finally, if SAS prices fall between the two exercise prices, the option the investor owns will be in the money while the contract he sold will not. This situation is summarized by the net profit calculations shown in Exhibit 22.26.

This combination is sometimes called a bull money spread because it will be profitable when stock prices rise. With the initial cost of $4.83, the investor’s breakeven point occurs when the stock price rises to $39.83 (= 35 + 4.83). His benefit stops increasing if SAS shares reach $45, or where the short position in Call #3 becomes a liability. Exhibit 22.27 contrasts this situation with the outright purchase of the in-the-money call. This contract costs $8.07 initially, leading to the higher breakeven price of $43.07. It would not have a constraint on the upside profit potential, however, so once a share price of $48.24 is reached [= 45 + (8.07 – 4.83)], it would become the preferable alternative. Thus, in exchange for a lower initial purchase price, the bull spread investor is giving up the benefits of rising SAS prices after some point—a strategy that makes sense only if he expects the share price to settle within a fairly narrow range.

The profit for a bear money spread (the purchase of Call #3 and the sale of Call #1) is the opposite of that for the bull money spread. Consequently, a long bear spread position could be used by an investor who believed stock prices might decline but did not want to be short in the stock. A spread transaction also can be created using put options. For instance, suppose a new investor undertakes the simultaneous purchase of Put #3 and sale of Put #1. Her net cost to acquire the position would be $4.77 (= 6.47 – 1.70), which would then generate the

terminal profits displayed in Exhibit 22.28. If SAS stock settled at $45 or higher, both puts would be worthless. If the expiration date share price was $35 or less, both options would be in the money, leaving the investor with a net position of $5.23 (= 45 − 35 − 4.77). Thus, this is the put option version of a bear money spread.

A final extension of this concept is the butterfly spread. Suppose an investor designed the following portfolio of SAS options: long one Call #1, short two Calls #2, and long one Call #3. This position is equivalent to holding:

- a bull money spread (i.e., buy Call #1 and sell Call #2), and
- a bear money spread (i.e., buy Call #3 and sell Call #2)

The net purchase price for these transactions is $0.83 [= (8.07 − 5.24) + (3.24 − 5.24)]. The expiration date profits are listed in Exhibit 22.29 and show that the value of the position peaks at a stock price of $40 and that the investor can lose, at most, her initial investment. The breakeven stock prices are $35.83 and $44.17. This form of the butterfly spread is equivalent to a hedged
could lock in a three-month forward rate of USD 0.67/CHF without cost in two ways. First, he could commit to a long position in the CHF forward with a contract amount of CHF 1,000,000. Second, he could buy the CHF call option struck at USD 0.67/CHF and pay for it by selling the CHF put at the same exercise rate. As shown in Chapter 20, the put-call parity model indicates that buying a call and selling a put with the same exercise rate is equivalent to a long forward position. Further, this second strategy would generate a zero-cost forward (i.e., $C_0 = P_0$) only when the common exercise rate is set equal to the prevailing forward rate.

As a third alternative, what if the treasurer (1) bought the 0.70 call for USD $0.004 per franc and (2) sold the 0.64 put for the same price? Once again, this would be a costless combination of options; however, since the two options do not have a common exercise price, this combination is not equivalent to the actual forward—it is a range forward. At the expiration date, one of three things will happen: (1) if the spot FX rate is greater than USD 0.70/CHF, the treasurer will exercise his call and buy francs at that level; (2) if the spot FX rate is less than USD 0.64/CHF, the dealer to whom the treasurer sold the put will force him to buy francs for USD 0.64 per franc; and (3) if the spot FX rate is between these extremes, both options will finish out of the money and the treasurer will buy the required currency at the regular market price. This payoff scheme is contrasted with the regular forward contract in Exhibit 22.32.

If the treasurer takes a long position in the regular forward contract, he will buy his francs at USD 0.67/CHF, regardless of the prevailing exchange rate in three months. Thus, although he is version of a short straddle position. That is, in exchange for receiving a smaller potential payoff (i.e., $4.17$ vs. $8.91$) from a view on low volatility, the investor has limited her losses if SAS’s stock price is more explosive than she expected. This trade-off is shown in Exhibit 22.30.

### 22.4.7 Range Forwards

In Chapter 20, we discussed an equity collar as a way that an investor could protect her stock portfolio from adverse movements while allowing for some upside gain potential. We saw that although the equity collar had some of the same attributes as a forward contract (e.g., no up-front premium expense), it was actually a combination of two options—the purchase of an out-of-the-money put and sale of an out-of-the-money call. Equity collars are an example of a strategy also known as range (or flexible) forwards.

To see how range forward positions might be used in a different context, assume that the treasurer of a U.S. multinational corporation knows today that he will have a bill for imported goods that must be paid in three months. This bill, requiring payment of 1,000,000 Swiss francs, presents a challenge for a dollar-based company, which must buy the francs it needs. This is a classic opportunity to use derivatives to hedge the firm’s FX exposure.

The treasurer establishes prices and terms for several CHF forward and option contracts, as listed in Exhibit 22.31, which states prices on a direct (i.e., USD/CHF) basis. The treasurer
could lock in a three-month forward rate of USD 0.67/CHF without cost in two ways. First, he could commit to a long position in the CHF forward with a contract amount of CHF 1,000,000. Second, he could buy the CHF call option struck at USD 0.67/CHF and pay for it by selling the CHF put at the same exercise rate. As shown in Chapter 20, the put-call parity model indicates that buying a call and selling a put with the same exercise rate is equivalent to a long forward position. Further, this second strategy would generate a zero-cost forward (i.e., \( C_0 = P_0 \)) only when the common exercise rate is set equal to the prevailing forward rate.

As a third alternative, what if the treasurer (1) bought the 0.70 call for USD 50.004 per franc and (2) sold the 0.64 put for the same price? Once again, this would be a costless combination of options; however, since the two options do not have a common exercise price, this combination is not equivalent to the actual forward—it is a range forward. At the expiration date, one of three things will happen: (1) if the spot FX rate is greater than USD 0.70/CHF, the treasurer will exercise his call and buy francs at that level; (2) if the spot FX rate is less than USD 0.64/CHF, the dealer to whom the treasurer sold the put will force him to buy francs for USD 0.64 per franc; and (3) if the spot FX rate is between these extremes, both options will finish out of the money and the treasurer will buy the required currency at the regular market price. This payoff scheme is contrasted with the regular forward contract in Exhibit 22.32.

If the treasurer takes a long position in the regular forward contract, he will buy his francs at USD 0.67/CHF, regardless of the prevailing exchange rate in three months. Thus, although he is
2. Put-call-forward parity and range forward positions both involve the purchase of a call option and the sale of a put option (or vice versa) on the same underlying asset. Describe the relationship between these two trading strategies. Is one a special case of the other?

3. Techno-Logical Inc. is a smart-phone manufacturer and has issued a five-year discount note in the amount of 160 million Japanese yen for procurement from its suppliers in Japan. Techno-Logical wants to hedge its currency exposure and the firm’s financial director has the following suggestions.
(a) At-the-money Japanese yen call option contracts;
(b) Japanese yen forward contracts; or
(c) Japanese yen futures contracts.
Explain the exact way in which the company could use any of these products in their hedging strategy, being sure to compare and contrast the advantages and disadvantages of each.

4. In the Black-Scholes option pricing model, there are six factors that affect the value of call options on stocks. Three of these factors include (1) the current price of the underlying stock, (2) the time to maturity for the option contract, and (3) the dividend on the stock. Identify the remaining three factors, and explain how they affect the value of call options.

5. “Although options are risky investments, they are valued by virtue of their ability to convert the underlying asset into a synthetic risk-free security.” Explain what this statement means, being sure to describe the basic three-step process for valuing option contracts.

6. In valuing currency options with the Black-Scholes model, we saw that the risk-free rate on the foreign currency was equivalent to the dividend yield when an individual stock or stock index was the underlying asset. Discuss the appropriateness of this analogy. What sort of transaction involving foreign currency would be required to make this parallel exact?

7. Describe the condition under which it would be rational to exercise both an American-style put and call stock option before the expiration date. In both cases, comment specifically on the role that dividends play.

8. Explain why a change in the time to expiration (i.e., T) can have either a positive or negative impact on the value of a European-style put option. In this explanation, it will be useful to contrast the put’s reaction with that of a European-style call, for which an increase in T has an unambiguously positive effect.

9. Currency option traders often speak of “buying low volatility (or ‘vol’) and selling high vol” rather than buying or selling the option itself. What does this mean exactly? From this perspective, what is the real underlying asset: volatility or foreign currency?

10. On October 19, 1987, the stock market (as measured by the Dow Jones Industrial Average) lost almost one-quarter of its value in a single day. Nevertheless, some traders made a profit buying call options on the stock index and then liquidating their positions before the market closed. Explain how this is possible, assuming that it was not a case of the traders taking advantage of spurious upward ticks in stock prices.

PROBLEMS

1. You work on a proprietary trading desk of a large investment bank, and you have been asked for a quote on the sale of a call option with a strike price of $50 and one year of expiration. The call option would be written on a stock that does not pay a dividend. From your analysis, you expect that the stock will either increase to $70 or decrease to $35 over the next year. The current price of the underlying stock is $50, and the risk-free interest rate is 4% per annum.
   a. Briefly describe the steps involved in applying binomial option pricing model to value the call option in this situation.
   b. What is this fair market value for the call option under these conditions?

SUGGESTED READINGS

QUESTIONS

1. Straddles have been described as “volatility plays.” Explain what this means for both long and short straddle positions. Given the fact that volatility is a primary factor in how options are priced, under what conditions might an investor who believes that markets are efficient ever want to create a straddle?
2. Put-call-forward parity and range forward positions both involve the purchase of a call option and the sale of a put option (or vice versa) on the same underlying asset. Describe the relationship between these two trading strategies. Is one a special case of the other?

3. Techno-Logical Inc. is a smart-phone manufacturer and has issued a five-year discount note in the amount of 160 million Japanese yen for procurement from its suppliers in Japan. Techno-Logical wants to hedge its currency exposure and the firm’s financial director has the following suggestions.

**PROBLEMS**

1. You work on a proprietary trading desk of a large investment bank, and you have been asked for a quote on the sale of a call option with a strike price of $50 and one year of expiration. The call option would be written on a stock that does not pay a dividend. From your analysis, you expect that the stock will either increase to $70 or decrease to $35 over the next year. The current price of the underlying stock is $50, and the risk-free interest rate is 4% per annum.
   a. Briefly describe the steps involved in applying binomial option pricing model to value the call option in this situation.
   b. What is this fair market value for the call option under these conditions?
Consider the following questions on the pricing of options on the stock of ARB Inc.:

a. A share of ARB stock sells for $75 and has a standard deviation of returns equal to 20 percent per year. The current risk-free rate is 9 percent and the stock pays two dividends: (1) a $2 dividend just prior to the option's expiration day, which is 91 days from now (i.e., exactly one-quarter of a year), and (2) a $2 dividend 182 days from now (i.e., exactly one-half year). Calculate the Black-Scholes value for a European-style call option with an exercise price of $70.

b. What would be the price of a 91-day European-style put option on ARB stock having the same exercise price?

c. Calculate the change in the call option's value that would occur if ARB's management suddenly decided to suspend dividend payments and this action had no effect on the price of the company's stock.

d. Briefly describe (without calculations) how your answer in Part a would differ under the following separate circumstances: (1) the volatility of ARB stock increases to 30 percent, and (2) the risk-free rate decreases to 8 percent.

Consider the following data relevant to valuing a European-style call option on a non-dividend-paying stock:

X = 40, RFR = 9 percent, T = six months (i.e., 0.5), and σ = 0.25.

a. Compute the Black-Scholes option and hedge ratio values for the series of hypothetical current stock price levels shown in Exhibit 22.12.

b. Explain why the values in Part a differ from those shown in Exhibit 22.12.

c. For S = 40, calculate the Black-Scholes value for a European-style put option. How much of this value represents time premium?

Suppose the current value of a popular stock index is 653.50 and the dividend yield on the index is 2.8 percent. Also, the yield curve is flat at a continuously compounded rate of 5.5 percent.

a. If you estimate the volatility factor for the index to be 16 percent, calculate the value of an index call option with an exercise price of 670 and an expiration date in exactly three months.

b. If the actual market price of this option is $17.40, calculate its implied volatility coefficient.

c. Besides volatility estimation error, explain why your valuation and the option's traded price might differ from one another.

Consider the following price data for TanCo stock in two different subperiods:

Subperiod A:
168.375; 162.875; 162.5; 161.625; 160.75; 157.75; 157.25; 157.75; 161.125; 162.5; 157.5; 156.625; 157.875; 155.375; 150.5; 155.75; 154.25; 155.875; 156; 152.75; 150.5; 150.75

Subperiod B:
122.5; 124.5; 121.875; 120.625; 119.5; 118.125; 117.75; 119.25; 122.25; 121.625; 120; 117.75; 118.375; 115.625; 117.75; 117.5; 118.5; 117.625; 114.625; 110.75

a. For each subperiod, calculate the annualized historical measure of stock volatility that could be used in pricing an option for TanCo. In your calculations, you may assume that there are 250 trading days in a year.

b. Suppose now that you decide to gather additional data for each subperiod. Specifically, you obtain information for a call option with a current price of $12.25 and the following characteristics:

X = 115; S = 120.625; time to expiration = 62 days; RFR = 7.42 percent; and dividend yield = 3.65 percent. Here the risk-free rate and dividend yields are stated on an annual basis. Use the volatility measure from Subperiod B and the Black-Scholes model to obtain the “fair value” for this call option. Based on your calculations, is the option currently priced as it should be? Explain.

4. Following is a two-period price tree for a share of stock in SAB Corp.:

Using the binomial model, calculate the current fair value of a regular call option on SAB stock with the following characteristics: X = 28, RFR = 5 percent (per subperiod). You should also indicate the composition of the implied riskless hedge portfolio at the valuation date.
5. Consider the following questions on the pricing of options on the stock of ARB Inc.:
   a. A share of ARB stock sells for $75 and has a standard deviation of returns equal to 20 percent per year. The current risk-free rate is 9 percent and the stock pays two dividends: (1) a $2 dividend just prior to the option’s expiration day, which is 91 days from now (i.e., exactly one-quarter of a year), and (2) a $2 dividend 182 days from now (i.e., exactly one-half year). Calculate the Black-Scholes value for a European-style call option with an exercise price of $70.
   b. What would be the price of a 91-day European-style put option on ARB stock having the same exercise price?
   c. Calculate the change in the call option’s value that would occur if ARB’s management suddenly decided to suspend dividend payments and this action had no effect on the price of the company’s stock.
   d. Briefly describe (without calculations) how your answer in Part a would differ under the following separate circumstances: (1) the volatility of ARB stock increases to 30 percent, and (2) the risk-free rate decreases to 8 percent.
6. Consider the following data relevant to valuing a European-style call option on a non-dividend-paying stock: \( X = 40 \), \( RFR = 9 \) percent, \( T = \) six months (i.e., 0.5), and \( \sigma = 0.25 \).
   a. Compute the Black-Scholes option and hedge ratio values for the series of hypothetical current stock price levels shown in Exhibit 22.12.
   b. Explain why the values in Part a differ from those shown in Exhibit 22.12.
   c. For \( S = 40 \), calculate the Black-Scholes value for a European-style put option. How much of this value represents time premium?
7. Suppose the current value of a popular stock index is 653.50 and the dividend yield on the index is 2.8 percent. Also, the yield curve is flat at a continuously compounded rate of 5.5 percent.
   a. If you estimate the volatility factor for the index to be 16 percent, calculate the value of an index call option with an exercise price of 670 and an expiration date in exactly three months.
   b. If the actual market price of this option is $17.40, calculate its implied volatility coefficient.
   c. Besides volatility estimation error, explain why your valuation and the option’s traded price might differ from one another.
8. Consider the following price data for TanCo stock in two different subperiods:
   \textit{Subperiod A:} 168.375; 162.875; 162.5; 161.625; 160.75; 157.75; 157.25; 157.75; 161.125; 162.5; 157.5; 156.625; 157.875; 155.375; 150.5; 153.75; 154.25; 155.875; 156; 152.75; 150.5; 150.75
   \textit{Subperiod B:} 122.5; 124.5; 121.875; 120.625; 119.5; 118.125; 117.75; 119.25; 122.25; 121.625; 120; 117.75; 118.375; 115.625; 117.75; 117.5; 118.5; 117.625; 114.625; 110.75
   a. For each subperiod, calculate the annualized historical measure of stock volatility that could be used in pricing an option for TanCo. In your calculations, you may assume that there are 250 trading days in a year.
   b. Suppose now that you decide to gather additional data for each subperiod. Specifically, you obtain information for a call option with a current price of $12.25 and the following characteristics: \( X = 115 \); \( S = 120.625 \); time to expiration = 62 days; \( RFR = 7.42 \) percent; and dividend yield = 3.65 percent. Here the risk-free rate and dividend yields are stated on an annual basis. Use the volatility measure from Subperiod B and the Black-Scholes model to obtain the “fair value” for this call option. Based on your calculations, is the option currently priced as it should be? Explain.
In March, a derivatives dealer offers you the following quotes for June British pound option contracts (expressed in U.S. dollars per GBP):

<table>
<thead>
<tr>
<th>Contract</th>
<th>Strike Price</th>
<th>Bid</th>
<th>Offer</th>
</tr>
</thead>
<tbody>
<tr>
<td>Call</td>
<td>USD 1.40</td>
<td>0.0642</td>
<td>0.0647</td>
</tr>
<tr>
<td>Put</td>
<td></td>
<td>0.0255</td>
<td>0.0260</td>
</tr>
<tr>
<td>Call</td>
<td>USD 1.44</td>
<td>0.0417</td>
<td>0.0422</td>
</tr>
<tr>
<td>Put</td>
<td></td>
<td>0.0422</td>
<td>0.0427</td>
</tr>
<tr>
<td>Call</td>
<td>USD 1.48</td>
<td>0.0255</td>
<td>0.0260</td>
</tr>
<tr>
<td>Put</td>
<td></td>
<td>0.0642</td>
<td>0.0647</td>
</tr>
</tbody>
</table>

a. Assuming each of these contracts specifies the delivery of GBP 31,250 and expires in exactly three months, complete a table similar to the following (expressed in dollars) for a portfolio consisting of the following positions:

1. Long one 1.44 call
2. Short one 1.48 call
3. Long one 1.40 put
4. Short one 1.44 put

<table>
<thead>
<tr>
<th>June USD/GBP</th>
<th>Net Initial Cost</th>
<th>Call 1.44 Profit</th>
<th>Call 1.48 Profit</th>
<th>Put 1.40 Profit</th>
<th>Put 1.44 Profit</th>
<th>Net Profit</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.36</td>

</tr>
<tr>
<td>1.48</td>
<td>—</td>
<td>—</td>
<td>—</td>
<td>—</td>
<td>—</td>
<td>—</td>
</tr>
<tr>
<td>1.52</td>
<td>—</td>
<td>—</td>
<td>—</td>
<td>—</td>
<td>—</td>
<td>—</td>
</tr>
</tbody>
</table>

b. Graph the total net profit (i.e., cumulative profit less net initial cost, ignoring time value considerations) relationship using the June USD/GBP rate on the horizontal axis (be sure to label the breakeven point(s)). Also, comment briefly on the nature of the currency speculation represented by this portfolio.

c. If in exactly one month (i.e., in April) the spot USD/GBP rate falls to 1.385 and the effective annual risk-free rates in the United States and England are 5 percent and 7 percent, respectively, calculate the equilibrium price differential that should exist between a long 1.44 call and a short 1.44 put position. (Hint: Consider what sort of forward contract this option combination is equivalent to and treat the British interest rate as a dividend yield.)

10. Melissa Simmons is the chief investment officer of a hedge fund specializing in options trading. She is currently back-testing various option trading strategies that will allow her to profit from large fluctuations—either up or down—in a stock’s price. An example of such typical trading strategy is straddle strategy that involves the combination of a long call and a long put with an identical strike price and time to maturity. She is considering the following pricing information on securities associated with Friendwork, a new Internet start-up hosting a leading online social network:

Friendwork stock: $100
Call option with an exercise price of $100 expiring in one year: $9
Put option with an exercise price of $100 expiring in one year: $8
a. Use the above information on Friendwork and draw a diagram showing the net profit/loss position at maturity for the straddle strategy. Clearly label on the graph the break-even points of the position.

b. Melissa’s colleague proposes another lower-cost option strategy that would profit from a large fluctuation in Friendwork’s stock price:

Long call option with an exercise price of $110 expiring in one year: $6
Long put option with an exercise price of $90 expiring in one year: $5

Similar to Part a, draw a diagram showing the net profit/loss position for the above alternative option strategy. Clearly label on the graph the break even points of the position.

11. In mid-May, there are two outstanding call option contracts available on the stock of ARB Co.:

<table>
<thead>
<tr>
<th>Call #</th>
<th>Exercise Price</th>
<th>Expiration Date</th>
<th>Market Price</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>$50</td>
<td>August 19</td>
<td>$8.40</td>
</tr>
<tr>
<td>2</td>
<td>60</td>
<td>August 19</td>
<td>3.34</td>
</tr>
</tbody>
</table>

a. Assuming that you form a portfolio consisting of one Call #1 held long and two Calls #2 held short, complete the following table showing your intermediate steps. In calculating net profit, be sure to include the net initial cost of the options.

<table>
<thead>
<tr>
<th>Price of ARB Stock at Expiration ($)</th>
<th>Profit on Call #1 Position</th>
<th>Profit on Call #2 Position</th>
<th>Net Profit on Total Position</th>
</tr>
</thead>
<tbody>
<tr>
<td>40</td>
<td>—</td>
<td>—</td>
<td>—</td>
</tr>
<tr>
<td>45</td>
<td>—</td>
<td>—</td>
<td>—</td>
</tr>
<tr>
<td>50</td>
<td>—</td>
<td>—</td>
<td>—</td>
</tr>
<tr>
<td>55</td>
<td>—</td>
<td>—</td>
<td>—</td>
</tr>
<tr>
<td>60</td>
<td>—</td>
<td>—</td>
<td>—</td>
</tr>
<tr>
<td>65</td>
<td>—</td>
<td>—</td>
<td>—</td>
</tr>
<tr>
<td>70</td>
<td>—</td>
<td>—</td>
<td>—</td>
</tr>
<tr>
<td>75</td>
<td>—</td>
<td>—</td>
<td>—</td>
</tr>
</tbody>
</table>

b. Graph the net profit relationship in Part a, using stock price on the horizontal axis. What is (are) the break even stock price(s)? What is the point of maximum profit?

c. Under what market conditions will this strategy (which is known as a call ratio spread) generally make sense? Does the holder of this position have limited or unlimited liability?

12. In developing the butterfly spread position, we showed that it could be broken down into two call option money spreads. Using the price data for SAS stock options from Exhibit 22.17, demonstrate how a butterfly profit structure similar to that shown in Exhibit 22.30 could be created using put options. Be specific as to the contract positions involved in the trade and show the expiration date net payoffs for the combined transaction.
CHAPTER 23
Swap Contracts,Convertible Securities, and Other Embedded Derivatives

After you read this chapter, you should be able to answer the following questions:

- What are forward rate agreements, and how can they be used to reduce the interest rate exposure of a borrower or an investor?
- What are interest rate swaps, and how can they transform the cash flows of a fixed or floating rate security?
- How does the swap market operate, and how are swap contracts quoted and priced?
- How are interest rate swaps valued?
- What are interest rate caps and floors, and how are they related to interest rate swaps?
- How can the swap contracting concept be adapted to manage equity price risk and credit risk?
- How do the derivatives in convertible securities and warrant issues differ from traditional exchange-traded products?
- What are the similarities and differences between convertible preferred stock and convertible bonds?
- What are structured notes, and what factors make their existence possible?
- How can securities with embedded derivatives reduce the funding cost of a corporate borrower?
- What are real options, and how can an investor use them to value company flexibility?

The preceding chapters have shown that forwards and options can be used in a virtually unlimited number of situations by simply changing the contract terms or the nature of the underlying asset. In this chapter, we discuss several more ways in which these instruments can be modified. Invariably, these modifications involve combining derivatives with other assets or liabilities to create the most highly valued cash flow pattern. We look at two general approaches to forming these combinations: “packages” of derivatives, such as interest rate swaps, caps, and floors; and derivatives that have been “embedded” in more fundamental assets, such as equity or debt issues.

To begin, we consider the market for OTC interest rate agreements—one of the fastest-growing segments of the derivatives industry in the past 30 years. We once again focus on the differences between forward-based and option-based agreements while exploring the connection between the two. We then extend our discussion of swap contracting to include agreements based on equity price movements and credit risk events. Next, we provide an overview of the myriad ways in which forwards and options are incorporated into other financial instruments, including convertible securities, warrants, and structured notes. These innovations allow investors to acquire various exposures (e.g., interest rate, currency, equity, or commodity price risk) in a creative and cost-effective manner. We conclude with a discussion of how investors can value the options embedded in real assets.
23.1 OTC INTEREST RATE AGREEMENTS

An extremely active OTC market exists for products designed to manage an investor’s or an issuer’s interest rate risk. In describing strategies involving these instruments, it is useful to classify them as either forward-based or option-based contracts.¹

23.1.1 Forward-Based Interest Rate Contracts

Forward Rate Agreements The forward rate agreement (FRA) is the most basic of the OTC interest rate contracts. Two parties agree today to a future exchange of cash flows based on two different interest rates. One of the cash flows is tied to a yield that is fixed at the deal’s origination (the fixed rate); the other is determined at some later date (the floating rate). On the contract’s settlement date, the difference between the two interest rates is multiplied by the FRA’s notional principal and prorated to the length of the holding period. The London Interbank Offer Rate (LIBOR) is frequently used as the floating rate index, making FRAs the OTC equivalent of the Eurodollar futures contracts.

An FRA’s settlement date and maturity are defined by its name: A 3 × 6 FRA allows the investor to lock in three-month LIBOR, three months forward; a 12 × 18 FRA locks in six-month LIBOR, one year forward. FRA market makers quote a bid-offer spread on a rate basis. Suppose the FRA rates for three-month LIBOR shown in Exhibit 23.1 prevail in the market at Date 0, with current three-month LIBOR assumed to be 4.50 percent. This means that on a 3 × 6 FRA, the market maker is prepared to pay a fixed rate of 4.81 percent for receipt of three-month LIBOR and to receive a fixed rate of 4.83 percent for payment of LIBOR. In either case, there will be no payment until LIBOR is revealed in Month 3. Settlement can then be made in arrears at Month 6 or in advance at Month 3. If in arrears, the settlement flow will be adjusted to the actual number of days in the holding period and calculated by the following formula:

\[
\text{Payment} = \text{Notional Principal} \times \frac{\text{LIBOR} - \text{Fixed Rate}}{360} \times \frac{\text{Number of Days}}{360}
\]

recalling that, in the U.S. market, LIBOR is based on a 360-day year. The advance settlement amount is calculated as the present value of the in-arrears amount, using the prorated level of the realized LIBOR as the discount rate. This settlement occurs on a net basis, with only a single check for the rate differential being written.

To see how FRAs are used, assume that Company Z decides to borrow financial capital for a six-month period, in two three-month installments. Thus, the firm finds itself exposed to

movements in six-month LIBOR.

In that case, several exposure dates would need to be hedged, which could be accomplished with a series of FRAs. For example, suppose that an investor holding a one-year FRN paying quarterly coupons of three-month LIBOR becomes concerned that rates may fall in the future, thereby depressing the level of her last three coupons. By convention, her first coupon, payable in three months, is based on current LIBOR, which was assumed to be 4.50 percent. She offsets this exposure by agreeing to receive the fixed rate on three separate FRA contracts: the 3 × 6, the 6 × 9, and the 9 × 12. Given the bid rates quoted in Exhibit 23.1, these positions transform the cash flows on the floating-rate asset as shown in Exhibit 23.3.

This series of FRAs locks in the coupon levels, but they are at different fixed rates and require three separate contracts. However, the investor might prefer a single contract that covers all the

870 Part 6: Derivative Security Analysis

As we discussed briefly in Chapter 17, a floating (or variable) rate note is a debt instrument that is similar to a fixed-income bond in that it pays coupons at regular (e.g., semiannual) dates during its life. The difference is that the floating-rate note, or FRN, pays a coupon that is adjusted with changes in some reference rate (e.g., reset the coupon every six months at LIBOR + 0.50 percent). Do not confuse the two acronyms FRA and FRN: The former is an over-the-counter forward contract; the latter is a bond.

rising interest rates over the next three months because the level of its second interest payment will not be established until the end of that period. (The amount of Company Z’s first three-month payment would be known at origination.) The firm can acquire a 3 × 6 FRA whereby it pays the dealer’s quoted fixed rate of 4.83 percent in exchange for receiving three-month LIBOR at the settlement date. This is illustrated on the right-hand side of Exhibit 23.2, which depicts both the borrowing and the derivative transactions.

Once the dealer has committed to the FRA with Company Z, two things occur. First, Company Z is no longer exposed to a rising funding cost because it now has a forward contract that obligates the dealer to “sell” the LIBOR it needs in Month 3 at a “price” of 4.83 percent. Second, the dealer is now exposed to rising LIBOR because it will be obligated to make the net settlement payment if LIBOR exceeds 4.83 percent three months from now. Company Z has effectively used the FRA to transfer its interest rate exposure to the dealer. That exposure can be hedged by “buying” LIBOR from another counterparty for its bid rate of 4.81 percent. This is shown on the left-hand side of Exhibit 23.2 as a second FRA with Company Y, which is assumed to be an investor in a variable-rate asset who is naturally concerned about falling rates.

Now suppose that three-month LIBOR is 5.00 percent on the rate-determination date in Month 3, and that the agreements with Companies Y and Z were negotiated to have a notional principal of $10 million. If its contract specified settlement in arrears at Month 6, Company Y would be obligated to pay the market maker $4,750, calculated as:

\[
[0.0500 - 0.0481] \times [10,000,000] \times \left(\frac{90}{360}\right)
\]

assuming there are 90 days between Months 3 and 6. If settled in advance, the Month 3 payment would be:

\[
4,750 \times \left(1 + \frac{90 \times 0.0500}{360}\right) = 4,691.36
\]

Similarly, the payment from the dealer to Company Z would be $4,250 \([= (0.0500 - 0.0483) \times 10,000,000 \times (90/360)]\) in Month 6, or $4,197.53 if accelerated to Month 3. By matching the FRAs, the market maker is fully hedged from interest rate risk. Its spread of two basis points, which translates into $500, compensates for the costs (e.g., transaction costs, credit risk) of making a market in these contracts.

**Interest Rate Swaps** Both investors and borrowers are routinely exposed to interest rate movements at regular intervals over an extended period of time, such as with a floating-rate note (FRN) that resets its coupon rate twice annually for several years according to

---

**Exhibit 23.2 A Matched Pair of 3 × 6 FRA Transactions**

- **Lenders**
movements in six-month LIBOR. In that case, several exposure dates would need to be hedged, which could be accomplished with a series of FRAs. For example, suppose that an investor holding a one-year FRN paying quarterly coupons of three-month LIBOR becomes concerned that rates may fall in the future, thereby depressing the level of her last three coupons. By convention, her first coupon, payable in three months, is based on current LIBOR, which was assumed to be 4.50 percent. She offsets this exposure by agreeing to receive the fixed rate on three separate FRA contracts: the 3 × 6, the 6 × 9, and the 9 × 12. Given the bid rates quoted in Exhibit 23.1, these positions transform the cash flows on the floating-rate asset as shown in Exhibit 23.3.

This series of FRAs locks in the coupon levels, but they are at different fixed rates and require three separate contracts. However, the investor might prefer a single contract that covers all the

---

2As we discussed briefly in Chapter 17, a floating (or variable) rate note is a debt instrument that is similar to a fixed-income bond in that it pays coupons at regular (e.g., semiannual) dates during its life. The difference is that the floating-rate note, or FRN, pays a coupon that is adjusted with changes in some reference rate (e.g., reset the coupon every six months at LIBOR + 0.50 percent). Do not confuse the two acronyms FRA and FRN: The former is an over-the-counter forward contract; the latter is a bond.
future coupon dates using the same fixed rate. This is exactly what an interest rate swap does; it can be viewed as a prepackaged series of LIBOR forward contracts (i.e., FRAs) at the same fixed rate. For the swap and FRA markets to remain efficient, the single fixed rate on the swap would have to be the appropriate average of 4.50 percent, 4.81 percent, 5.20 percent, and 5.64 percent. For simplicity, assume that each quarterly settlement period is exactly 0.25 year. This average can be approximated by solving for the internal rate of return on the hedged FRN:

$$100 = \frac{4.50 \times 0.25}{(1 + IRR)^1} + \frac{4.81 \times 0.25}{(1 + IRR)^2} + \frac{5.20 \times 0.25}{(1 + IRR)^3} + \frac{100 + [5.64 \times 0.25]}{(1 \times IRR)^4}$$

or $IRR = 1.258$ percent. Thus, 5.03 percent (1.258 × 4) would be the fixed rate on a one-year, receive-fixed swap consistent with the forward rate agreements listed in Exhibit 23.1. This IRR calculation is a very accurate approximation for the forward rate annuitization process we saw in Chapter 21. A more general way to determine the swap fixed rate (SFR) that represents the appropriate average of this sequence of spot and forward LIBOR would be to solve the following equation:

$$\left( \frac{4.50}{4} \right)(0.25)(NP) + \left( \frac{4.81}{4} \right)(0.25)(NP) + \left( \frac{5.20}{4} \right)(0.25)(NP) + \left( \frac{5.64}{4} \right)(0.25)(NP)$$

$$= \frac{(SFR)(0.25)(NP)}{1 + \frac{i_{0.25}}{4}} + \frac{(SFR)(0.25)(NP)}{1 + \frac{i_{0.6}}{4}} + \frac{(SFR)(0.25)(NP)}{1 + \frac{i_{0.9}}{4}} + \frac{(SFR)(0.25)(NP)}{1 + \frac{i_{0.12}}{4}}$$

where $NP$ is the swap’s notional principal and $i_{0.25}$ is the spot discount rate for a cash flow received or paid at a date $t$ months in the future. For a given interest rate term structure and contract notional principal, SFR is the only unknown element in this equation and can be solved for accordingly; see Bansal, Ellis, and Marshall (1993) and Brooks (1997).

Interest rate swaps are quoted using the Treasury bond yield curve. That is, the fixed rate side of a U.S. dollar-based swap generally is broken down to two components for trading purposes: (1) the yield of a Treasury bond with a maturity comparable to that of the swap, and (2) a risk premium term known as the swap spread. Exhibit 23.4 lists a representative set of fixed-rate quotes from a recent market period for U.S. dollar swaps, both in absolute and in swap spread terms. Each of the swaps represented in this exhibit assumes semiannual settlement dates with six-month LIBOR as the floating rate. For example, the swap dealer would be willing to receive the fixed rate of 4.720 percent on a five-year contract, a rate that is 65.90 basis points greater than the five-year T-bond yield.

With the fixed rate on the swap linked to a bond (i.e., 30/360 day count) yield and the floating rate as a money market (i.e., actual/360 day count in the U.S. market) yield, the swap settlement cash flows are calculated in a slightly different manner than for FRAs. While the swap is still a net settlement contract, the Date $t$ fixed- and floating-rate payments are determined separately as:

$$(\text{Fixed-Rate Payment})_t = (\text{Swap Fixed Rate}) \times \left( \frac{\text{Number of “30/360” Days}}{360} \right) \times (\text{Notional Principal})$$

and

$$(\text{Floating-Rate Payment})_t = (\text{Reference Rate})_{t-1} \times \left( \frac{\text{Number of Days}}{360} \right) \times (\text{Notional Principal})$$

In these equations, the fixed rate never changes and the floating-rate reference rate (i.e., LIBOR) always is determined at the beginning of a given settlement period.
illiquid bond. The net annualized cash flow he will receive after accounting for the swap position will be (again ignoring day count differentials):

\[
\text{Fixed-Rate Bond Coupon Receipt} = 4.800\% \\
\text{Swap: (1) LIBOR Receipt} = \text{LIBOR} \\
\text{(2) Fixed Payment} = 4.546\%
\]

Net Interest Income:
\[
= \text{LIBOR} + 0.254\%
\]

Thus, the net impact of combining the swap with the fixed-rate bond is to convert that security into a variable-rate asset paying a coupon of LIBOR plus 25.4 basis points.

Counterparty A is effectively paying the fixed-rate coupons he receives from his bond in exchange for receiving floating-rate coupons. That is, the pay-fixed swap position is equivalent to holding a portfolio consisting of (1) a long position in a par-value FRN paying semiannual coupons of LIBOR, and (2) a short position in a par-value fixed-rate note paying semiannual coupons of 4.546 percent. This capital market interpretation is illustrated in Exhibit 23.7. By essentially buying and selling two different par-value instruments, no net principal amount exists at origination or maturity; this is what allows the swap’s principal to be notional. Thus, all the swap agreement really does is transform the nature of the coupon payments.

Assume that Counterparty A is an institutional investor who currently holds a three-year bond paying a semiannual coupon of 4.80 percent. He feels that interest rates are likely to rise in the near term and decides to convert his investment into a synthetic floating-rate note whose coupons will rise with future LIBOR increases. He accomplishes this by agreeing to pay the fixed rate on a three-year interest rate swap contract with Counterparty B (i.e., the swap dealer). The terms of this agreement can be summarized as follows:

- Origination date: October 23, Year 0
- Maturity date: October 23, Year 3
- Notional principal: $30 million
- Fixed-rate payer: Counterparty A (i.e., the investor)
- Swap fixed rate: 4.546 percent (semiannual, 30/360 bond basis)
- Fixed-rate receiver: Counterparty B (i.e., the swap dealer)
- Floating rate: Six-month LIBOR (money market basis)
- Settlement dates: October 23 and April 23
- LIBOR determination: Set in advance, paid in arrears

This “fixed-for-floating” transaction—the most basic form of a swap—is often called a plain vanilla agreement. Exhibit 23.5 illustrates the approximate effect (ignoring slight day count differentials) of combining the swap with the underlying bond position, while Exhibit 23.6 lists the precise settlement cash flows from the investor’s perspective for a hypothetical time series of six-month LIBOR. In this agreement, the fixed-rate payer makes the net settlement payment when the day count-adjusted level of LIBOR is less than 4.546 percent; the fixed-rate receiver makes the settlement payment when LIBOR exceeds 4.546 percent.

Plain vanilla swaps are generally used for the same reason as FRAs: to restructure the cash flows of an interest-sensitive asset or liability. In this example, the investor has reduced the price sensitivity (i.e., duration) of his asset by converting the fixed-rate coupon into one that adjusts to shifting market conditions without having to actually sell what might be a highly
With this interpretation, at any point in time, the value of the pay-fixed swap position can be calculated as the present value of the floating-rate cash flows held as an asset minus the present value of the fixed-rate bond cash flow that is a liability, or:

\[
(PV_{\text{of Pay-Fixed Swap}}) = (PV_{\text{of FRN Paying LIBOR}}) - (PV_{\text{of Fixed-Rate Bond Paying 4.546%}}).
\]

Suppose that one year after this swap was originated, yields have generally risen so that the fixed rate on a new two-year swap (i.e., the remaining time until the original maturity) is 5.546 percent. The contract’s value under these conditions can be established in two steps. First, on any settlement date, the FRN will be valued at par, since its coupon always is reset according to current market conditions. Second, the market value of a bond paying a coupon of only 4.546 percent will fall, which benefits Counterparty A, to whom this is a liability. Using the new swap rate as a discount factor, A’s position in the agreement (which had no value at origination) is now worth:

\[
100 - X_{4t=1} \left( \frac{4.546}{2} \right) \left( 1 + 0.05546\% \right)^t + 100 \left( 1 + 0.05546\% \right)^4 \approx 1.8687
\]

or 1.8687 percent of notional principal. Therefore, if Counterparty A chose to unwind his contract at this time, the dealer would be willing to pay as much as $560,610 (= 0.018687 × $30 million) and then find a new swap counterparty who would pay the now current fixed rate of 5.546 percent. The $560,610 is considered to be the marked-to-market value of the swap. Given that interest rates have risen since inception, the original contract is now an asset to the fixed-rate payer (i.e., Counterparty A) and a liability to the fixed-rate receiver (i.e., the dealer).

The fact that the swap agreement becomes an asset to one participant and a liability to the other as soon as market conditions change means that swaps entail credit risk. Consider what would happen to Counterparty A if, on a particular settlement date when LIBOR was 8 percent, the swap dealer was unable to make the net settlement payment. In that case, the investor would receive only the 4.8 percent coupon from his bond rather than the 8.254 percent (= LIBOR + 0.254 percent) coupon he expected from his synthetic FRN. This means that the synthetic

With this interpretation, at any point in time, the value of the pay-fixed swap position can be calculated as the present value of the floating-rate cash flows held as an asset minus the present value of the fixed-rate cash flow that is a liability, or:

\[
(PV \text{ of Pay-Fixed Swap}) = (PV \text{ of FRN Paying LIBOR}) - (PV \text{ of Fixed-Rate Bond Paying 4.546%})
\]

Suppose that one year after this swap was originated, yields have generally risen so that the fixed rate on a new two-year swap (i.e., the remaining time until the original maturity) is 5.546 percent. The contract’s value under these conditions can be established in two steps. First, on any settlement date, the FRN will be valued at par, since its coupon always is reset according to current market conditions. Second, the market value of a bond paying a coupon of only 4.546 percent will fall, which benefits Counterparty A, to whom this is a liability. Using the new swap rate as a discount factor, A’s position in the agreement (which had no value at origination) is now worth:

\[
100 - \left[ \sum_{t=1}^{4} \frac{(4.546/2)}{(1 + 0.05546/2)^t} + \frac{100}{(1 + 0.05546/2)^4} \right] = 1.8687
\]

or 1.8687 percent of notional principal. Therefore, if Counterparty A chose to unwind his contract at this time, the dealer would be willing to pay as much as $560,610 (= 0.018687 × $30 million) and then find a new swap counterparty who would pay the now current fixed rate of 5.546 percent. The $560,610 is considered to be the marked-to-market value of the swap. Given that interest rates have risen since inception, the original contract is now an asset to the fixed-rate payer (i.e., Counterparty A) and a liability to the fixed-rate receiver (i.e., the dealer).

The fact that the swap agreement becomes an asset to one participant and a liability to the other as soon as market conditions change means that swaps entail credit risk. Consider what would happen to Counterparty A if, on a particular settlement date when LIBOR was 8 percent, the swap dealer was unable to make the net settlement payment. In that case, the investor would receive only the 4.8 percent coupon from his bond rather than the 8.254 percent (= LIBOR + 0.254 percent) coupon he expected from his synthetic FRN. This means that the synthetic...
Consider a three-year, semiannual settlement, 8 percent cap on six-month LIBOR. The buyer of the cap pays the writer an up-front premium, quoted as a percentage of the notional principal. Assuming the cost is 120 basis points and the notional principal is $100 million, the cost of the cap is $1,200,000.

Suppose that settlement dates are on the 15th of May and November of each year and that LIBOR on one particular May 15th is 9.125 percent. The holder of the cap will receive settlement in arrears the following November in the amount of $575,000, calculated as \((9.125\% - 8\%) \times 100,000,000 \times (184/360)\).

The payoff relationships for caps and floors can be illustrated using traditional, option-style diagrams. Exhibit 23.8 portrays an 8 percent cap and a 4 percent floor on LIBOR. Notice that the payoff diagram for the cap looks like a typical call option on a commodity and the floor takes the form of a put option. Indeed, following the convention where LIBOR is the commodity, caps are referred to as "calls on LIBOR," and floors as "puts on LIBOR."

Collars
In Chapter 20, we saw that an equity collar arrangement consisted of a long position in an equity put option that was paid for with a short position in a call option on the same stock. Similarly, an interest rate collar is a combination of a cap and a floor, a long position in one and a short position in the other. Acquiring a 4 percent – 8 percent collar on LIBOR is

In practice, interest rate caps and floors are quoted by market makers on a volatility basis—for instance, 18.5 percent bid and 19.5 percent offered. That measure of volatility (stated as a standard deviation) plus the exercise rate, the current term structure of interest rates, and the time frame for the contract are then entered into an option pricing model to obtain the actual amount of the premium. Hull (2009) has shown that this amount can be established by adapting Black’s model for valuing futures options to price each separate option in the contract and then summing them across all settlement dates.

23.1.2 Option-Based Interest Rate Contracts
In this section, we discuss two types of OTC interest rate option arrangements as well as their relationship with interest rate swaps: (1) caps and floors, the most basic products, and (2) collars, special combinations of caps and floors.

**Caps and Floors** Interest rate cap and floor agreements are equivalent to portfolios of interest rate option contracts, each corresponding to a different settlement period. A cap agreement is a series of cash settlement interest rate options, typically based on LIBOR. The seller of the cap, in return for the option premium, is obliged to pay the difference between LIBOR and the exercise, or cap, rate (times the fraction of the year, times the notional principal) whenever that difference is positive. The seller of a floor agreement makes settlement payments only when LIBOR is below the floor rate. No payment is made if LIBOR is above the floor or below the cap rate. Settlement can be either in advance or in arrears, with the latter more common because these contracts usually are used to hedge exposure to floating-rate loans and notes that typically settle in arrears.

The Date \( t \) settlement payments on cap and floor agreements can be written as follows:

23.2 **Cap Settlement:** \((\text{Notional Principal}) \times \left(\frac{\text{Number of Days}}{360}\right) \times \max[\text{LIBOR}_{t-1} - X_c, 0]\) and

23.3 **Floor Settlement:** \((\text{Notional Principal}) \times \left(\frac{\text{Number of Days}}{360}\right) \times \max[X_f - \text{LIBOR}_{t-1}, 0]\)

where:
- \( X_c \) = the cap exercise rate
- \( X_f \) = the floor exercise rate

---

\(^3\)For interesting discussions of default risk in the swap market, see Sorensen and Bollier (1994) and Bornfim (2003).
Consider a three-year, semiannual settlement, 8 percent cap on six-month LIBOR. The buyer of the cap pays the writer an up-front premium, quoted as a percentage of the notional principal. Assuming the cost is 120 basis points and the notional principal is $100 million, the cost of the cap is $1,200,000. Suppose that settlement dates are on the 15th of May and November of each year and that LIBOR on one particular May 15th is 9.125 percent. The holder of the cap will receive settlement in arrears the following November in the amount of $575,000, calculated as (9.125 percent − 8 percent) × $100 million × (184/360).

The payoff relationships for caps and floors can be illustrated using traditional, option-style diagrams. Exhibit 23.8 portrays an 8 percent cap and a 4 percent floor on LIBOR. Notice that the payoff diagram for the cap looks like a typical call option on a commodity and the floor takes the form of a put option. Indeed, following the convention where LIBOR is the commodity, caps are referred to as “calls on LIBOR,” and floors as “puts on LIBOR.”

**Collars** In Chapter 20, we saw that an equity collar arrangement consisted of a long position in an equity put option that was paid for with a short position in a call option on the same stock. Similarly, an interest rate collar is a combination of a cap and a floor, a long position in one and a short position in the other. Acquiring a 4 percent–8 percent collar on LIBOR is
rate. This relationship is known as cap-floor-swap parity and is equivalent to the put-call-forward parity formula first discussed in Chapter 20 and extended to the range forward strategy in Chapter 22. Yaksick (1992) explains how this parity relationship allows the option valuation models discussed in Chapter 22 to be used in the valuation of swap contracts.

23.2 SWAP CONTRACTING EXTENSIONS

Although interest rate swaps are by far the most prevalent OTC rate contract, other extensions that are important for portfolio managers have been developed as well. All these variations preserve the essential feature of a swap contract by exchanging cash flows based on two different rates or prices. We will examine two such agreements in detail.

23.2.1 Equity Index-Linked Swaps

Equity-index-linked swaps, or equity swaps, are equivalent to portfolios of forward contracts calling for the exchange of cash flows based on two different investment rates: (1) a variable-debt rate (e.g., three-month LIBOR) and (2) the return to an equity index (e.g., Standard & Poor's 500). The index-linked payment is based on either the total return (i.e., dividends plus capital gain or loss) or just the percentage index change for the settlement period plus a fixed spread adjustment. The floating-rate payments typically are based on LIBOR flat (i.e., no adjustment). Equity swaps are traded in the OTC markets and can have maturities out to 10 years or beyond.

In addition to the S&P 500, equity swaps can be structured around foreign indexes, such as TOPIX (Japan), FT-SE 100 (Great Britain), DAX (Germany), CAC 40 (France), TSE 35 (Canada), and Hang Seng (Hong Kong). These agreements also can be designed so that the cash flows are denominated in the same currency or in two different currencies. The equity-index-based cash flow typically is denominated in the currency of the index's country of origination, but this payment can be automatically hedged into a different currency. Further, these agreements specify a notional principal that is not exchanged at origination but serves the purpose of converting percentage returns into cash flows. This notional principal can be either variable or fixed during the life of the agreement, but the same notional principal applies to both sides of the transaction.

As Allen and Showers (1991) and Chance (2004) noted, the equity swap market has developed for several reasons. First, these agreements allow investors to take advantage of overall price movements in a specific country's stock market without having to purchase the equity securities directly. This has the advantage of reducing both the transaction costs and the tracking errors associated with assembling a portfolio that mimics the index as well as avoiding dividend withholding taxes. Second, creating a direct equity investment in a foreign country may be difficult for some investors where prohibited by law or policy. Finally, an investment fund wanting to accumulate foreign index returns denominated in their domestic currency may not be able or legally permitted to obtain sufficient exchange-traded derivative contracts to hedge a direct equity investment. The equity swap can be structured so that there is no need for separate hedging transactions.

The most common application for an equity swap involves a counterparty that receives the index-based payment in exchange for making the floating-rate payment. Consider a pension fund that currently has a substantial portion of its asset portfolio invested in floating-rate notes paying quarterly coupons based on LIBOR. If the fund manager wants to alter her existing asset allocation by converting some of this debt into equity, she has two ways to do so. First, she can sell the existing floating-rate notes and purchase a portfolio of stock directly in the market. Alternatively, the manager can enter into an equity swap with an initial notional principal equal to the amount of the existing debt holdings she wants to convert. From the standpoint of reducing transaction costs, the second alternative is clearly preferable. The mechanics of this arrangement are illustrated in Exhibit 23.10.

To summarize, buying a 6 percent cap and writing a 6 percent floor on LIBOR are equivalent in terms of settlement cash flows to an interest rate swap paying a fixed rate of 6 percent and receiving LIBOR. When LIBOR is above 6 percent, the net settlement receipt on the swap is the same as the receipt on the in-the-money cap that is owned. When LIBOR is below 6 percent, the net settlement payment on the swap is the same as the payment on the in-the-money floor that has been sold. Similarly, writing a cap and buying a floor at the same exercise rate are identical to a receive-fixed interest rate swap. A cap-floor combination at the same exercise rate always has the same payoffs as a swap contract. However, only when the combination also nets to a zero initial cost does that common rate match the prevailing swap fixed
rate. This relationship is known as cap-floor-swap parity and is equivalent to the put-call-forward parity formula first discussed in Chapter 20 and extended to the range forward strategy in Chapter 22. Yaksick (1992) explains how this parity relationship allows the option valuation models discussed in Chapter 22 to be used in the valuation of swap contracts.

### 23.2 Swap Contracting Extensions

Although interest rate swaps are by far the most prevalent OTC rate contract, other extensions that are important for portfolio managers have been developed as well. All these variations preserve the essential feature of a swap contract by exchanging cash flows based on two different rates or prices. We will examine two such agreements in detail.

#### 23.2.1 Equity Index-Linked Swaps

Equity-index-linked swaps, or **equity swaps**, are equivalent to portfolios of forward contracts calling for the exchange of cash flows based on two different investment rates: (1) a variable-debt rate (e.g., three-month LIBOR) and (2) the return to an equity index (e.g., Standard & Poor’s 500). The index-linked payment is based on either the total return (i.e., dividends plus capital gain or loss) or just the percentage index change for the settlement period plus a fixed spread adjustment. The floating-rate payments typically are based on LIBOR “flat” (i.e., no adjustment). Equity swaps are traded in the OTC markets and can have maturities out to 10 years or beyond.

In addition to the S&P 500, equity swaps can be structured around foreign indexes, such as TOPIX (Japan), FT-SE 100 (Great Britain), DAX (Germany), CAC 40 (France), TSE 35 (Canada), and Hang Seng (Hong Kong). These agreements also can be designed so that the cash flows are denominated in the same currency or in two different currencies. The equity-index-based cash flow typically is denominated in the currency of the index’s country of origination, but this payment can be automatically hedged into a different currency. Further, these agreements specify a notional principal that is not exchanged at origination but serves the purpose of converting percentage returns into cash flows. This notional principal can be either variable or fixed during the life of the agreement, but the same notional principal applies to both sides of the transaction.

As Allen and Showers (1991) and Chance (2004) noted, the equity swap market has developed for several reasons. First, these agreements allow investors to take advantage of overall price movements in a specific country’s stock market without having to purchase the equity securities directly. This has the advantage of reducing both the transaction costs and the tracking errors associated with assembling a portfolio that mimics the index as well as avoiding dividend withholding taxes. Second, creating a direct equity investment in a foreign country may be difficult for some investors where prohibited by law or policy. Finally, an investment fund wanting to accumulate foreign index returns denominated in their domestic currency may not be able or legally permitted to obtain sufficient exchange-traded derivative contracts to hedge a direct equity investment. The equity swap can be structured so that there is no need for separate hedging transactions.

The most common application for an equity swap involves a counterparty that receives the index-based payment in exchange for making the floating-rate payment. Consider a pension fund that currently has a substantial portion of its asset portfolio invested in floating-rate notes paying quarterly coupons based on LIBOR. If the fund manager wants to alter her existing asset allocation by converting some of this debt into equity, she has two ways to do so. First, she can sell the existing floating-rate notes and purchase a portfolio of stock directly in the market. Alternatively, the manager can enter into an equity swap with an initial notional principal equal to the amount of the existing debt holdings she wants to convert. From the standpoint of reducing transaction costs, the second alternative is clearly preferable. The mechanics of this arrangement are illustrated in Exhibit 23.10.
and Derivatives Association reported that by mid-2010 contracts exceeding $25 trillion in notional value were in place. These contracts cover exposures to credit markets throughout the world and include as end-users institutions ranging from banks and corporations to traditional asset managers and hedge funds. Hull (2009) provides a detailed examination of how these products are structured and valued.

One of the first attempts to provide credit risk protection in the derivatives market was the total return swap. These contracts provide for the periodic exchange of cash flows based on (1) a variable-debt rate (e.g., LIBOR) and (2) the total return (i.e., periodic interest and any capital gain or loss) to a reference entity specified by the agreement. The reference entity can be either a specific bond obligation or a portfolio (index) of bonds. When an individual security is designated as the reference entity, it is possible to design the total return swap to allow for physical delivery of the bond at maturity in exchange for a payment of the bond’s initial value. However, neither party in the swap transaction is required to own the reference entity, nor does the maturity or notional principal in the agreement need to match those of the underlying security.

The net return to the fund in this example is simply the return on the equity index plus the spread adjustment. Further, if the floating-rate notes yield more than LIBOR, this would increase the overall net return. Assuming both cash flows are denominated in the same currency, the net settlement payment on the equity swap from the company’s standpoint can be calculated as the difference between the variable-rate outflow and the equity-linked inflow, where:

\[
\text{23.4} \quad \text{Payment} = [\text{LIBOR} - \text{Spread}] \times [\text{Notional Principal}] \times \left[\frac{(\text{Number of Days})}{360}\right]
\]

and

\[
\text{Receipt} = \left[\frac{\text{Index}_{\text{new}} - \text{Index}_{\text{old}}}{\text{Index}_{\text{old}}}\right] \times [\text{Notional Principal}]
\]

where \(\text{Index}_{\text{new}}\) and \(\text{Index}_{\text{old}}\) represent the index levels occurring on the current and immediate past settlement dates, assuming all dividends are reinvested. To minimize calculations, the settlement payment is computed using \([\text{LIBOR} - \text{Spread}]\) rather than adding a separate inflow for the equity spread itself. Gastineau (1993) and Chance and Rich (1998) investigated indicative spread quotes for various indexes throughout the world and found that, while some were positive (e.g., 90 BP for DAX, 25 BP for FT-SE), others were negative (e.g., −10 BP for S&P 500, −60 BP for Hang Seng).

Another way to view this swap-based cash flow transformation is shown in Exhibit 23.11. It should be clear that equity swaps differ from interest rate swaps in one important way. Specifically, because there is no guarantee that the equity index will appreciate in value from one settlement period to the next, it is possible that the company receiving the equity index will have to make a double payment. First, the usual debt-related cash flow, based on LIBOR, will have to be paid. Second, whenever \(\text{Index}_{\text{new}}\) is less than \(\text{Index}_{\text{old}}\), the company will make an equity-index-based payment to (i.e., “receive” a negative payment from) its counterparty. Rather than netting one cash flow against the other, the company will pay both when the value of the equity index declines. (Examples of this situation are represented by the third and fifth payments in the exhibit.)

### 23.2.2 Credit-Related Swaps

One of the newest swap contracting extensions has been the development of agreements designed to help investors manage their credit risk exposures. From their introduction in the late 1990s, credit-related swaps have grown in popularity to where the International Swap
The top panel of Exhibit 23.12 illustrates how this agreement might be used to hedge credit risk. Suppose a fixed-income portfolio manager holds a bond issued by Company BAB in his portfolio, but he is concerned that the firm’s credit rating might be downgraded. In lieu of trying to sell what might be an illiquid position outright, he arranges an agreement whereby every quarter for the next five years (i.e., the remaining maturity of the BAB bond) he pays the interest received on the bond plus any gain or loss of principal and receives a cash flow based on LIBOR times the notional principal, which here is set equal to the face value of the reference bond. If BAB’s credit does not deteriorate during a given settlement period and interest rates in the market fall, the bond will appreciate in value but the manager will have to pay this capital gain, along with the interest from the bond, to the swap dealer in exchange for the LIBOR-based receipt. If BAB is downgraded—or if market rates increase for any other reason—the reference bond will experience a capital loss, which will reduce the manager’s swap payment. If the loss in value is severe enough, it could more than offset any interest income (i.e., a negative total return), which would lead to the swap dealer making a double payment, similar to what Exhibit 23.12

and Derivatives Association reported that by mid-2010 contracts exceeding $25 trillion in notional value were in place. These contracts cover exposures to credit markets throughout the world and include as end-users institutions ranging from banks and corporations to traditional asset managers and hedge funds. Hull (2009) provides a detailed examination of how these products are structured and valued.

One of the first attempts to provide credit risk protection in the derivatives market was the **total return swap**. These contracts provide for the periodic exchange of cash flows based on (1) a variable-debt rate (e.g., LIBOR) and (2) the total return (i.e., periodic interest and any capital gain or loss) to a reference entity specified by the agreement. The reference entity can be either a specific bond obligation or a portfolio (index) of bonds. When an individual security is designated as the reference entity, it is possible to design the total return swap to allow for physical delivery of the bond at maturity in exchange for a payment of the bond’s initial value. However, neither party in the swap transaction is required to own the reference entity, nor does the maturity or notional principal in the agreement need to match those of the underlying security.
The top panel of Exhibit 23.12 illustrates how this agreement might be used to hedge credit risk. Suppose a fixed-income portfolio manager holds a bond issued by Company BAB in his portfolio, but he is concerned that the firm’s credit rating might be downgraded. In lieu of trying to sell what might be an illiquid position outright, he arranges an agreement whereby every quarter for the next five years (i.e., the remaining maturity of the BAB bond) he pays the interest received on the bond plus any gain or loss of principal and receives a cash flow based on LIBOR times the notional principal, which here is set equal to the face value of the reference bond. If BAB’s credit does not deteriorate during a given settlement period and interest rates in the market fall, the bond will appreciate in value but the manager will have to pay this capital gain, along with the interest from the bond, to the swap dealer in exchange for the LIBOR-based receipt.

If BAB is downgraded—or if market rates increase for any other reason—the reference bond will experience a capital loss, which will reduce the manager’s swap payment. If the loss in value is severe enough, it could more than offset any interest income (i.e., a negative total return), which would lead to the swap dealer making a double payment, similar to what

happened with the equity swap when stock prices declined. Of course, the additional swap payment linked to a decline in value for the BAB reference bond simply offsets the loss that the manager experiences in his actual portfolio. Thus, the total return swap enables the manager to transfer the credit risk of holding the BAB bond to the counterparty by essentially “selling” that total exposure to the dealer via the swap agreement in exchange for “buying” a floating-rate note paying LIBOR.

One drawback of using total return swaps to manage credit risk is that they require cash flow exchanges for events—such as general interest rate movements—that have nothing to do with the default potential of the reference entity. A credit default swap (CDS) addresses this shortcoming by making the payment of any compensation for loss contingent on the actual occurrence of a credit-related event. This contingent payment makes the credit default contract closer in form to an insurance policy than a traditional swap agreement. As illustrated in the bottom panel of Exhibit 23.12, the protection buyer pays an annual premium in exchange for the protection seller’s obligation to make a settlement payment if a credit-related event occurs to the reference entity during the life of the swap. The range of credit-related events covered by a CDS agreement can be wide, but typically includes bankruptcy, failure to pay in a timely fashion, and a default-rating downgrade resulting from a corporate restructuring.

Suppose that the portfolio manager holding the BAB bond decides to hedge his credit exposure with a CDS agreement. Assume further that he owns $5 million in par value of a security that matures in five years and that the swap premium is 160 basis points. This means he will pay an annual protection premium to the swap dealer of $80,000 ( = 0.016 \times 5,000,000), usually in quarterly installments of $20,000. These payments continue until the expiration of the contract—assumed here to match the bond’s maturity—or until a credit event occurs. If, for instance, Company BAB does default after two years, the swap dealer will be obligated to either purchase the BAB bond from the portfolio manager at par value (i.e., physical settlement) or pay him the difference between par value and the post-default market value of the bond (i.e., cash settlement), depending on how the swap contract is structured. If BAB bonds trade at 31 percent of their par value after default, the settlement payment would be $3,450,000 ( = [1.00 - 0.31] \times 5,000,000). This credit-event contingent payment then cancels the remainder of the agreement. If no credit event occurs, the portfolio manager continues to make premium payments to the swap dealer and receives his invested principal back from Company BAB when the bond matures.

The bondholder in this example used the CDS contract to hedge his credit exposure to a specific bond by effectively paying the swap dealer to bear that risk for him. From the protection seller’s perspective, in the absence of any other offsetting agreements, the swap dealer is effectively speculating that Company BAB will not suffer a credit event before the expiration of the contract, allowing them to continue to collect the protection premium without having to make a contingency payment. If BAB’s credit quality improves during the life of the agreement, it is likely that the market value of the swap premium will decline in price—say, to 110 basis points—and the swap dealer can “sell” (i.e., unwind or transfer) the remainder of its existing contract at a profit.

Since any risky bond yield can be decomposed into (1) the yield for a risk-free bond with the same maturity, and (2) a credit spread (i.e., risk premium), it is easy to see that protection payer is using the CDS contract to transfer just the credit spread to the protection seller. That is, if the BAB bond does not default before maturity, the bond manager’s net return on that position should be the risk-free rate. This means that the CDS premium should be approximately equal to the difference between the par yield on the risk bond and the par yield on a Treasury bond with comparable maturity. Hull and White (2003), Greatrex (2009), and Benzschawel and Corlu (2011) demonstrate that this amount can be calculated from default probability estimates that allow for the estimation of the value of the cash flows expected to be paid by the risky bond. Exhibit 23.13 lists five-year CDS premium prices for a number of
The valuation of warrants is complicated by many factors, such as how and when the number of outstanding warrants will be exercised, what the company’s current capital structure looks like, and what the company plans to do with the new funds if and when the warrant is exercised. Galai and Schneller (1978) proposed a simple warrant valuation model in which a firm is presently financed with all equity and the warrants it issues are European-style. On its expiration date \( T \), the warrant will be worth:

\[
W_T = \max(V_T + N_w X - N - N_w, 0) / C_{20}/C_{21}
\]

where:

- \( N \) = the current number of outstanding shares
- \( N_w \) = the number of new shares created if the warrants are exercised
- \( V_T \) = the value of the firm before the warrants are exercised
- \( X \) = the exercise price

This terminal value can be rewritten as:

\[
W_T = \frac{1 + (N_w / N)}{C_{20}/C_{21}}
\]

where:

- \( C_T \) = the expiration date value of a regular call option with otherwise identical terms as the warrant

Consequently, at any point prior to expiration, the value of the warrant should be equal to the value of the call deflated (i.e., diluted) by the factor \( 1 + (N_w / N) \) - 1.

Frequently, a company will attach warrants to a bond issue to lower its initial funding cost. Warrants created in this manner usually can be detached from the debt instrument by the buyer and traded separately. Suppose a firm with 1,000,000 shares of common stock outstanding at a current share price of $100 attempts to raise an additional $10 million by issuing a 10-year bond paying annual coupons. The yield it would have to pay for a straight debt issue is 8.50 percent. The firm could lower this borrowing cost by attaching to the bond European-style equity warrants that mature in exactly one year and have an exercise price of $115 per share. If the firm eventually hopes to raise an additional $5.75 million with these warrants, it will have to create new derivative contracts to cover 50,000 shares ($5.75 million ÷ $115).

Assuming that the one-year risk-free rate is 7 percent and the volatility of the firm’s stock is 25 percent, the Black-Scholes value for a one-year call option to buy one share at \( X \) = $115 can be calculated as $7.09, meaning the warrants are worth $6.75 (= 7.09 ÷ \( [1 + (50,000 / 1,000,000)] \)) per share. If each warrant allows for the purchase of one share and the face value of a single bond is $1,000, the firm will issue 10,000 bonds with five warrants attached to each. Assuming that a coupon of 8.50 percent, the total proceeds it would generate from the sale of each bond with the warrants attached would be $1,033.75, or $1,000 for the bond and $33.75 (= 5 × $6.75) for the warrants. Thus, the firm can reduce its funding cost to 8.00 percent — the solution to the yield to maturity in the following bond calculation:

\[
\frac{1033.75}{X} = \frac{10}{85} \left( 1 + y \right)^{10} + \frac{1000}{1 + y}^{10}
\]

Packaging warrants with bonds can be done in a variety of ways. A recent trend in financial markets is for a firm to attach to its bonds an option that is based on an underlying asset other than the company’s own stock, such as foreign exchange and stock index transactions. For instance, Rogalski and Seward (1991) detail the development of the market for foreign

U.S. corporations as of April 2011. These data emphasize the wide range of spreads that can occur for firms with credit ratings ranging from A (e.g., 38.5 basis points for BellSouth) to CCC (e.g., 780.0 basis points for Boyd Gaming). As in other credit markets, CDS spreads increase dramatically for credit ratings that fall below investment grade status.

### 23.3 Warrants and Convertible Securities

A popular investment strategy in recent years has involved the creation of security “packages” in which derivatives are combined with more basic instruments, such as stock shares or bonds. In this section, we examine two important variations on this theme: (1) bonds with warrants that give the investor the right to buy additional shares of the company’s common stock, and (2) securities, such as debt or preferred stock, that the investor can convert into other securities.

#### 23.3.1 Warrants

A warrant is an equity call option issued directly by the company whose stock serves as the underlying asset. The key feature is that, if exercised, the company will create new shares of stock to give to the warrantholder. Thus, the exercise of a warrant will increase the total number of outstanding shares, which reduces the value of each individual share. Because of this dilutive effect, the warrant is not as valuable as an otherwise comparable call option contract.

The valuation of warrants is complicated by many factors, such as how and when the number of outstanding warrants will be exercised, what the company’s current capital structure looks like, and what the company plans to do with the new funds if and when the warrant is exercised.

Galai and Schneller (1978) proposed a simple warrant valuation model in which a firm is presently financed with all equity and the warrants it issues are European-style. On its expiration date \( T \), the warrant will be worth:

\[
W_T = \max \left\{ \frac{V_T + N_w X}{N + N_w} - X, 0 \right\}
\]

where:

- \( N \) = the current number of outstanding shares
- \( N_w \) = the number of new shares created if the warrants are exercised
- \( V_T \) = the value of the firm before the warrants are exercised
- \( X \) = the exercise price

This terminal value can be rewritten as:

\[
W_T = \left[ \frac{1}{1 + (N_w/N)} \right] C_T
\]

where:

- \( C_T \) = the expiration date value of a regular call option with otherwise identical terms as the warrant

Consequently, at any point prior to expiration, the value of the warrant should be equal to the value of the call deflated (i.e., diluted) by the factor \( [1 + (N_w/N)]^{-1} \).

Frequently, a company will attach warrants to a bond issue to lower its initial funding cost. Warrants created in this manner usually can be detached from the debt instrument by the buyer and traded separately. Suppose a firm with 1,000,000 shares of common stock outstanding at a current share price of $100 attempts to raise an additional $10 million by issuing a 10-year bond paying annual coupons. The yield it would have to pay for a straight debt issue is 8.50 percent. The firm could lower this borrowing cost by attaching to the bond European-style equity warrants that mature in exactly one year and have an exercise price of $115 per share. If the firm eventually hopes to raise an additional $5.75 million with these warrants, it will have to create new derivative contracts to cover 50,000 shares ($5.75 million ÷ $115).

Assuming that the one-year risk-free rate is 7 percent and the volatility of the firm’s stock is 25 percent, the Black-Scholes value for a one-year call option to buy one share at \( X = $115 \) can be calculated as $7.09, meaning the warrants are worth $6.75 (= 7.09 ÷ [1 + (50,000/1,000,000)]) per share. If each warrant allows for the purchase of one share and the face value of a single bond is $1,000, the firm will issue 10,000 bonds with five warrants attached to each. With an 8.50 percent coupon, the total proceeds it would generate from the sale of each bond with the warrants attached would be $1,033.75, or $1,000 for the bond and $33.75 (= 5 × $6.75) for the warrants. Thus, the firm can reduce its funding cost to 8.00 percent—the solution to the yield to maturity in the following bond calculation:

\[
1033.75 = \sum_{t=1}^{10} \frac{85}{(1 + y)^t} + \frac{1000}{(1 + y)^{10}}
\]

Packaging warrants with bonds can be done in a variety of ways. A recent trend in financial markets is for a firm to attach to its bonds an option that is based on an underlying asset other than the company’s own stock, such as foreign exchange and stock index transactions. For instance, Rogalski and Seward (1991) detail the development of the market for foreign
currency exchange warrants, which give the holder the right, but not the obligation, to purchase a fixed number of U.S. dollars for a price denominated in a foreign currency. Although called warrants, these contracts are closer in form to traditional call options on the dollar (or, equivalently, put options on the foreign currency) because they do not result in any direct change to the issuing firm’s capital structure. That is, no dilutive valuation effect exists for these derivatives since there are no new shares of stock issued. Beyond that, these instruments generally can be settled only in cash but can be detached and traded separately from the original bond.5

23.3.2 Convertible Securities
A convertible security gives its owner the right, but not the obligation, to convert the existing investment into another form. Typically, the original security is either a bond or a share of preferred stock, which can be exchanged into common stock according to a predetermined formula. A convertible security is a hybrid issue consisting of a regular bond or preferred stock holding and a call option that allows for the conversion. Similar to warrants, they have been popular with issuers because they generally lead to a lower initial borrowing cost and represent a future supply of equity capital. McGuire (1991) and Schmidt (2003) have noted that these securities help align managerial incentives and generate capital without immediately diluting the equity base of the acquiring firm. Investors in convertibles gain the upside potential of common stock while actually holding a less-risky asset.

23.3.3 Convertible Preferred Stock
Consider the dynamics of convertible preferred stock. As previously suggested, owning a share of convertible preferred is equivalent to holding a portfolio long in a normal share of preferred stock and long in a call option on the firm’s common stock that can be exercised by surrendering the preferred stock. There generally is no waiting period before the conversion can be made, and the conversion privilege usually never expires. This means that the minimum value of the convertible issue must be:

\[
\text{max} \{\text{Preferred Stock Value, Conversion Value}\}
\]

where the conversion value is the value of the common stock into which the preferred issue can be exchanged.

Suppose that for a $1,000,000 investment, an institutional investor could purchase 25,000 shares of a convertible preferred issue with the following terms (per share):

- Current convertible share price $40.00
- Annual convertible dividend $3.00
- Convertible yield 7.50% (= $3 ÷ $40)
- Regular preferred yield 10.00%
- Current common stock price $20.00
- Conversion ratio 1.75

With these conditions, the share value of a regular preferred stock issue paying a $3 dividend would be $30.00 (= 3 ÷ 0.10), or the perpetual dividend divided by the prevailing regular yield. This means that the convertible issue sells at a 33 percent premium to the regular preferred. Also, given the conversion ratio of 1.75 shares of common to each share of preferred, the conversion value of the convertible issue is $35 (= 1.75 × 20). Thus, the minimum price of the convertible security would be $35, the greater of the regular preferred price and the conversion

\[5\]

For additional information about how warrants are used in capital markets, see Francis, Toy, and Whittaker (2000) and Howe and Su (2001).
value. Since the market price of the convertible is above this level, this implies a **conversion premium** of 14.29 percent \(= (40 - 35) \div 35\), meaning that the convertible currently is selling based on its option value.

The future value of the convertible issue will depend on two events: (1) interest rate movements, which directly affect the yield on the regular preferred stock component, and (2) changes in common stock prices, given the 1.75 conversion ratio. Consider the matrix of minimum values for various levels of these two variables shown in Exhibit 23.14. In this situation, the value of the convertible preferred stock will likely be driven by its conversion value when interest rates and common stock prices are high and by its preferred stock value when rates and share prices are low.

### 23.3.4 Convertible Bonds

A convertible bond can be viewed as a prepackaged portfolio containing two distinct securities: a regular bond and an option to exchange the bond for a prespecified number of shares of the issuing firm’s common stock. Thus, a convertible bond represents a hybrid investment involving elements of both the debt and the equity markets. From the investor’s standpoint, there are both advantages and disadvantages to this packaging. Although the buyer receives equity-like returns with a “guaranteed” terminal payoff equal to the bond’s face value, he must also pay the option premium, which is embedded in the price of the security. Lummer and Riepe (1993) argue that the risk-return dynamics convertible bonds offer are sufficiently unique as to merit their own asset class. Arak and Martin (2005) note that the issuer of a convertible bond increases the company’s leverage while providing a potential source of equity financing in the future. Exhibit 23.15 shows a page from *Standard & Poor’s Bond Guide* summarizing details for a sample of these instruments.

Consider the 2.25 percent coupon convertible bonds issued by Best Buy (BBY), the consumer electronics retailer whose stock trades on the NYSE. The listing for this issue, which is scheduled to mature in January 2022, is highlighted in the middle of the display. The second and third columns indicate that this bond pays interest semiannually on January 15 and July 15 and has a default rating of BB+. The bond issue has over $400 million outstanding and is convertible until maturity. At the time of this report (i.e., January 2011), the listed price of the bond was 105.87 percent of par, and the price of BBY common stock was $34.30. Additional details of this security are shown in Exhibit 23.16.

As spelled out at the top of Exhibit 23.16, each $1,000 face value of this bond can be converted into 21.7391 shares of Best Buy common stock. As before, this statistic is called the instrument’s **conversion ratio**. At the listed share price of $34.30, an investor exercising her conversion option would have received $745.65 \(= 34.30 \times 21.7391\) worth of stock, an amount less than the bond’s current market value. In fact, the **conversion parity price** (i.e., the common stock price at which immediate conversion would make sense) is equal to $48.70, which is the bond price of $1,058.70 divided by the conversion ratio of 21.7391. The prevailing

market price of $34.30 is below this parity level, so the conversion option is currently out of the money. If the conversion parity price ever fell below the market price for the common stock, an astute investor could buy the bond and immediately exchange it into stock with a greater market value.

As indicated in the Security Information and Redemption Information boxes of Exhibit 23.16, this BBY convertible bond is also putable by the investor and callable by the issuer at par value any time after April 2011. A company will never call a bond selling for less than its call price, and firms often wait until the bond is selling for significantly more than its call price before calling it.

If the company calls the bond under these conditions, investors will have an incentive to convert the bond into stock that is worth more than they would receive from the call price, a situation known as forcing conversion. Two other factors also increase the investors’ incentive to convert their bonds. First, some instruments have conversion prices that step up over time. Since a stepped-up conversion price leads to a lower number of shares received, it becomes more likely that investors will exercise their option just before the conversion price increases. Second, a firm can encourage conversion by increasing the dividends on the stock, making the income generated by the shares more attractive relative to the income from the bond.

The payback or break-even time, measures how long the higher interest income from the convertible bond (compared to the dividend income from the common stock) must persist to make up for the difference between the price of the bond and its conversion value (i.e., the conversion premium). The calculation is as follows:

\[
\text{Payback} = \frac{\text{Bond Price} - \text{Conversion Value}}{\text{Bond Income} - \text{Income from Equal Investment in Common Stock}}
\]

The annual coupon payment on the Best Buy convertible bond is $22.50, while the firm’s annual dividend is $0.58 per share, or $12.61 per converted bond. Thus, assuming you sold the bond for 1,058.70 and used the proceeds to purchase 30.87 shares (= 1058.70/34.30) of BBY stock, the payback period would be:

\[
\$1,058.70 - \$745.65 = 31.65 \text{ years}
\]

This implies a point in the future considerably after when the bond matures (i.e., 11 years), suggesting that investors are not likely to make back the conversion premium with the incremental cash flow from the bond alone.

It is also possible to calculate the combined value of the investor’s conversion option, put option, and the issuer’s call feature that are embedded in the security. With a market price of $1,058.70, the BBY convertible’s yield-to-maturity can be calculated as the solution to:

\[
\$1,058.70 = \sum_{t=1}^{11} \frac{22.50}{1 + y} + \frac{1000}{(1 + y)^{11.25}}
\]

This means that the net value of the combined options is $376.30, or $1,058.70 minus $682.40. Using the Black-Scholes valuation model, it is easily confirmed that an 11-year call option to buy one share of Best Buy stock at an exercise price of $48.70 (i.e., the conversion parity value) is equal to $8.287. Thus, the value of the investor’s conversion option must be $180.14 (= 21.7391 × $8.287). The joint consequence of the bond’s other embedded options (i.e., long a put, short a call) is therefore costing the bondholder an additional $196.16 (= 376.30 – 180.14).

The market price of $34.30 is below this parity level, so the conversion option is currently out of the money. If the conversion parity price ever fell below the market price for the common stock, an astute investor could buy the bond and immediately exchange it into stock with a greater market value.

As indicated in the “Security Information” and “Redemption Information” boxes of Exhibit 23.16, this BBY convertible bond is also putable by the investor and callable by the issuer at par value any time after April 2011. A company will never call a bond selling for less than its call price, and firms often wait until the bond is selling for significantly more than its call price before calling it.\(^6\) If the company calls the bond under these conditions, investors will have an incentive to convert the bond into stock that is worth more than they would receive from the call price, a situation known as forcing conversion. Two other factors also increase the investors’ incentive to convert their bonds. First, some instruments have conversion prices that step up over time. Since a stepped-up conversion price leads to a lower number of shares received, it becomes more likely that investors will exercise their option just before the conversion price increases. Second, a firm can encourage conversion by increasing the dividends on the stock, making the income generated by the shares more attractive relative to the income from the bond.

\(^6\)In an empirical study of this issue, Ingersoll (1977) showed that almost all of the convertible securities studied were called later than the theoretically optimal time. This topic was also investigated by Asquith and Mullins (1991).
The **payback** or **break-even time**, measures how long the higher interest income from the convertible bond (compared to the dividend income from the common stock) must persist to make up for the difference between the price of the bond and its conversion value (i.e., the conversion premium). The calculation is as follows:

\[
\text{Payback} = \frac{\text{Bond Price} - \text{Conversion Value}}{\text{Bond Income} - \text{Income from Equal Investment in Common Stock}}
\]

The annual coupon payment on the Best Buy convertible bond is $22.50, while the firm’s annual dividend is $0.58 per share, or $12.61 per converted bond. Thus, assuming you sold the bond for 1,058.70 and used the proceeds to purchase 30.87 shares (= 1058.70/34.30) of BBY stock, the payback period would be:

\[
\frac{1058.70 - 745.65}{22.50 - 12.61} = 31.65 \text{ years}
\]

This implies a point in the future considerably after when the bond matures (i.e., 11 years), suggesting that investors are not likely to make back the conversion premium with the incremental cash flow from the bond alone.

It is also possible to calculate the combined value of the investor’s conversion option, put option, and the issuer’s call feature that are embedded in the security. With a market price of $1,058.70, the BBY convertible’s yield-to-maturity can be calculated as the solution to:

\[
1058.70 = \sum_{i=1}^{22} \frac{11.25}{(1 + y/2)^i} + \frac{1000}{(1 + y/2)^{22}}
\]

or \(y = 1.664\) percent (reported as 1.67 percent in the fourteenth column of Exhibit 23.15). This computation assumes 22 semiannual coupon payments of $11.25 (= 22.50 ÷ 2). Since the indicative yield on a Best Buy debt issue with no embedded options and the same (BB+) credit rating and maturity was 6.295 percent, the present value of a “straight” fixed-income security with the same cash flows would be:

\[
682.40 = \sum_{i=1}^{22} \frac{11.25}{(1 + 0.031475)^i} + \frac{1000}{(1 + 0.031475)^{22}}
\]

This means that the net value of the combined options is $376.30, or $1,058.70 minus $682.40. Using the Black-Scholes valuation model, it is easily confirmed that an 11-year call option to buy one share of Best Buy stock at an exercise price of $48.70 (i.e. the conversion parity value) is equal to $8.287.7 Thus, the value of the investor’s conversion option must be $180.14 (= 21.7391 × $8.287). The joint consequence of the bond’s other embedded options (i.e., long a put, short a call) is therefore costing the bondholder an additional $196.16 (= 376.30 − 180.14).

Exhibit 23.17 illustrates the value of a convertible bond in a more general way. Since it cannot sell for more than the company’s assets, the value of the firm is an upper bound for the value of a convertible. The “straight” bond value component is relatively flat for a wide range of firm values because, at some point, higher firm values do not benefit bondholders who receive only their promised payments. At fairly low firm values, the value of the bond drops off as bankruptcy becomes more likely. Conversion value rises directly with the value of the firm. The value of the convertible shows that when firm value is low, the convertible will act more like a bond, trading for only a slight premium over the bond value. Alternatively, when firm values are high, the convertible will act more like a stock, selling for only a slight premium over the conversion

---

7This calculation assumes the following input values: \(S = 34.30\), \(X = 48.70\), \(T = 11.0\), \(RFR = 0.0332\), \(\sigma = 0.27\), and \(D = 0.0169\).
23.4 Other Embedded Derivatives

For many years, the nature of borrowing and lending in securitized capital markets remained quite stable, with companies typically issuing bonds at par value and paying either a fixed or a floating rate of interest in the same currency in which the money was borrowed. The choice of maturity or coupon structure was driven by the economic situation faced by the borrower, rather than the investor. This scenario has greatly changed with the development of the structured note market. Structured notes are debt issues that have their principal or coupon payments linked to some other underlying variable. Examples include bonds whose coupons are tied to the appreciation of an equity index, such as the S&P 500, or a zero coupon bond with a principal amount tied to the appreciation of an oil price index.

Crabbe and ArGilagos (1994) and Das (2005) point out several common features that distinguish structured notes from regular fixed-income securities, two of which are important here. First, structured notes are designed for a specific investor with a very particular need. These are not generic instruments but products tailored to address an investor’s special constraints, which often result from tax, regulatory, or institutional policy restrictions. Second, after structuring the financing to meet the investor’s needs, the issuer typically will hedge any unwanted exposure with swaps or exchange-traded derivatives. Since the structured note likely required an embedded derivative to create the investor’s desired payoff structure, unwinding of the derivative position by the issuer generates an additional profit opportunity for the bond underwriter.

The growth of this market has been quite rapid, with about $60 billion of these notes issued annually by 2011. Equally impressive is the wide variety of economic risks that have been embedded and the maze of new acronyms that has accompanied these innovations (e.g., FLAG, LYON, SPEL, STEER, PERCS, and ICON). We take a detailed look at four structures representative of the major exposures an investor might desire: currency, equity, commodity, and interest rates.
23.4.1 Dual Currency Bonds

A dual currency bond is a debt instrument that has coupons denominated in a different currency than its principal amount. They have been popular funding instruments for several years and have been designed to include virtually all the world’s major currencies. These bonds can be viewed as a combination of two simpler financial instruments: (1) a single-currency fixed-coupon bond, and (2) a forward contract to exchange the bond’s principal into a predetermined amount of a foreign currency. They often are sold to investors who are willing to take a long-term view in the foreign exchange markets. By attaching the currency forward to the bond, fixed-income portfolio managers who might otherwise be restricted from trading in FX have the potential to enhance their performance if their beliefs about future market conditions prove correct.

Consider a five-year bond paying an annual coupon of 9 percent in U.S. dollars and redemption amount of JPY 110,000. The initial price of the bond is USD 1,020, relative to a par value of USD 1,000. If a regular five-year, dollar-denominated bond of comparable risk yielding 9 percent could have been issued at par, this means that the forward contract portion of the dual currency instrument is off market because it carries a present value of USD 20. Exhibit 23.18 shows the cash flows for this structure from the investor’s point of view. It also demonstrates how it can be assembled from its more basic component parts.

The embedded forward contract allows the bondholder to exchange the USD 1,000 for JPY 110,000, generating an implied nominal exchange rate of JPY 1,100/USD (or, equivalently, USD 0.9091/JPY). However, given that the investor has to pay an additional USD 20 today for this future transaction, this is not the effective exchange rate that the investor faces; the fact that the investor is willing to pay the additional USD 20 suggests that JPY 110/USD is a favorable price to purchase yen forward. The effective exchange rate built into this transaction can be established by dividing JPY 110,000 by the sum of USD 1,000 and the future value (in Year 5) of USD 20. Calculating this latter amount as 30.77 [= 20 × (1.09)5], the effective exchange rate becomes JPY 106.72/USD [= 110,000 ÷ (1,000 + 30.77)].

There are at least two reasons why this dual currency bond might trade at a premium over a comparable single-currency 9 percent coupon bond. First, it is possible that the five-year forward exchange rate between yen and dollars is JPY 106.72/USD, meaning that at USD 1,020, the bond is priced properly. More likely, though, the five-year forward rate actually is JPY 110/USD and investors are paying up for a desirable FX exposure that they cannot acquire in any other way. If this is true, the issuer—who is effectively short the regular dollar bond and short in the yen forward—can unwind its derivative position at a profit, thereby reducing its funding cost below 9 percent. That is, the issuer’s commitment to sell JPY 110,000 to the investor in Year 5 can be offset by a long position in a separate yen forward at the market forward

Exhibit 23.18: Cash Flows for a Dual Currency Bond from the Investor’s Perspective
Thus, given that a regular index option would have a terminal payoff from $F_{\text{Final SPX}} - X$, where $X$ is the exercise price, the derivative in the VPR represents 7.63 percent of this amount. The terminal payoffs to the VPR embedded option are shown in Exhibit 23.19, along with those to a regular index call option, for several potential April 2013 levels of the S&P 500 Index. Although both the VPR and regular options become in the money at the same point (i.e., 1311.28), only the latter produces a "dollar-for-dollar" payoff with increasing values of the index beyond this level. The payoff to the call feature in the structured note still rises for any S&P 500 level exceeding the exercise price, but gains only $0.0763 for every one point gained by the index.

Exhibit 23.20 provides a different way to visualize the VPR investment structure. For the initial (i.e., April 2006) payment of $100, the investor has purchased the equivalent of a seven-year zero-coupon bond maturing in April 2013 plus a partial call option on the index on the S&P 500 Index. Thus, the $100 initial payment can be split into the value of the zero-coupon bond—which is simply $100 discounted to the present at JPMorgan’s seven-year bond yield—and the remainder, which must be the value of the embedded SPX call option at the origination date. This also makes valuing the VPR at any point in its life more transparent since the entire structure is just the value of the bond portion plus the value of the option component.

Consider that on April 26, 2010, the closing level for the S&P 500 was 1212.05. Further, the semiannually compounded yield of a zero-coupon (i.e., "stripped") Treasury bond on this date was 1.69 percent, while a JPMorgan bond maturing at about the same time as the VPR issue carried a yield of 2.66 percent. (This 97-basis-point credit spread was appropriate for JPMorgan’s credit rating of Aa3 and A+ by Moody’s and Standard & Poor’s, respectively.) Given the remaining time to maturity (i.e., three years, or six half-years), the bond portion of the VPR issue should be worth:

\[
VPR \text{ Bond Value} = \frac{100}{(1 + y)^6} = 92.379
\]

### 23.4.2 Equity-Index Linked Notes

In April 2006, JPMorgan Chase raised capital by issuing a class of unsecured senior debt securities called Principal Protected Notes Linked to the S&P 500 Index. These instruments are an example of a wider class of structured notes known as variable principal redemption (VPR) securities because the amount of the bond’s principal refunded at maturity is not fixed but depends on the returns to an equity index. These particular VPR bonds mature on April 26, 2013, and, as their name implies, have their redemption amount tied to movements in the S&P 500 Index between the origination and maturity dates. Other VPR notes that have traded in the market in recent years have tied the principal redemption to a wide variety of global stock indexes, including the Dow Jones Industrial Average, the Russell 1000, the FT-SE 100, and the Nikkei 225, as well as to “baskets” of those indexes.

This VPR note pays no coupons prior to maturity. At maturity, the bondholder receives the original issue price (stated here as 100 percent of minimum face value) plus a “supplemental redemption amount,” which depends on where the S&P 500 Index settles relative to a predetermined initial level. This supplemental amount cannot be less than zero, so the total payout to the investor at maturity is:

\[
100 + \max \left[ 0, \left( \frac{100 \times (\text{Final SPX Value} - \text{Initial SPX Value})}{\text{Initial SPX Value}} \right) \times 1.00 \right]
\]

where the initial S&P 500 (i.e., SPX) index value was specified as 1311.28. The “market participation” factor of 1.00 indicates that the investor receives 100 percent of the return to the SPX over the seven-year period, provided that return is positive.

Recognize that the VPR structure combines a seven-year, zero-coupon bond with a SPX index call option, both of which were issued by JPMorgan. Thus, the structured note investor essentially owns a “portfolio” that is: (1) long in a bond, and (2) long in an index call option position. This particular security might have been designed for investors who wanted to participate in the equity market but, for regulatory or taxation reasons, were not permitted to do so directly. For example, the manager of a fixed-income mutual fund might be able to enhance her return performance by purchasing this “bond” and then hoping for an appreciating stock market. The use of the call option in this design makes it easy for JPMorgan to market to its institutional customers as a “no lose” proposition; the worst-case scenario for the investor is that she simply gets her money back without interest in seven years. (Of course, the customer does carry the bank’s credit risk for this period.) Thus, unlike the dual currency bond where the investor could either gain or lose from changing FX rates, at origination this VPR issue had no downside exposure to stock price declines.

The call option embedded in this structure is actually a partial position. To see this, we can rewrite the option portion of the note’s redemption value as:

\[
\max \left[ 0, \left( 100 \times \frac{\text{Final SPX} - 1311.28}{1311.28} \right) \right] = \max \left[ 0, \left( \frac{100}{1311.28} \right) (\text{Final SPX} - 1311.28) \right]
\]

or

\[
0.0763 (\max [0, (\text{Final SPX} - 1311.28)])
\]
Thus, given that a regular index option would have a terminal payoff of $\max(0, (\text{Final SPX} - X))$, where $X$ is the exercise price, the derivative in the VPR represents 7.63 percent of this amount. The terminal payoffs to the VPR embedded option are shown in Exhibit 23.19, along with those to a regular index call option, for several potential April 2013 levels of the S&P 500 Index. Although both the VPR and regular options become in the money at the same point (i.e., 1311.28), only the latter produces a “dollar-for-dollar” payoff with increasing values of the index beyond this level. The payoff to the call feature in the structured note still rises for any S&P 500 level exceeding the exercise price, but gains only $0.0763 for every one point gained by the index.

Exhibit 23.20 provides a different way to visualize the VPR investment structure. For the initial (i.e., April 2006) payment of $100, the investor has purchased the equivalent of a seven-year zero-coupon bond maturing in April 2013 plus a partial call option on the index on the S&P 500 Index. Thus, the $100 initial payment can be split into the value of the zero-coupon bond—which is simply $100 discounted to the present at JPMorgan’s seven-year bond yield—and the remainder, which must be the value of the embedded SPX call option at the origination date. This also makes valuing the VPR at any point in its life more transparent since the entire structure is just the value of the bond portion plus the value of the option component.

Consider that on April 26, 2010, the closing level for the S&P 500 was 1212.05. Further, the semiannually compounded yield of a zero-coupon (i.e., “stripped”) Treasury bond on this date was 1.69 percent, while a JPMorgan bond maturing at about the same time as the VPR issue carried a yield of 2.66 percent. (This 97-basis-point credit spread was appropriate for JPMorgan’s credit rating of Aa3 and A+ by Moody’s and Standard & Poor’s, respectively.) Given the remaining time to maturity (i.e., three years, or six half-years), the bond portion of the VPR issue should be worth:

\[
VPR \text{ Bond Value} = \frac{100}{\left(1 + \frac{0.0266}{2}\right)^6} = 92.379
\]

</table>
The theoretical value of a regular SPX call option can be calculated with the dividend yield-adjusted version of the Black-Scholes model. To perform this computation, three additional inputs are needed. First, the S&P 500 dividend yield on April 26, 2010, was 1.76 percent. Second, the continuously compounded equivalent of the quoted risk-free rate is 1.68 percent. Finally, the volatility of SPX index returns over the time to VPR issue’s maturity is assumed to be 15.28 percent, based on prevailing implied volatilities for traded index options on that date.

The value of an index call option with an exercise price of 1311.28 can now be generated by the Black-Scholes formula using the following inputs: $S = 1212.05$, $X = 1311.28$, $T = 3.00$, $RFR = 0.0168$, $D = 0.0176$, and $\sigma = 0.1528$. Under these conditions:

$$d_1 = \frac{\ln(1212.05e^{-0.0176\times 0.00}/1311.28) + (0.0168 + 0.5(0.1528)^2)(3.00))}{(0.1528(3.00))^{1/2}} = -0.1741$$

and

$$d_2 = -0.1741 - 0.1528(3.00)^2 = -0.4387$$

so that $N(d_1) = 0.4308$ and $N(d_2) = 0.3303$. Thus, the index call’s Black-Scholes value is:

$$C_0 = (1212.05)(e^{-0.0176\times 0.00})(0.4308) - (1311.28)(e^{-0.0168\times 0.00})(0.3303) = 83.393$$

The value of the embedded VPR call is then established by multiplying 83.393 by 0.0763, which leaves $6.363$. As shown in Exhibit 23.20, on this particular date the VPR issue was priced in the market at $95.400 (= 92.379 + 3.021), meaning that the VPR call option was significantly undervalued. Finally, notice that since the April 26, 2010, index value (i.e., 1212.05) was lower than the initial (i.e., exercise) level, the VPR call feature is out of the money so the value of the embedded option can be viewed as pure time premium.

### 23.4.3 Commodity-Linked Bull and Bear Bonds

Fixed-income securities can be designed to give an investor exposure to commodity price movements as well. The commodities involved in these structures are seldom exchanged but instead

---

This value can be established by solving for $r$ in the following equation:

$$e^r = (1 + (0.0169/2))^2$$

or

$$r = \ln((1 + (0.0169/2))^2) = 0.0168$$
represented in the form of “cash settlement only” derivatives. Thus, virtually no limit exists to the number of different underlying assets that can be embedded into a bond issue. To date, investors for these products have tended to concentrate on either oil or precious metals. As in the previous examples, the primary attractions to the investor using structured notes are their convenience and their ability to avoid restrictions on taking commodity positions directly.

A particularly interesting form of the commodity-linked bond is the so-called bull-and-bear note. This structure gets its name from a bond that is issued in two portions: a bull tranche, whose principal redemption amount increases directly with the price of the designated commodity, and a bear tranche, whose principal declines with increasing commodity prices. One of the first issues of this kind occurred in October 1986, when the Kingdom of Denmark raised $120 million in two separate $60 million tranches, each having a payoff structure tied to an index of gold prices. Both of these gold-linked note tranches had a seven-year maturity, paid an annual coupon of 3 percent, and were issued at a price of 100.125 percent of par value. The principal redemptions for each $1,000 of face value for the two tranches were:

\[
\text{Bull Redemption: } 1,000 \times [1.158 \times (\text{Index at Redemption} - \text{Initial Index})]
\]

and

\[
\text{Bear Redemption: } 1,000 \times [2.78 - 1.158 \times (\text{Index at Redemption} - \text{Initial Index})]
\]

For both tranches, maximum and minimum redemption levels of $2,280 and $500, respectively, were set.

Exhibit 23.21 shows the redemption amount that the Kingdom of Denmark is obligated to pay on each tranche for a series of gold index levels relative to the initial level, which was set at 426.50. The final column of this display shows what the average redemption value is when the two tranches are considered together. This average amount does not vary, so the issuer has

\[^*\text{Additional details of this bull-and-bear structure are explained in Walmsley }(1998), \text{ who also provides descriptions of an exhaustive set of such deals.}\]
no net exposure to gold price movements. Unlike the dual currency bond considered earlier, the virtue of this two-tranche approach is that the commodity exposure is neutralized internally. That is, the Kingdom of Denmark is effectively both long and short gold in equal amounts across the bear and bull segments, respectively. This leaves a fixed funding cost for the full $120 million issue of:

$$1,001.25 = \sum_{i=1}^{30} \frac{1,390}{(1+y)^i} + \frac{30}{(1+y)^i}$$

or $y = 7.42$ percent. At the time this deal was launched, a regular seven-year, par-value debt issue would have required a yield of about 8 percent, which underscores the Kingdom of Denmark’s incentive to create this structure in the first place.

The attraction for the investors, of course, is the ability to purchase a fixed-income security that also allows for participation in gold price movements. In exchange for accepting a lower-than-market coupon, buyers of the bull (bear) tranche receive a redemption value that exceeds their purchase price if the gold index increases (declines). Exhibit 23.22, which graphs the redemption values for the two tranches, suggests that the commodity derivatives embedded in this transaction are not simple forward or option positions. Rather, the minimum and maximum principal payoffs effectively convert the gold exposure into a call option money spread—a bull spread for the bull tranche, a bear for the bear—as described in Chapter 22. The investors, undoubtedly different people for the two positions, pay for this spread position through a reduction in their average yield to maturity relative to the regular bond.

23.4.4 Swap-Linked Notes

As we have seen, interest rate swaps are efficient mechanisms for transforming the cash flows of existing debt issues. They also are quite useful in the new-issue market when the desired rate exposures of the borrower and lender do not coincide naturally. Imagine, for example, that Company LMN wishes to raise $50 million by issuing a fixed-rate note with semiannual

---

**Exhibit 23.22 Redemption Values for the Bull-and-Bear Gold-Linked Note**

![Chart showing redemption values for bull and bear tranches based on gold index.](chart.png)
Recall that an interest rate swap can be interpreted as a pair of capital market transactions. In this particular case, a "receive 6.5 percent fixed, pay LIBOR" swap can be viewed as a portfolio long in a fixed-rate note paying 6.5 percent and short in a LIBOR-based floating-rate note. Recalling also that + represents a long position and − represents a short position, the synthetic fixed-rate issue from Company LMN’s perspective can be written:

\[-(\text{Synthetic Fixed Rate Bond at 5\%}) = -(\text{Reverse Floater at 12\%} - \text{LIBOR}) + (\text{Receive 6.5\%, Pay LIBOR Swap}) + (\text{Cap at 12\% Exercise Rate})\]

Brown and Smith (1995b) argue that this structured solution would only make sense to the issuer if it led to a funding cost that was lower than a direct fixed-rate loan. The biggest reason for this is that while a direct fixed-rate loan would carry no credit risk for the borrower, the structured loan would because of the swap and cap positions. Thus, the swap-based borrowing requires a lower cost to entice the issuer.

Although this design satisfies the investor’s requirements, it does not do the same for the issuer. This shortcoming can be easily remedied, though, by combining Company LMN’s debt position with a swap in which it receives the fixed rate and pays LIBOR. This is illustrated in Exhibit 23.23, assuming a three-year fixed swap rate of 6.5 percent against six-month LIBOR. Notice that paying a coupon of 12 percent minus LIBOR is equivalent to paying a coupon of 12 percent and receiving one of LIBOR. Thus, to neutralize LMN’s floating-rate exposure, it must pay out LIBOR on the swap.

Exhibit 23.23 also shows that the net synthetic fixed-rate funding cost to Company LMN is 5.5 percent. This will only be true, however, whenever LIBOR does not exceed 12 percent. If LIBOR is greater than 12 percent, the benefit from paying lower coupons to the investor will stop—the coupon rate can never go negative—but LMN will continue having to make the higher net settlement payment on the swap, which raises the effective borrowing cost above 5.5 percent. So, because there is an implicit cap on LIBOR built into the reverse floating-rate loan, Company LMN will need to offset this by purchasing an actual cap agreement with an exercise rate of 12 percent and a notional principal of $50 million. This option will not be expensive because it is quite far out of the money, but it will not be free, so the net funding cost will be somewhat greater than 5.5 percent.

**Exhibit 23.23 Converting a Reserve Floating-Rate Note with a Swap**

\[\text{LMN's Net Funding Cost:} \quad (12\% - \text{LIBOR}) + (\text{LIBOR} - 6.5\%) = 5.5\%\]
Although real options have existed ever since humans first walked the earth—for instance, storing food and other necessities gave people a valuable option, allowing them to consume more (or less) than the amount produced in a given time period—a number of recent changes have made understanding them more important than ever. These factors include (1) the pace of technological innovation, (2) deregulation and privatization, and (3) advances in derivatives pricing theory and decreases in the computing costs.

23.5 Company Valuation with Real Options

To highlight the advantages of the real options approach over traditional company valuation methods, we present the case of the fictional GoldFlex Corporation.

One of GoldFlex’s assets is a lease on a gold mine, which expires exactly one year from now (i.e., Year 1). GoldFlex geologists estimate that the mine—which is currently idle—holds 100,000 Troy ounces of gold and that extraction costs are $260/ounce. The current (i.e., Year 0) spot price of an ounce of gold is $264.40, while the Year 1 forward contract price equals $268.40. For simplicity, assume that all the gold is extracted at the end of the year. To be able to mine gold in a year, the company must spend $1,000,000 today to restore the mining facilities to working order. Suppose further that the spot price of gold in one year will be either $290 or $240 and that the one-year risk-free rate is 5 percent. How should an investor establish the value of GoldFlex’s mining lease?

Recognize that GoldFlex could sell all of its gold at the current forward price. Since the resulting sales proceeds a year from now would then be known, assuming that extraction costs and the quantity of gold are known with certainty, the appropriate discount rate is the one-year T-bill (i.e., risk-free) yield. Thus, the value of the mine calculated using a traditional net present value approach would be:

\[
\text{NPV} = \frac{\frac{1}{2}(268.40 - 260) \times 100,000}{1.05} - 1,000,000 = -200,000
\]

Of course, this implies that the lease has no value because opening the mine would be a money-losing project. However, the traditional approach ignores the value of flexibility: If gold prices decline in the future, management can shut down production and leave the gold in the ground. Once we consider the possibility of shutting down, the cash flows from the mine can be viewed in a different and more realistic manner.

The main premise to valuing a real asset with embedded timing options (such as the mine) is that it is possible for an investor to assemble a portfolio of financial securities that has the same pattern of future cash flows with the same level of risk. Such an investor could value the potential future cash flows by creating a hypothetical portfolio consisting of risk-free, one-year T-bills and gold forward contracts that would exactly mimic the mining operation. This replicating portfolio will have the same possible cash flows as the gold mine, so its value in an efficient capital market should also be the same. We can use a two-state framework to view the valuation question as follows:

<table>
<thead>
<tr>
<th>TODAY (YEAR 0)</th>
<th>IN ONE YEAR (YEAR 1)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Gold Price</td>
<td>Cash Flow</td>
</tr>
<tr>
<td>$290</td>
<td>$3,000,000</td>
</tr>
<tr>
<td>$240</td>
<td>$0 (No Production)</td>
</tr>
</tbody>
</table>

How many forward contracts are necessary to build a security position that duplicates these cash flows? Since the other asset involved in this process is risk free, all the variation in the one-year T-bill will be captured by the forward contracts. Thus, the number of contracts needed is:

\[
\frac{3,000,000 - 0}{290 - 240} = 10 \text{ contracts}
\]

Brown and Smith (1995b) argue that this structured solution would only make sense to the issuer if it led to a funding cost that was lower than a direct fixed-rate loan. The biggest reason for this is that while a direct fixed-rate loan would carry no credit risk for the borrower, the structured loan would because of the swap and cap positions. Thus, the swap-based borrowing requires a lower cost to entice the issuer.

23.5 Valuing Flexibility: An Introduction to Real Options

Recently, energy companies have begun to open gas-fired power plants that generate electricity at an expense 50 percent to 70 percent greater than those of other, more cost-effective plants. McGrath and MacMillan (2005) note that these new, “inefficient” plants are intended to operate only when the price of electricity is high enough to justify the cost. The energy firms hope to make a profit on the new plants because power prices have become increasingly volatile and the new plants—although they cost more to run—are much less costly than traditional plants to fire up and shut down on short notice. Although these “peaking” plants are also cheaper to build, their main attraction lies in their flexibility. They allow energy companies to supply more electricity when prices are high and to cease production almost immediately when electricity prices have dropped.

How should investors value companies that possess this sort of operational flexibility? Conventional net present value calculations ignore the benefits of flexibility and may therefore undervalue projects that allow companies to react rapidly to changing circumstances. For instance, predicting future cash flows based on factors like expected running time, expected electricity prices, or expected production costs will fail to capture the most valuable feature of these plants: namely, that they will only be generating electricity when the price of a megawatt-hour of electricity exceeds the cost of producing it. This is in contrast to conventional plants that produce electricity more cheaply overall but are sometimes forced to sell below-cost power because shutting down and then restarting the facility would be prohibitively expensive.

So far, the derivative contracts we have discussed are exchanged in financial markets and the asset underlying the derivative contract is often another financial instrument (such as a share of common stock, a government bond, or a futures contract). However, options are also embedded in real assets owned by firms; these are known as real options. A pharmaceutical company, for example, owns valuable options in the form of its collection of drug patents. The firm has the right, but not the obligation, to develop marketable drugs based on its patents and will do so if the discounted present value of those drugs exceeds the cost of development and regulatory approval. In the language of derivative contracting, these costs can be considered as the strike price for the development option. In the energy example, the peaking plant in effect gives the firm the right but not the obligation to buy Y megawatt-hours of electricity at an exercise price X, where Y is the total capacity of the plant and X is the generating cost per megawatt-hour.
Although real options have existed ever since humans first walked the earth—for instance, storing food and other necessities gave people a valuable option, allowing them to consume more (or less) than the amount produced in a given time period—a number of recent changes have made understanding them more important than ever. These factors include (1) the pace of technological innovation, (2) deregulation and privatization, and (3) advances in derivatives pricing theory and decreases in the computing costs.

### 23.5.1 Company Valuation with Real Options

To highlight the advantages of the real options approach over traditional company valuation methods, we present the case of the fictional GoldFlex Corporation. One of GoldFlex’s assets is a lease on a gold mine, which expires exactly one year from now (i.e., Year 1). GoldFlex geologists estimate that the mine—which is currently idle—holds 100,000 Troy ounces of gold and that extraction costs are $260/ounce. The current (i.e., Year 0) spot price of an ounce of gold is $264.40, while the Year 1 forward contract price equals $268.40. For simplicity, assume that all the gold is extracted at the end of the year. To be able to mine gold in a year, the company must spend $1,000,000 today to restore the mining facilities to working order. Suppose further that the spot price of gold in one year will be either $290 or $240 and that the one-year risk-free rate is 5 percent. How should an investor establish the value of GoldFlex’s mining lease?

Recognize that GoldFlex could sell all of its gold at the current forward price. Since the resulting sales proceeds a year from now would then be known, assuming that extraction costs and the quantity of gold are known with certainty, the appropriate discount rate is the one-year T-bill (i.e., risk-free) yield. Thus, the value of the mine calculated using a traditional net present value approach would be:

\[
NPV = \left[ \frac{[268.40 - 260]}{1.05} \times 100,000 \right] - 1,000,000 = -200,000
\]

Of course, this implies that the lease has no value because opening the mine would be a money-losing project. However, the traditional approach ignores the value of flexibility: If gold prices decline in the future, management can shut down production and leave the gold in the ground. Once we consider the possibility of shutting down, the cash flows from the mine can be viewed in a different and more realistic manner.

The main premise to valuing a real asset with embedded timing options (such as the mine) is that it is possible for an investor to assemble a portfolio of financial securities that has the same pattern of future cash flows with the same level of risk. Such an investor could value the potential future cash flows by creating a hypothetical portfolio consisting of risk-free, one-year T-bills and gold forward contracts that would exactly mimic the mining operation. This replicating portfolio will have the same possible cash flows as the gold mine, so its value in an efficient capital market should also be the same. We can use a two-state framework to view the valuation question as follows:

<table>
<thead>
<tr>
<th>TODAY (YEAR 0)</th>
<th>IN ONE YEAR (YEAR 1)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Gold Price</td>
<td>Cash Flow</td>
</tr>
<tr>
<td>$290</td>
<td>$3,000,000</td>
</tr>
<tr>
<td>$240</td>
<td>$0 (No Production)</td>
</tr>
</tbody>
</table>

How many forward contracts are necessary to build a security position that duplicates these cash flows? Since the other asset involved in this process is risk-free, all the variation in the

---

10This example follows a greatly simplified approach based on the valuation method first introduced by Brennan and Schwartz (1985).
The present value of an at-market forward contract is zero, the replicating portfolio (and therefore the lease on the mine) is worth $1,622,857, which is greater than the $1,000,000 required to restore the facilities. Investors using traditional discounted cash flow analysis will consider the lease worthless and ignore an important asset when valuing GoldFlex. Also, increased volatility in future gold prices will have no effect on the traditional valuation estimate, but would increase the value of the lease when using the real options methodology, since greater uncertainty generally leads to higher option values.

In practice, real options are much more complex than this example. For instance, gold production typically takes place steadily during the year, so the analysis may require either a continuous-time (e.g., Black-Scholes) option valuation model or an expansion of the prior binomial tree approach to include a large number of subintervals. Also, extraction costs and the exact amount of the gold deposits are rarely known with certainty. The problem of having uncertain extraction costs can be solved by realizing that the lease on the mine in effect becomes an exchange option, a problem that was first considered by Margrabe (1978). In this example, the leaseholder effectively has an option to exchange the gold in the mine for the extraction costs (e.g., the cost of the required equipment, material, and manpower).

## Summary

The genius of modern financial markets is that they provide new products and strategies to meet the constantly changing needs of anyone willing to pay the required price. In this chapter, we explore several ways in which derivatives can aid that development process. We see that innovation sometimes takes the form of creating a new set of instruments, such as interest rate swaps, while at other times it involves packaging existing securities in a creative way. Structured notes, which combine bonds with a derivative position based on a different sort of underlying asset, are a good example of this latter approach. Ultimately, the purpose of financial engineering is to help borrowers and lenders manage one of four types of potential exposures: interest rate, currency, equity, or commodity price risk.

We began our discussion with an examination of the market for OTC interest rate agreements. Although forward rate agreements are the most basic product, interest rate swaps are the most popular. Swap contracts can be interpreted in three ways: as a series of FRAs, as a portfolio of bond positions, or as a zero-cost collar, which consists of a pair of cap and floor agreements. We then extended the plain vanilla swap concept to include contracts designed to handle other exposures, such as credit and equity swaps.

We conclude with an analysis of several ways in which derivatives can be embedded into other securities to create customized payoff distributions. Warrants, which are call options on common stock issued directly by the company itself, can be attached to a debt issue to offer investors the upside potential of equity with the safety of a bond. Further, bonds and preferred stock issues can be set up to allow for conversion into common stock at the investor’s option. A class of instruments known as structured notes carries this concept even further by embedding into bonds derivatives that often are based on exposures that may not appear on the issuer’s balance sheet. These instruments epitomize how much value derivatives can add when they are used properly. Finally, we discuss how the derivative features embedded in physical assets (i.e., real options) can be used by investors to value companies.

---

**Exhibit 23.24 Creating a “Real Options” Replicating Portfolio**

**Step 1: Design a portfolio containing F forward contracts and T invested in a risk-free security that has the same future payoffs as the mine:**

- **“Up” State (Gold Price = $290):** 
  \[ F \times (290 - 268.4) + [(1.05) \times (T)] = 3,000,000 \]
- **“Down” State (Gold Price = $240):** 
  \[ F \times (240 - 268.4) + [(1.05) \times (T)] = 0 \]

**Step 2: Solve for F and T simultaneously:**

a. Rewrite the “down” state cash flow equation:

\[ T = F \times (28.4 + 1.05) = F \times (28.4 + 1.05) \]

b. Insert the “down” state T value into the “up” state cash flow equation:

\[ F \times (21.6) + [(1.05) \times F \times (28.4 + 1.05)] = 50 \times F = 3,000,000 \]

c. Solve for F:

\[ F = 3,000,000 / 50 = 60,000 \]

d. Solve for T from 2(a):

\[ T = (60,000) \times (28.4 + 1.05) = 1,622,857 \]

(Note: This is the “real options” value of the mine lease cash flows, before netting out the initial reopening expense.)

**Step 3: Confirm the equality of replicating portfolio and mine future cash flows:**

- **“Up” State:** 
  \[ [(60,000) \times (21.6)] + (1.05)(1,622,857) = 3,000,000 \]
- **“Down” State:** 
  \[ [(60,000) \times (28.4)] + (1.05)(1,622,857) = 0 \]
Since the present value of an “at-market” forward contract is zero, the replicating portfolio (and therefore the lease on the mine) is worth $1,622,857, which is greater than the $1,000,000 required to restore the facilities. Investors using traditional discounted cash flow analysis will consider the lease worthless and ignore an important asset when valuing GoldFlex. Also, increased volatility in future gold prices will have no effect on the traditional valuation estimate, but would increase the value of the lease when using the real options methodology, since greater uncertainty generally leads to higher option values.

In practice, real options are much more complex than this example. For instance, gold production typically takes place steadily during the year, so the analysis may require either a continuous-time (e.g., Black-Scholes) option valuation model or an expansion of the prior binomial tree approach to include a large number of subintervals. Also, extraction costs and the exact amount of the gold deposits are rarely known with certainty. The problem of having uncertain extraction costs can be solved by realizing that the lease on the mine in effect becomes an exchange option, a problem that was first considered by Margrabe (1978). In this example, the leaseholder effectively has an option to exchange the gold in the mine for the extraction costs (e.g., the cost of the required equipment, material, and manpower).}

**SUMMARY**

- The genius of modern financial markets is that they provide new products and strategies to meet the constantly changing needs of anyone willing to pay the required price. In this chapter, we explore several ways in which derivatives can aid that development process. We see that innovation sometimes takes the form of creating a new set of instruments, such as interest rate swaps, while at other times it involves packaging existing securities in a creative way. Structured notes, which combine bonds with a derivative position based on a different sort of underlying asset, are a good example of this latter approach. Ultimately, the purpose of financial engineering is to help borrowers and lenders manage one of four types of potential exposures: interest rate, currency, equity, or commodity price risk.

- We began our discussion with an examination of the market for OTC interest rate agreements. Although forward rate agreements are the most basic product, interest rate swaps are the most popular. Swap contracts can be interpreted in three ways: as a series of FRAs, as a portfolio of bond positions, or as a zero-cost collar, which consists of a pair of cap and floor agreements. We then extended the plain vanilla swap concept to include contracts designed to handle other exposures, such as credit and equity swaps.

- We conclude with an analysis of several ways in which derivatives can be embedded into other securities to create customized payoff distributions. Warrants, which are call options on common stock issued directly by the company itself, can be attached to a debt issue to offer investors the upside potential of equity with the safety of a bond. Further, bonds and preferred stock issues can be set up to allow for conversion into common stock at the investor’s option. A class of instruments known as structured notes carries this concept even further by embedding into bonds derivatives that often are based on exposures that may not appear on the issuer’s balance sheet. These instruments epitomize how much value derivatives can add when they are used properly. Finally, we discuss how the derivative features embedded in physical assets (i.e., real options) can be used by investors to value companies.

---

11We would like to thank Professor Andras Marosi for his contributions to this section.
On the same notional amount, BI arranges another swap with Bank B under which BI receives the return on the S&P 500 Index (in U.S. dollars) in exchange for paying the interest rate on the U.S. Treasury bill plus 0.1 percent (10 basis points). Both swaps would be for a one-year term.

From BI’s perspective, identify and briefly describe:
(a) the major risk that this transaction would eliminate,
(b) the major risk that this transaction would not eliminate (i.e., retain), and
(c) three risks that this transaction would create.

7. Kyle Morgan is the manager of a large pension fund for the Firefighters’ Union. As the pension fund is currently underfunded by approximately $300 million, Kyle is arranging for the plan sponsor to issue a privately placed two-year bond that will be held by the plan to maturity. The bond will carry an interest rate of 80 basis points (0.8% per annum) above the U.S. Treasury bill yield. However, Kyle notes that after the private placement the allocation of the pension fund will significantly skew toward the fixed-income asset class. Moreover, the duration of the pension fund will be shortened for the next two years due to the private placement. Kyle’s colleagues advise him that he may adjust the portfolio weight and duration to any target level (including the target portfolio allocation of 50% in equity and 50% in fixed income instruments) using either futures and swap contracts during the two-year horizon prior to the bond’s maturity.

a. What are the possible strategies for Kyle to restore the 50:50 portfolio allocation using (1) futures and (2) swap contracts? Briefly describe the transactions involved.

b. Compare and contrast the advantages and disadvantages of using futures and swaps as described in Part a.

8. We have seen that equity warrants are not as valuable as an otherwise identical call option on the stock of the same company. Explain why this must be the case. Also, what is the incentive for a firm to issue a warrant rather than issuing stock directly?

9. Bonds and preferred stock that are convertible into common stock are said to provide investors with both upside potential and downside protection. Explain how one security can possess both attributes. What implications do these features have for the way a convertible security is priced?

10. You are the new CFO of a multinational soft drink company. Currently, you are assisting your board of directors in evaluating the company’s pension fund strategy. Specifically, the board is considering investing in the following structured products: (1) equity-linked notes (ELNs), and (2) commodity-linked bonds.

a. Briefly explain how these two structure products work and how they differ from a traditional debt security.

b. The company generates substantial revenues in Japanese yen subsequent to the introduction of its soft drink in Japan, and the board expects that the Japanese yen will appreciate against U.S. dollars in the next six months. Consequently, the board is also considering investing in a dual currency bond.

i. What is a dual currency bond? Briefly describe the principal and coupon payments of this instrument.

ii. Why might a dual currency bond trade at a premium over an otherwise identical single currency bond?

iii. If the board is correct and the Japanese yen appreciates against the U.S. dollar during the life of the structured security, what would be the impact on the value of the dual currency bond?
1. With the interest rate swap quotations shown in Exhibit 23.4, calculate the swap cash flows from the point of view of the fixed-rate receiver on a two-year swap with a notional principal of $22.5 million. You may assume the relevant part of the settlement date pattern and the realized LIBOR path shown in Exhibit 23.6 for the three-year agreement. Also, calculate the fixed-rate payment on a 30/360-day count and the floating-rate payments on an actual/360-day basis.

2. To protect the value of the Star Hospital Pension Plan’s bond portfolio against the rising interest rates that she expects, Sandra Kapple enters into a one-year pay fixed, receive floating U.S. LIBOR interest rate swap, as described in the following table:

<table>
<thead>
<tr>
<th>U.S. LIBOR Interest Rate Swap Terms</th>
</tr>
</thead>
<tbody>
<tr>
<td>1-year Fixed Rate (annualized)</td>
</tr>
<tr>
<td>1.5%</td>
</tr>
<tr>
<td>90-day U.S. LIBOR Rate $L_{(90)}$ (annualized)</td>
</tr>
<tr>
<td>1.1%</td>
</tr>
<tr>
<td>Notional Principal</td>
</tr>
<tr>
<td>$1</td>
</tr>
<tr>
<td>Day Count Convention</td>
</tr>
<tr>
<td>90/360</td>
</tr>
</tbody>
</table>

Note: $L_i(m)$ is the m-day LIBOR on Day $i$.

Sixty days have passed since initiation of the swap, and interest rates have changed. Kapple is concerned that the value of her swap has also changed. The U.S. LIBOR term structure and present value factors of interest rates are described in this table:

<table>
<thead>
<tr>
<th>U.S. LIBOR TERM STRUCTURE AND PRESENT VALUE FACTORS</th>
</tr>
</thead>
<tbody>
<tr>
<td>U.S. LIBOR Term Structure (annualized)</td>
</tr>
<tr>
<td>Present Value Factors</td>
</tr>
<tr>
<td>$L_{60}(30)$ = 1.25 percent</td>
</tr>
<tr>
<td>0.9990</td>
</tr>
<tr>
<td>$L_{60}(120)$ = 1.50 percent</td>
</tr>
<tr>
<td>0.9950</td>
</tr>
<tr>
<td>$L_{60}(210)$ = 1.75 percent</td>
</tr>
<tr>
<td>0.9899</td>
</tr>
<tr>
<td>$L_{60}(300)$ = 2.00 percent</td>
</tr>
<tr>
<td>0.9836</td>
</tr>
</tbody>
</table>

Note: $L_i(m)$ is the m-day LIBOR on Day $i$.

Calculate the dollar market value of the interest rate swap entered into by Kapple, at 60 days after the initiation of the swap and using a $1 notional principal. Show your calculations. (Note: Your calculations should be rounded to 4 decimal places.)

3. The treasurer of a British brewery is planning to enter a plain vanilla, three-year, quarterly settlement interest rate swap to pay a fixed rate of 8 percent and to receive three-month sterling LIBOR. But first he decides to check various cap-floor combinations to see if any might be preferable. A market maker in British pound sterling OTC options presents the treasurer with the following price list for three-year, quarterly settlement caps and floors:

<table>
<thead>
<tr>
<th>INTEREST RATE CAPS</th>
<th>INTEREST RATE FLOORS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Strike Rate</td>
<td>Buy</td>
</tr>
<tr>
<td>7%</td>
<td>582 GBP</td>
</tr>
<tr>
<td>8%</td>
<td>398</td>
</tr>
<tr>
<td>9%</td>
<td>205</td>
</tr>
</tbody>
</table>

The prices are in basis points, which when multiplied by the notional principal give the actual purchase or sale price in pounds sterling. These quotes are from the perspective of 904 Part 6: Derivative Security Analysis.

On the same notional amount, BI arranges another swap with Bank B under which BI receives the return on the S&P 500 Index (in U.S. dollars) in exchange for paying the interest rate on the U.S. Treasury bill plus 0.1 percent (10 basis points).

Both swaps would be for a one-year term.

From BI’s perspective, identify and briefly describe:
(a) the major risk that this transaction would eliminate,
(b) the major risk that this transaction would not eliminate (i.e., retain), and
(c) three risks that this transaction would create.

2. To protect the value of the Star Hospital Pension Plan’s bond portfolio against the rising interest rates that she expects, Sandra Kapple enters into a one-year pay fixed, receive floating U.S. LIBOR interest rate swap, as described in the following table:

**U.S. LIBOR Interest Rate Swap Terms**

<table>
<thead>
<tr>
<th>Term</th>
<th>Rate</th>
</tr>
</thead>
<tbody>
<tr>
<td>1-year Fixed Rate (annualized)</td>
<td>1.5%</td>
</tr>
<tr>
<td>90-day U.S. LIBOR Rate [L₉₀(90)] (annualized)</td>
<td>1.1%</td>
</tr>
<tr>
<td>Notional Principal</td>
<td>$1</td>
</tr>
<tr>
<td>Day Count Convention</td>
<td>90/360</td>
</tr>
</tbody>
</table>

Note: Lₙ(m) is the m-day LIBOR on Day i.

Sixty days have passed since initiation of the swap, and interest rates have changed. Kapple is concerned that the value of her swap has also changed. The U.S. LIBOR term structure and present value factors of interest rates are described in this table:

**U.S. LIBOR Term Structure and Present Value Factors (60 Days After Swap Initiation)**

<table>
<thead>
<tr>
<th>Term Structure (annualized)</th>
<th>Present Value Factors</th>
</tr>
</thead>
<tbody>
<tr>
<td>L₉₀(30) = 1.25 percent</td>
<td>0.9990</td>
</tr>
<tr>
<td>L₉₀(120) = 1.50 percent</td>
<td>0.9950</td>
</tr>
<tr>
<td>L₉₀(210) = 1.75 percent</td>
<td>0.9899</td>
</tr>
<tr>
<td>L₉₀(300) = 2.00 percent</td>
<td>0.9836</td>
</tr>
</tbody>
</table>

Note: Lₙ(m) is the m-day LIBOR on Day i.

Calculate the dollar market value of the interest rate swap entered into by Kapple, at 60 days after the initiation of the swap and using a $1 notional principal. Show your calculations. (Note: Your calculations should be rounded to 4 decimal places.)

3. The treasurer of a British brewery is planning to enter a plain vanilla, three-year, quarterly settlement interest rate swap to pay a fixed rate of 8 percent and to receive three-month sterling LIBOR. But first he decides to check various cap-floor combinations to see if any might be preferable. A market maker in British pound sterling OTC options presents the treasurer with the following price list for three-year, quarterly settlement caps and floors:

<table>
<thead>
<tr>
<th>Strike Rate</th>
<th>Buy</th>
<th>Sell</th>
</tr>
</thead>
<tbody>
<tr>
<td>7%</td>
<td>582 GBP</td>
<td>597 GBP</td>
</tr>
<tr>
<td>8%</td>
<td>398</td>
<td>413</td>
</tr>
<tr>
<td>9%</td>
<td>205</td>
<td>220</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Strike Rate</th>
<th>Buy</th>
<th>Sell</th>
</tr>
</thead>
<tbody>
<tr>
<td>320 GBP</td>
<td>335 GBP</td>
<td></td>
</tr>
<tr>
<td>401</td>
<td>416</td>
<td></td>
</tr>
<tr>
<td>502</td>
<td>517</td>
<td></td>
</tr>
</tbody>
</table>

The prices are in basis points, which when multiplied by the notional principal give the actual purchase or sale price in pounds sterling. These quotes are from the perspective of
the market maker, not the firm. That is, the treasurer could buy a 9 percent cap from the market maker for 220 BP, or sell one for 205 BP. The strike rates are quoted on a 365-day basis, as is sterling LIBOR.

In financial analysis of this sort, the treasurer assumes that the three-year cost of funds on fully amortizing debt would be about 8.20 percent (for quarterly payments). Should another structure be considered in lieu of the plain vanilla swap?

4. Takeda Development Corporation has issued a $100 million floating rate note (FRN) that will mature in three years. The FRN has quarterly coupons equal to three-month LIBOR, payable in arrears and due on the first business day of each quarter. Anne Yelland, Takeda Development’s treasurer, wants to hedge against an increase in three-month LIBOR during the remaining term to maturity of the FRN. To implement the hedge, she realizes she can use either of two alternatives: an interest rate cap or a package of over-the-counter (OTC) call options on interest rates.

a. State whether, to correctly implement the hedge using each of the two alternatives, Yelland should (1) buy or sell an interest rate cap, or (2) buy or sell a package of over-the-counter (OTC) call options on interest rates. Discuss one requirement that both alternatives must meet for Yelland’s hedge to be effective.

Yelland decides to implement the hedge using an interest rate cap with the following characteristics:

- The reference rate on the interest rate cap is three-month LIBOR.
- The cap rate (strike rate) is 5.50 percent.
- The length of the agreement is for the remaining three-year life of the FRN.
- The notional principal of the cap is $100 million.
- There is quarterly settlement of the cap, payable in arrears.

The following table shows the three-month annualized LIBOR observed on the first business day of each quarter during the first year of the cap:

<table>
<thead>
<tr>
<th>Quarter</th>
<th>Three-month Annualized LIBOR</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>4.50%</td>
</tr>
<tr>
<td>2</td>
<td>6.50%</td>
</tr>
<tr>
<td>3</td>
<td>7.50%</td>
</tr>
<tr>
<td>4</td>
<td>7.00%</td>
</tr>
</tbody>
</table>

b. Compute the payoff (in dollars) to the interest rate cap at the beginning of each of the following two quarters: (1) Quarter 2, and (2) Quarter 3.

5. On December 2, the manager of a tactical asset allocation fund that is currently invested entirely in floating-rate debt securities decides to shift a portion of her portfolio to equities. To effect this change, she has chosen to enter into the “receive equity index” side of a one-year equity swap based on movements in the S&P 500 Index plus a spread of 10 basis points. The swap is to have quarterly settlement payments, with the floating-rate side of the agreement pegged to three-month LIBOR denominated in U.S. dollars. At the origination of the swap, the value of the S&P 500 Index was 463.11 and three-month LIBOR was 3.50 percent. The notional principal of the swap is set for the life of the agreement at $50 million, which matches the amount of debt holdings in the fund that she would like to convert to equity.

a. Calculate the net cash receipt or payment—from the fund manager’s perspective—on each future settlement date, assuming the value for the S&P 500 index (with all dividends reinvested) and LIBOR are as follows:
On May 26, 1991, Svensk Exportkredit (SEK), the Swedish export credit corporation, is-
sued a Bull Indexed Silver Opportunity Note (BISON). Consider an extended version of
this BISON issue that has the following terms:

- **Maturity**: May 26, 1993
- **Coupon**: 6.50%, paid annually in arrears
- **Face value**: USD 30 million
- **Purchase price**: 100.125% of par value

Additionally, this BISON includes a redemption feature that, for each USD 1,000 of face
value held at maturity, repays the investor’s principal according to the following formula:

\[ \text{USD 1,000} + \left( \text{Spot Silver Price per Ounce} - \text{USD 4.46} \right) \times \text{USD 224.21525} \]

a. Demonstrate that, from SEK’s perspective, the BISON represents a combination of a
straight debt issue priced at a small premium and a derivative contract. Be explicit as
the type of derivative contract and the underlying asset on which it is based. What
implicit speculative position are the investors who buy these bonds taking?

b. Calculate the yield to maturity for an investor holding USD 10,000 in face value
of these BISON if the May 1993 spot price for silver is (1) USD 4.96 per ounce, or
(2) USD 3.96 per ounce.

c. In May 1991 (i.e., when the BISON were used), the prevailing delivery price on a two-
year silver futures contract was USD 4.35 per ounce. If SEK wanted to hedge its
BISON-related exposure to silver prices with an offsetting futures position at this price,
what type of position would need to be entered? Ignoring margin accounts and under-
writing fees, calculate SEK’s average annualized borrowing cost of funds for the result-
ning synthetic straight bond.

In July 1986, Guinness Finance B.V. placed a three-year, $100 million Eurobond issue
known as Stock Performance Exchange Linked (SPEL) bonds. The concept of the SPEL is
that the bond has its principal redemption amount tied to the level of the NYSE compos-
site index at maturity (i.e., NY³) by the following formula:

\[ \text{Variable Redemption Amount} = \max\{100, 100 \times (1 + \frac{\text{NY³} - 166}{166})\} \]

Notice that the investor is guaranteed redemption at par as a minimum. The bond also
pays an annual coupon of 3 percent, which is 0.5 percent below the average annual divi-
dend yield of shares on the NYSE. At the time the SPEL was launched, the NYSE compos-
ite index stood at 134.

a. Demonstrate that the SPEL is a combination of a regular debt issue and an equity op-
ton by analyzing the pattern of annual cash flows generated by the issue. In your
work, assume a par value of 100.

b. The SPEL bonds were issued at a price of 100.625. Assuming that Guinness would or-
ordinarily have to pay a borrowing cost of 7.65 percent on a three-year
“straight” bond (i.e., one with no attached options), calculate the implicit dollar price of the equity in-
dex option embedded in this issue. How much of this amount represents intrinsic
value, and how much is time premium?

7. Rajiv Singh, a bond analyst, is analyzing a convertible bond. The characteristics of the
bond and the underlying common stock follow:

**CONVERTIBLE BOND AND UNDERLYING STOCK CHARACTERISTICS**

<table>
<thead>
<tr>
<th>Convertible Bond Characteristics</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Par value</td>
<td>$1,000</td>
</tr>
<tr>
<td>Annual coupon rate (annual pay)</td>
<td>6.5%</td>
</tr>
<tr>
<td>Conversion ratio</td>
<td>22</td>
</tr>
<tr>
<td>Market price</td>
<td>105% of par value</td>
</tr>
<tr>
<td>Straight value</td>
<td>99% of par share</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Underlying Stock Characteristics</th>
</tr>
</thead>
<tbody>
<tr>
<td>Current market price</td>
</tr>
<tr>
<td>Annual cash dividend</td>
</tr>
</tbody>
</table>

a. Compute the bond’s
(1) Conversion value
(2) Market conversion price
(3) Premium payback period

b. Determine whether the value of a callable convertible bond will increase, decrease, or
remain unchanged in response to each of the following changes, and justify each of your
responses with one reason:
(1) An increase in stock price volatility
(2) An increase in interest rate volatility
8. On May 26, 1991, Svensk Exportkredit (SEK), the Swedish export credit corporation, issued a Bull Indexed Silver Opportunity Note (BISON). Consider an extended version of this BISON issue that has the following terms:

<table>
<thead>
<tr>
<th>Maturity</th>
<th>May 26, 1993</th>
</tr>
</thead>
<tbody>
<tr>
<td>Coupon</td>
<td>6.50%, paid annually in arrears</td>
</tr>
<tr>
<td>Face value</td>
<td>USD 30 million</td>
</tr>
<tr>
<td>Purchase price</td>
<td>100.125% of par value</td>
</tr>
</tbody>
</table>

Additionally, this BISON includes a redemption feature that, for each USD 1,000 of face value held at maturity, repays the investor’s principal according to the following formula:

\[ \text{USD 1,000} + \left[(\text{Spot Silver Price per Ounce} - \text{USD 4.46}) \times (\text{USD 224.21525})\right] \]

a. Demonstrate that, from SEK’s perspective, the BISON represents a combination of a straight debt issue priced at a small premium and a derivative contract. Be explicit as to the type of derivative contract and the underlying asset on which it is based. What implicit speculative position are the investors who buy these bonds taking?

b. Calculate the yield to maturity for an investor holding USD 10,000 in face value of these BISON if the May 1993 spot price for silver is (1) USD 4.96 per ounce, or (2) USD 3.96 per ounce.

c. In May 1991 (i.e., when the BISON were used), the prevailing delivery price on a two-year silver futures contract was USD 4.35 per ounce. If SEK wanted to hedge its BISON-related exposure to silver prices with an offsetting futures position at this price, what type of position would need to be entered? Ignoring margin accounts and underwriting fees, calculate SEK’s average annualized borrowing cost of funds for the resulting synthetic straight bond.

9. In July 1986, Guinness Finance B.V. placed a three-year, $100 million Eurobond issue known as Stock Performance Exchange Linked (SPEL) bonds. The concept of the SPEL is that the bond has its principal redemption amount tied to the level of the NYSE composite index at maturity (i.e., NYSE) by the following formula:

\[ \text{Variable Redemption Amount} = \max[100,100 \times (1 + [\text{NYSE} - 166] \div 166)] \]

Notice that the investor is guaranteed redemption at par as a minimum. The bond also pays an annual coupon of 3 percent, which is 0.5 percent below the average annual dividend yield of shares on the NYSE. At the time the SPEL was launched, the NYSE composite index stood at 134.

a. Demonstrate that the SPEL is a combination of a regular debt issue and an equity option by analyzing the pattern of annual cash flows generated by the issue. In your work, assume a par value of 100.

b. The SPEL bonds were issued at a price of 100.625. Assuming that Guinness would ordinarily have to pay a borrowing cost of 7.65 percent on a three-year “straight” bond (i.e., one with no attached options), calculate the implicit dollar price of the equity index option embedded in this issue. How much of this amount represents intrinsic value, and how much is time premium?

10. A firm has 100,000 shares of stock outstanding priced at $35 per share. The firm has no debt and does not pay a dividend. To raise more capital, it plans to issue 10,000 warrants, each allowing for the purchase of one share of stock at a price of $50. The warrants are European-style and expire in five years. The standard deviation of the firm’s common stock is 34 percent, and the continuously compounded, five-year risk-free rate is 5.2 percent.
a. Estimate the fair value of the warrants, first using the relevant information to calculate the Black-Scholes value of an analogous call option.

b. Determine the stock price at expiration, assuming the warrants are exercised if the value of the firm is at least $5,200,000.

c. Using the information in Parts a and b about initial and terminal warrant and stock prices, discuss the relative merits of these two ways of making an equity investment in the firm.

11. You are an investor trying to value a gold mining company’s lease on a gold mine that is currently not operating. It would cost $1,000,000 for the company to reopen the mine, and it is expected to produce 100,000 ounces of gold at the end of next year. The forward contract price on a one-year gold forward contract is $268.40/ounce, and the current one-year risk-free rate is 5 percent. Extraction costs are estimated to be $260/ounce.

a. Assuming the per-ounce gold price in the spot market one year from now is forecasted to be either $300 or $230, calculate (1) the composition of a portfolio of T-bills and gold forward contracts that would replicate the cash flows from the mine, and (2) the “real options” value of the mine lease.

b. Assuming the per-ounce gold price in the spot market one year from now is forecasted to be either $280 or $250, calculate (1) the composition of a portfolio of T-bills and gold forward contracts that would replicate the cash flows from the mine, and (2) the real options value of the mine lease.

c. What do your answers in Parts a and b tell you about the effect that the volatility of future gold prices has on the current value of the mine lease?
This final section of the book contains two chapters: The first deals with professional asset management, and the second is concerned with the evaluation of portfolio performance. The discussions of both of these topics are designed to address the needs of individual and institutional investors alike; both individual and institutional investors periodically need the services of a professional money manager, and both types of investors also need to be aware of how one evaluates the performance of a portfolio.

Because many investors employ professional asset managers to manage their assets, Chapter 24 is an important wrap-up to their asset allocation and portfolio construction process. After a broad overview of the different ways that professional asset management firms can be organized, the chapter describes how the asset management industry has changed over time and how professional managers are compensated for their expertise. Particular emphasis is paid to the role of investment companies (also more commonly called mutual funds), which manage the majority of assets held by individual investors. The discussion includes a description of the major forms of investment companies and the general types of funds available, such as money market, growth, aggressive growth, income, balanced, and bond funds. It is argued that almost any investment objective can be met by investing in one or several investment companies. The chapter also provides a detailed examination of how alternative asset investments—hedge funds and private equity—are structured and managed. These investments are among the fastest growing segments of the money management industry.

We conclude Chapter 24 with a discussion of ethical and regulatory issues that arise when hiring a professional asset manager. We argue that most of these issues arise from the classical principal-agent problem that defines many economic relationships. After first examining the myriad regulations that govern the behavior of professional portfolio managers, we then describe the set of standards that the industry has adopted voluntarily in an effort to foster an atmosphere of trust and responsibility. The chapter ends with several examples of ethical conflicts that can arise when investors employ professional money managers. Two issues that are of special concern are designing compensation contracts to provide managers with the proper incentives to act in the investor’s best interest and the proper use of trading commission fees.

We conclude the book with Chapter 25, which deals with the evaluation of portfolio performance. Perhaps the most important concept to understand from this discussion is that any meaningful evaluation of an investment manager’s performance must consider both the return and the riskiness of the portfolio. Thus, after a discussion of what is required of a portfolio manager, we review in detail the major risk-adjusted portfolio performance models, including a recent performance attribution model that, in turn, is capable of evaluating a global portfolio that necessarily includes the effect of currency allocation. We also consider how the alternative models relate to each other. This is followed by a demonstration of their use with a sample of mutual funds.

As always, it is important to understand potential problems with a technique or model. Therefore, we discuss holdings-based measures, which evaluate a manager’s performance by examining the contents of the portfolio rather than relying on a statistical model to measure expected returns (e.g., CAPM). We also consider potential problems with the traditional performance measures, including a review of Roll’s benchmark problem and its effect on these performance models. It is demonstrated that this benchmark problem has become more significant with the growth of global investing. Also, because the factors that determine success in bonds differ from what is important in equities, we review alternative models used to evaluate the performance of bond portfolio managers. The chapter finishes with a consideration of how investment performance results should be presented so as to be consistent with industry practice.
This final section of the book contains two chapters: The first deals with professional asset management, and the second is concerned with the evaluation of portfolio performance. The discussions of both of these topics are designed to address the needs of individual and institutional investors alike; both individual and institutional investors periodically need the services of a professional money manager, and both types of investors also need to be aware of how one evaluates the performance of a portfolio.

Because many investors employ professional asset managers to manage their assets, Chapter 24 is an important wrap-up to their asset allocation and portfolio construction process. After a broad overview of the different ways that professional asset management firms can be organized, the chapter describes how the asset management industry has changed over time and how professional managers are compensated for their expertise. Particular emphasis is paid to the role of investment companies (also more commonly called mutual funds), which manage the majority of assets held by individual investors. The discussion includes a description of the major forms of investment companies and the general types of funds available, such as money market, growth, aggressive growth, income, balanced, and bond funds. It is argued that almost any investment objective can be met by investing in one or several investment companies. The chapter also provides a detailed examination of how alternative asset investments—hedge funds and private equity—are structured and managed. These investments are among the fastest growing segments of the money management industry.

We conclude Chapter 24 with a discussion of ethical and regulatory issues that arise when hiring a professional asset manager. We argue that most of these issues arise from the classical principal-agent problem that defines many economic relationships. After first examining the myriad regulations that govern the behavior of professional portfolio managers, we then describe the set of standards that the industry has adopted voluntarily in an effort to foster an atmosphere of trust and responsibility. The chapter ends with several examples of ethical conflicts that can arise when investors employ professional money managers. Two issues that are of special concern are designing compensation contracts to provide managers with the proper incentives to act in the investor’s best interest and the proper use of trading commission fees.

We conclude the book with Chapter 25, which deals with the evaluation of portfolio performance. Perhaps the most important concept to understand from this discussion is that any meaningful evaluation of an investment manager’s performance must consider both the return and the riskiness of the portfolio. Thus, after a discussion of what is required of a portfolio manager, we review in detail the major risk-adjusted portfolio performance models, including a recent performance attribution model that, in turn, is capable of evaluating a global portfolio that necessarily includes the effect of currency allocation. We also consider how the alternative models relate to each other. This is followed by a demonstration of their use with a sample of mutual funds.

As always, it is important to understand potential problems with a technique or model. Therefore, we discuss holdings-based measures, which evaluate a manager’s performance by examining the contents of the portfolio rather than relying on a statistical model to measure expected returns (e.g., CAPM). We also consider potential problems with the traditional performance measures, including a review of Roll’s benchmark problem and its effect on these performance models. It is demonstrated that this benchmark problem has become more significant with the growth of global investing. Also, because the factors that determine success in bonds differ from what is important in equities, we review alternative models used to evaluate the performance of bond portfolio managers. The chapter finishes with a consideration of how investment performance results should be presented so as to be consistent with industry practice.
After you read this chapter, you should be able to answer the following questions:

- What are the different ways that professional money management firms can be organized, and how has the structure of the industry changed over time?
- Who manages the portfolios at investment advisory firms and investment companies, and how are those managers compensated?
- How do you compute the net asset value (NAV) for investment companies?
- What is the difference between closed-end and open-end investment companies?
- What are load fees, 12b-1 fees, and management fees, and how do they influence investment company performance?
- How are funds classified by investment objective, and which groups have experienced relative growth or decline?
- What are hedge funds, and how do they differ from other professionally managed investment products?
- What investment strategies do hedge funds employ, and what has been the performance of those fund types over time?
- What attributes do private equity investments possess that make them a unique asset class?
- How do venture capital and buyout-oriented private equity investments differ from one another, and what has been their historical performance?
- What are some of the ethical dilemmas involved in the professional money management industry?
- What functions should investors expect professional asset managers to perform for them?

So far, we have discussed how investors can analyze the aggregate market, different industry sectors, and individual companies when organizing their investment portfolios. We have also considered how those portfolio positions can be augmented with various derivative positions to create additional risk-return possibilities. This chapter introduces another possibility to the investor: entrusting one’s money to a professional portfolio manager. Using a professional money manager can entail establishing a private account with an investment advisor, purchasing shares of an established mutual fund, or becoming a limited partner in an organization managed by a general partner. In any form, professionally managed investments often represent a substantial portion of an individual’s total holdings.

Both individual and institutional (e.g., corporate pension plans, university endowments) investors alike seek the services of professional money managers for several reasons. First and foremost, these managers may possess superior investment skills that will lead to higher returns than investors could obtain on their own. Beyond that, there are a number of additional benefits professional managers supply, such as offering access to asset classes and investment strategies that might otherwise be unavailable or
providing a cost-effective way to choose among a wide variety of diversified portfolios. However, these relationships also create potential conflicts of interest between the goals of the investor and those of the manager that need to be considered.

After explaining the various ways in which asset management firms are typically organized and charge for their services, we explore three different types of professional money management firms: traditional private management firms, investment (i.e., fund) companies, and “alternative asset” companies (i.e., hedge funds, private equity firms) created through limited partnership vehicles. We pay particular attention to the contrast between investment companies, which are the most prevalent way in which investors employ professional counsel, and alternative asset vehicles, which represent the most rapidly growing segment of the industry. We conclude with a description of the legal and regulatory environment that governs professional investors, as well as some of the ethical implications of the investor-manager relationship.

### 24.1 The Asset Management Industry: Structure and Evolution

There are two basic ways that traditional professional asset management firms are organized. In the most straightforward structure, investors make contracts directly with a management and advisory firm for its services. These services can range from providing standard banking transactions (savings accounts, personal loans) to advising clients on structuring their own portfolios to actually managing the investment funds themselves. Although banking and financial advice were once the main services these firms offered, there has recently been a dramatic shift toward the assets under management (AUM) approach. In that arrangement, the management firm becomes the custodian of the investor’s capital, usually with full discretion as to how those funds are invested. An important feature of this structure is that each client of the management firm has a separate account. Even if investors select the firm because of its expertise in a particular niche—say, selecting small-cap growth stocks—the assets of each client will be accounted for separately, regardless of whether the firm employs a single “model” portfolio. This situation is illustrated in Panel A of Exhibit 24.1.

A second general approach to asset management involves the commingling of investment capital from several clients. An investment company invests a pool of funds belonging to many individuals in a single portfolio of securities. In exchange for this capital, the investment company issues to each investor new shares representing his or her proportional ownership of the mutually held securities portfolio, which is commonly known as a fund. For example, assume an investment company sells 10 million shares to the public at $10 a share, thereby raising $100 million. If the fund’s purpose is to emphasize large-cap common stocks, the manager would invest the proceeds of the fund share sale ($100 million less any brokerage fees) in the stock of such companies as Merck, IBM, ExxonMobil, and General Electric. Each investor who bought shares of the investment company would then own the appropriate percentage of the overall fund, rather than any portion of the shares held in the portfolio. Panel B of Exhibit 24.1 shows how this structure might work.

There are important differences between these two organizational forms. Private management and advisory firms typically develop a personal relationship with their clients, getting to know the specific investment objectives and constraints of each. The collection of assets held in the various separate accounts can then be tailored to these special needs, even if a general blueprint portfolio is used for all clients. Of course, special attention comes at a cost, and for this reason private management firms are used mainly by investors with substantial levels of
capital, such as pension fund sponsors and high-net-worth individuals. Conversely, a mutual fund offered by an investment company is formed as a general solution to an investment problem and then marketed to investors who might fit that profile. The primary clients who seek professional asset management through investment companies are individual investors with relatively small pools of capital. The Investment Company Institute (a nonprofit industry trade association) reported that in 2009, 85 percent of mutual fund shares were held by households, with only 15 percent being held by business organizations.\(^1\)

It is not unusual for professional asset management firms to combine these two structures by offering private advisory services as well as publicly traded funds. For instance, consider T. Rowe Price Associates, a multi-asset, independent advisory firm located in Baltimore, Maryland. Founded in 1937, T. Rowe Price has seen its business grow to the point where it managed almost $400 billion by the end of 2009, compared with less than $54 billion AUM just 15 years earlier. The majority of this capital is invested in the firm’s various public mutual fund portfolios, but T. Rowe Price also has several hundred private clients, including corporate retirement funds, public funds and unions, foundations and endowments, and individual investors.\(^2\)

The AUM growth that T. Rowe Price has experienced during the past few years has been typical for the entire industry. Exhibit 24.2 charts the top 50 asset management companies as of the end of 1994 and 2009. A striking feature of these lists is the rapid increase in the number of large asset management firms, defined as those organizations with AUM of more than $100 billion. In 1994, there were only 10 such firms; by 2009, there were 74, including all 50 listed on the left side of Exhibit 24.2. Much of this asset growth can be explained by the strong performance of global equity markets during this period, but another important contributing factor was the consolidation trend that marked the industry. Typical of this phenomenon was the merger of the asset management groups Union Bank of Switzerland and Brinson Partners (ranked 36th and 39th on the 1994 list, respectively) to become UBS Global Asset Management.

---

</table>
Management (ranked 17th on the 2009 list). This consolidation trend is likely to continue, because the competition among existing asset management firms for the flow of new investment capital is expected to increase significantly.

While larger management companies offer a broader range of services and products, the majority of private management and advisory firms are still much smaller and more narrowly focused on a particular niche of the market. To examine one typical organization in greater detail, consider Prudent Capital Management (PCM), a growth-oriented equity and fixed-income manager located in Southern California. PCM utilizes a "bottom-up" security selection process, with its portfolio managers looking for companies that have exceptional profitability, market share, return on equity, and earnings growth. PCM’s clients include both institutional investors and high-net-worth individuals (with between $2 million and $5 million in assets) in both separate and commingled accounts. The firm offers management of both taxed and non-taxed products. Exhibit 24.3 shows the myriad investment products that PCM offers, along with the minimum investment accepted in each.

Like the industry as a whole, PCM saw its assets under management increase steadily over the past several years. Panel A of Exhibit 24.4 reports that over a recent five-year period, the firm’s AUM grew by almost 80 percent, from $11.8 billion to $21.2 billion. During the same period, the firm’s net income increased by over 100 percent, from $120 million to $243 million.

Management (ranked 17th on the 2009 list). This consolidation trend is likely to continue, because the competition among existing asset management firms for the flow of new investment capital is expected to increase significantly.\(^3\)

### 24.2 Private Management and Advisory Firms

While larger management companies offer a broader range of services and products, the majority of private management and advisory firms are still much smaller and more narrowly focused on a particular niche of the market. To examine one typical organization in greater detail, consider Prudent Capital Management (PCM),\(^4\) a growth-oriented equity and fixed-income manager located in Southern California. PCM utilizes a “bottom-up” security selection process, with its portfolio managers looking for companies that have exceptional profitability, market share, return on equity, and earnings growth. PCM’s clients include both institutional investors and high-net-worth individuals (with between $2 million and $5 million in assets) in both separate and commingled accounts. The firm offers management of both taxed and non-taxed products. Exhibit 24.4 shows the myriad investment products that PCM offers, along with the minimum investment accepted in each.

Like the industry as a whole, PCM saw its assets under management increase steadily over the past several years. Panel A of Exhibit 24.4 reports that over a recent five-year period, the firm’s AUM grew by almost 80 percent, from $11.8 billion to $21.2 billion. During the same

\(^3\)Good economic analysis of the professional asset management business can be found in Hurley et al. (1995) and Brinson (2005).

\(^4\)Prudent Capital Management is a pseudonym for a real firm whose name has been changed by request. However, all of the subsequent information reported is real.
An investor’s assets managed at a private money management firm (PCM) are held in separate accounts. This separation aligns the interests of the investor and the manager. The client’s portfolio is likely to reflect the firm’s overall investment philosophy, which is designed to attract clients. Exhibit 24.5 provides examples of PCM’s investment strategies and major holdings for two portfolios: one in equities and one in fixed-income securities.

**Panel A:** Large-Cap Growth Equity Portfolio

- **Investment Approach:** Focused, fundamental research based on in-house analysts. Specialization in key growth sectors: technology, telecom, health care, retail, consumer, and finance. The approach seeks companies with growth catalysts and strong earnings per share growth.

- **Largest Holdings:**
  1. Microsoft
  2. Nokia
  3. Cisco Systems
  4. Qualcomm
  5. Genentech
  6. Motorola
  7. Sun Microsystems
  8. EMC
  9. Amgen
  10. Flextronics

**Benchmark Used:** Russell 1000 Growth Index.

**Panel B:** Active Fixed Income Portfolio

- **Investment Approach:** Risk-adjusted returns achieved by active yield curve management, sector rotation, and security selection. The process is based on current conditions and historical relationships, not on future forecasts.

- **Largest Holdings:**
  1. A–Baa rated corporates (56.9%)
  2. Treasury/agencies (33.6%)
  3. Aaa–Aa rated corporates (9.5%)

**Benchmark Used:** Barclays Government/Corporate Index.

**Source:** Data adapted from Nelson’s Directory of Investment Managers.

During the reporting period, the median separate account size jumped from $24.8 million to over $39 million. This increase suggests that PCM’s clients tend to be institutional investors, and the client profile summarized in Panel B of Exhibit 24.4 confirms this. The company offers services to more than 350 clients, but the majority of these are institutional investors. Perhaps because of the minimum investment restrictions, relatively few of the clients are individual investors, and the assets they represent are slightly less than 3 percent (535 ÷ 21,165) of PCM’s business.

Panel C of Exhibit 24.4 shows fee schedules representative of both the equity and the fixed-income management services that PCM offers. Typical of the industry, these fees are not flat amounts but are expressed as percentages of invested capital on an annual basis. They are also graduated on a declining scale so that the more capital an investor commits to the firm, the lower his or her average cost would be. An individual with $15 million invested would pay annual fees of $137,500 (10,000,000 × 0.01 + 5,000,000 × 0.0075), or 0.92 percent of total invested capital. On the other hand, the fee paid by a pension fund with $115 million under management would be $650,000 (10,000,000 × 0.01 + 10,000,000 × 0.0075 + 95,000,000 × 0.005), or 0.57 percent. One advantage to the investor of having the fee schedule tied directly to the size of the investment is that it aligns the interests of the investor and the manager.
to AUM is that, as the management firm performs better for the client, its fees will increase. This reward system helps to align the incentives of the investor and the manager.

24.2.1 Investment Strategy at a Private Money Management Firm

The representation of a private money management firm shown in Panel A of Exhibit 24.1 indicated that each client’s assets were held in a separate account. It was also noted that the security portfolios formed for each client are likely to be guided by the firm’s overall investment philosophy. It is this investment philosophy—along with the returns it produces—that attracts clients to a particular money manager in the first place. Exhibit 24.5 reproduces the investment strategy and major holdings for two of PCM’s model portfolios, one in equities and one in fixed-income securities.

| **Benchmark Used:** Barclays Government/Corporate Index |

**Source:** Data adapted from Nelson’s Directory of Investment Managers.
The investment approach expressed in Panel A of Exhibit 24.5 makes it clear that clients choosing to invest in PCM’s large-cap growth stock product will have their money invested primarily in technology companies. While the specific stock allocations might vary from one client to another, the same fundamental orientation toward stock selection will be applied to all accounts. Similarly, a client choosing to invest in PCM’s core fixed-income product will end up holding a portfolio of bonds split between government and investment-grade corporate names. The stated investment process at PCM requires extensive interaction between the firm’s 11 equity portfolio managers, 10 equity analysts, 3 equity traders, and 6 additional manager/analysts.

24.3 Organization and Management of Investment Companies

An investment company typically is a corporation that has as its major assets the portfolio of marketable securities referred to as a fund. The management of the portfolio of securities and most of the other administrative duties are handled by a separate investment management company hired by the board of directors of the investment company. This legal description oversimplifies the typical arrangement. The actual management usually begins with an investment advisory firm that starts an investment company and selects a board of directors for the fund. Subsequently, this board of directors hires the investment advisory firm as the fund’s portfolio manager.

The contract between the investment company (the portfolio of securities) and the investment management company details the duties and compensation of the latter. The major duties of the investment management company include investment research, the management of the portfolio, and administrative duties, such as issuing securities and handling redemptions and dividends. The management fee is generally stated as a percentage of the total value of the fund and typically ranges from \( \frac{1}{4} \) to \( \frac{1}{2} \) of 1 percent, with a sliding scale as the size of the fund increases.

To achieve economies of scale, many management companies launch numerous funds with different characteristics. The variety of funds allows the management group to appeal to many investors with different risk–return preferences. In addition, it allows investors to switch among funds as economic or personal conditions change. This “family of funds” promotes flexibility and increases the total capital managed by the investment firm.

24.3.1 Valuing Investment Company Shares

When clients have invested capital held in separate accounts, the value of any given account can be calculated by simply totaling the market value of the securities held in the portfolio, less fees. When the securities are held jointly, as they are in an investment company, the appropriate way to value a client’s investment is to multiply the number of shares in the fund owned by the per-share value of the entire security fund. This per-share value is known as the net asset value (NAV) of the investment company. It equals the total market value of all the firm’s assets divided by the total number of fund shares outstanding, or:

\[
\text{Fund NAV} = \frac{(\text{Total Market Value of Fund Portfolio}) - (\text{Fund Expenses})}{(\text{Total Fund Shares Outstanding})}
\]

The NAV for an investment company is analogous to the share price of a corporation’s common stock; like common stock, the NAV of the fund shares will increase as the value of the underlying assets increases.

In an earlier example, we saw that an investment company with a $100 million large-cap stock portfolio and 10 million outstanding shares would have a NAV of $10. What would
happen if during a holding period the value of the stock portfolio increased to $112.5 million while the fund incurred $0.1 million in trading expenses and management fees? If no new shares were sold during the period, the net value of the total investment company is $112.4 million, which leaves a net asset value for each existing fund share of $11.24 ([112,500,000 – 100,000] / 10,000,000). Thus, the NAV provides an immediate reflection of the investment company’s market value net of operating expenses. Had the investment company made any capital gain or dividend distributions to its investors, these would reduce the value of the fund portfolio. For publicly traded funds, NAVs are calculated and reported on a daily basis.

24.3.2 Closed-End versus Open-End Investment Companies

Investment companies begin like any other company by selling common stock to a group of investors. However, it uses the proceeds to purchase the securities of other publicly held companies rather than buildings and equipment. An open-end investment company (often referred to as a mutual fund) differs from a closed-end investment company (typically referred to as a closed-end fund) in the way each operates after the initial public offering.

A closed-end investment company functions like any other public firm. Its stock trades on the regular secondary market, and the market price of its shares is determined by supply and demand conditions. Thus, if you want to buy or sell shares in a closed-end fund, you must make transactions in the market where its shares are listed (e.g., NYSE). No new investment dollars are available for the investment company unless it makes another public sale of securities. Similarly, no funds can be withdrawn unless the investment company decides to repurchase its stock, which is quite unusual. Exhibit 24.6 lists the number of closed-end funds traded on U.S. exchanges, broken down by investment objective and category AUM. More than 650 funds are represented in over 30 categories, including general domestic equity and bond funds, global equity funds, loan participation funds, flexible income funds, national municipal bond funds, and single state municipal bond funds.

The closed-end investment company’s NAV is computed throughout the day based on prevailing market prices for the portfolio securities, but the market price of the shares is determined by how they trade on the exchange. When buying or selling shares of a closed-end fund, investors pay or receive this market price plus or minus a regular trading commission. Recognize that the NAV and the market price of a closed-end fund are almost never the same. Over the long run, the market price of these shares has historically been from 5 to 20 percent below the NAV (i.e., closed-end funds typically sell at a discount to NAV).

This relationship has prompted questions from investors: Why do these funds sell at a discount? Why do the discounts differ between funds? What are the returns available to investors from funds that sell at large discounts? This final question arises because an investor who acquires a portfolio at a price below market value (i.e., below NAV) expects an above-average dividend yield. Still, the total rate of return on the fund depends on what happens to the discount during the holding period. If the discount relative to the NAV declines, the investment should generate positive excess returns. If the discount increases, the investor will likely experience negative excess returns. The analysis of these discounts remains a major question of modern finance.5

The interest in closed-end funds has led Thomas J. Herzfeld Advisors, a firm that specializes in closed-end funds, to create an index that tracks the market price performance of a sample of U.S. closed-end funds that invest principally in U.S. equities. The price-weighted series is based on fund market values rather than on NAVs. In addition to its market price

---

5Studies over the years include research by Lee, Shleifer, and Thaler (1991); Barclay, Holderness, and Pontiff (1993); Klibanoff, Lamont, and Wizman (1998); and Berk and Stanton (2007).
Open-end investment companies have enjoyed substantial growth since World War II, as shown by the figures in Exhibit 24.8. Clearly, open-end funds account for a substantial portion of invested assets, and they provide a very important service for almost 275 million accounts.

Load versus No-Load Open-End Funds

One distinction of open-end funds is that some charge a sales fee for share sales. The offering price for a share of a load fund equals the NAV of the share plus a sales charge, which can be as large as 8.5 percent of the NAV. A fund with an 8 percent sales charge (load) would give an individual who invested $1,000 in

**Note:** Assets are net assets after deductions of all operating costs, expressed in $ millions.

**Source:** Closed-End Fund Association, April 19, 2011. Reprinted with permission.

Index, Herzfeld also computes the average discount from NAV. The lower right-hand graph in Exhibit 24.7 indicates that the average discount from NAV changes over time and has a major impact on the market performance of the index. For example, during 2009–2010, this value changed from a discount of 14 percent to a discount of about 8 percent. The performance of the Herzfeld closed-end average at the end of this period was ahead of the DJIA.

**Open-end investment companies**, or mutual funds, continue to sell and repurchase shares after their initial public offerings. They stand ready to sell additional shares of the fund at the NAV, with or without sales charge, or to buy back (redeem) shares of the fund at the NAV, with or without redemption fees.
the fund shares that are worth only $920. Such funds generally charge no redemption fee, which means the shares can be redeemed at their NAV. These funds typically are quoted with an NAV and an offering price. The NAV price is the redemption (bid) price, and the offering (ask) price equals the NAV divided by 1.0 minus the percent load. For example, if the NAV of a fund with an 8 percent load is $8.50 a share, the offering price would be $9.24 ($8.50/0.92). The 74-cent differential is really 8.7 percent of the NAV. The load percentage typically declines with the size of the order.

A no-load fund imposes no initial sales charge, so it sells shares at their NAV. Some of these funds charge a small redemption fee of about one-half of 1 percent. In the financial press, quotes for these no-load funds list bid prices as the NAV with the designation "NL" (no load) for the offering price—that is, the bid and offer are the same. The number of no-load funds has increased substantially in recent years. In fact, the Investment Company Institute noted that in 2003, the number of no-load equity funds exceeded the number of load funds for the first time.

Between the full-load fund and the pure no-load fund, several important variations exist. The first is the low-load fund, which imposes a front-end sales charge when the fund is bought, but it is typically in the 3 percent range. Generally, low-load funds are used for bond funds or equity funds offered by management companies that also offer no-load funds. Alternatively, some funds—previously charging full loads—have reduced their loads.

The second major innovation is the 12b-1 plan, named after a 1980 SEC ruling. This plan permits funds to deduct as much as 0.75 percent of average net assets per year to cover distribution costs, such as advertising, brokers' commissions, and general marketing expenses. A large and growing number of no-load funds are adopting these plans, as are a few low-load funds. You can determine if a fund has a 12b-1 plan by reading the prospectus or using an investment service that reports charges in substantial detail.

Finally, some funds have instituted contingent, deferred sales loads in which a sales fee is charged when the fund is sold if it is held for less than some time period, perhaps three or four years.

24.3.3 Fund Management Fees

In addition to selling charges (loads or 12b-1 charges), all investment firms charge annual management fees to compensate professional managers of the fund. Similar to the compensation structure for private management firms, such a fee typically is a percentage of the average net assets of the fund varying from about 0.25 to 1.00 percent. Most of these management fees are on sliding scales that decline with the size of the fund. A fund with assets under $1 billion might charge 1 percent, funds with assets between $1 billion and $5 billion might charge 0.50 percent, and those over $5 billion would charge 0.25 percent. These management fees are a major factor driving the creation of new funds. More assets under management generate more fees, but the costs of management do not increase at the same rate as the managed assets because substantial economies of scale exist in managing financial assets. Once the research staff and management structure are established, the incremental costs do not rise in line with the assets under management. The cost of managing $1 billion of assets is not twice the cost of managing $500 million. Finally, one consequence of the industry consolidation we discussed earlier is that mutual fund fees have been declining. The Investment Company Institute reported that between 1980 and 2009, total shareholder costs to equity fund investors decreased by almost 60 percent, from 2.32 to 0.99 percent of average fund AUM.

24.3.4 Investment Company Portfolio Objectives

A mutual fund can be created around any portfolio of assets. However, mutual funds tend to exist for only the more liquid asset classes, such as stocks and bonds. There are four broad fund objective categories recognized by the Investment Company Institute: common stock funds, bond funds, hybrid funds, and money market funds. Each of these strategies is

Open-end investment companies have enjoyed substantial growth since World War II, as shown by the figures in Exhibit 24.8. Clearly, open-end funds account for a substantial portion of invested assets, and they provide a very important service for almost 275 million accounts.

**Load versus No-Load Open-End Funds** One distinction of open-end funds is that some charge a sales fee for share sales. The offering price for a share of a load fund equals the NAV of the share plus a sales charge, which can be as large as 8.5 percent of the NAV. A fund with an 8 percent sales charge (load) would give an individual who invested $1,000 in

the fund shares that are worth only $920. Such funds generally charge no redemption fee, which means the shares can be redeemed at their NAV. These funds typically are quoted with an NAV and an offering price. The NAV price is the redemption (bid) price, and the offering (ask) price equals the NAV divided by 1.0 minus the percent load. For example, if the NAV of a fund with an 8 percent load is $8.50 a share, the offering price would be $9.24 ($8.50/0.92). The 74-cent differential is really 8.7 percent of the NAV. The load percentage typically declines with the size of the order.

A no-load fund imposes no initial sales charge, so it sells shares at their NAV. Some of these funds charge a small redemption fee of about one-half of 1 percent. In the financial press, quotes for these no-load funds list bid prices as the NAV with the designation "NL" (no load) for the offering price—that is, the bid and offer are the same. The number of no-load funds has increased substantially in recent years. In fact, the Investment Company Institute noted that in 2003, the number of no-load equity funds exceeded the number of load funds for the first time.

Between the full-load fund and the pure no-load fund, several important variations exist. The first is the low-load fund, which imposes a front-end sales charge when the fund is bought, but it is typically in the 3 percent range. Generally, low-load funds are used for bond funds or equity funds offered by management companies that also offer no-load funds. Alternatively, some funds—previously charging full loads—have reduced their loads.

The second major innovation is the 12b-1 plan, named after a 1980 SEC ruling. This plan permits funds to deduct as much as 0.75 percent of average net assets per year to cover distribution costs, such as advertising, brokers’ commissions, and general marketing expenses. A large and growing number of no-load funds are adopting these plans, as are a few low-load funds. You can determine if a fund has a 12b-1 plan by reading the prospectus or using an investment service that reports charges in substantial detail.

Finally, some funds have instituted contingent, deferred sales loads in which a sales fee is charged when the fund is sold if it is held for less than some time period, perhaps three or four years.

24.3.3 Fund Management Fees
In addition to selling charges (loads or 12b-1 charges), all investment firms charge annual management fees to compensate professional managers of the fund. Similar to the compensation structure for private management firms, such a fee typically is a percentage of the average net assets of the fund varying from about 0.25 to 1.00 percent. Most of these management fees are on sliding scales that decline with the size of the fund. A fund with assets under $1 billion might charge 1 percent, funds with assets between $1 billion and $5 billion might charge 0.50 percent, and those over $5 billion would charge 0.25 percent.

These management fees are a major factor driving the creation of new funds. More assets under management generate more fees, but the costs of management do not increase at the same rate as the managed assets because substantial economies of scale exist in managing financial assets. Once the research staff and management structure are established, the incremental costs do not rise in line with the assets under management. The cost of managing $1 billion of assets is not twice the cost of managing $500 million. Finally, one consequence of the industry consolidation we discussed earlier is that mutual fund fees have been declining. The Investment Company Institute reported that between 1980 and 2009, total shareholder costs to equity fund investors decreased by almost 60 percent, from 2.32 to 0.99 percent of average fund AUM.

24.3.4 Investment Company Portfolio Objectives
A mutual fund can be created around any portfolio of assets. However, mutual funds tend to exist for only the more liquid asset classes, such as stocks and bonds. There are four broad fund objective categories recognized by the Investment Company Institute: common stock funds, bond funds, hybrid funds, and money market funds. Each of these strategies is
described briefly here, while Exhibit 24.9 provides a more detailed list of many of the more popular subcategories within these objective classes.

Equity funds invest almost exclusively in common stocks. Within that broad mission, however, substantial differences can be found, including funds that focus on specific industries (e.g., Chemical Fund, Oceanography Fund), a collection of industries (e.g., Technology Fund), security characteristics (e.g., Growth Fund, Large-Cap Fund), or even geographic areas (e.g., Global Funds, Northeast Fund). With several thousand to choose from, any investor should find an existing equity fund that matches his or her desired investment strategy. Thus, the important thing that an investor must do is to decide what that preferred strategy happens to be.

Bond funds concentrate on various types of bonds to generate high current income with minimal risk. They are similar to common stock funds; however, their investment policies differ. Some funds concentrate on U.S. government or high-grade corporate bonds, others hold a mixture of investment-grade bonds, and some concentrate on high-yield (junk) bonds. Management strategies also can differ, ranging from buy and hold to extensive trading of the portfolio bonds.

In addition to government, mortgage, and corporate bond funds, a change in the tax law in 1976 caused the creation of numerous municipal bond funds. These funds provide investors with monthly interest payments that are exempt from federal income taxes. Some municipal bond funds concentrate on bonds from specific states, such as the New York Municipal Bond Fund, which allows New York residents to avoid most state taxes on the interest income.

**Balanced funds** diversify outside a single market by combining common stock with fixed-income securities, including government bonds, corporate bonds, convertible bonds, or preferred stock. The ratio of stocks to fixed-income securities will vary by fund, as stated in each fund’s prospectus. Flexible portfolio (or asset allocation) funds seek high total returns by investing in a mix of stocks, bonds, and money-market securities. Target date (or life cycle) funds adjust the asset allocation weights in the portfolio to match the needs of an investor who is aging toward retirement.

**Money market funds** were initiated during 1973 when short-term interest rates were at record levels. These funds attempt to provide current income, safety of principal, and liquidity by investing in diversified portfolios of short-term securities, such as Treasury bills, banker certificates of deposit, bank acceptances, and commercial paper. Exhibit 24.10 documents the significant growth of these funds, which often depends on investor attitudes toward the stock market. When investors are bullish toward stocks, they withdraw funds from their money market accounts to invest; when they are uncertain, they shift from stocks to the money funds.

### 24.3.5 Breakdown by Fund Characteristics

Exhibit 24.11 groups funds by their method of sale and by investment objectives. The two major means of distribution are (1) by a sales force and (2) by direct purchase from the fund or direct marketing. Sales forces would include brokers, such as Morgan Stanley; commission-based financial planners; or dedicated sales forces, such as those of Ameriprise Financial Advisors. Mutual funds acquired from these companies will often charge sales fees (loads) from which salespeople are compensated.

Investors typically purchase shares of directly marketed funds through mail, telephone, a bank wire, or an office of the fund. These direct sales funds usually impose a low sales charge or none at all. In the past, because they had no sales fee, they had to be sold directly because a broker had no incentive to sell a no-load fund. This has changed recently because some brokerage firms, such as Charles Schwab & Co., have developed agreements with specific no-load funds whereby they will sell these funds to their clients and collect a fee from the fund. As of 2011, Schwab had a list of thousands of no-load funds that it would sell through its OneSource service. As seen in the most recent figures available in Exhibit 24.11, the division between these two major distribution channels is currently about 60 to 40 percent in favor of the sales force method.
The breakdown by investment objective indicates the investment companies’ response to a shift in investor emphasis toward equity funds and reflects not only the overall growth of the industry but also the creation of new funds in response to the evolving demands of investors. Capital appreciation and total return funds have continued to grow and have generally increased their

**Source:** Adapted from data in Investment Company Institute, 2010 Investment Company Fact Book.

### Exhibit 24.9 Mutual Fund Objectives

#### Stock Funds
- **Aggressive growth funds** invest primarily in common stock of small, growth companies with potential for capital appreciation.
- **Emerging market equity funds** invest primarily in equity securities of companies based in less-developed regions of the world.
- **Global equity funds** invest primarily in worldwide equity securities, including those of U.S. companies.
- **Growth and income funds** attempt to combine long-term capital growth with steady income dividends. These funds pursue this goal by investing primarily in common stocks of established companies with the potential for both growth and good dividends.
- **Growth funds** invest primarily in common stocks of well-established companies with the potential for capital appreciation. These funds’ primary aim is to increase the value of their investments (capital gain) rather than generate a flow of dividends.
- **Income equity funds** seek income by investing primarily in equity securities of companies with good dividends. Capital appreciation is not an objective.
- **International equity funds** invest at least 80 percent of their portfolios in equity securities of companies located outside the United States.
- **Regional equity funds** invest in equity securities of companies based in specific world regions, such as Europe, Latin America, the Pacific Region, or individual countries.
- **Sector equity funds** seek capital appreciation by investing in companies in related fields or specific industries, such as financial services, health care, natural resources, technology, or utilities.

#### Bond Funds
- **Corporate bond-general funds** seek a high level of income by investing 80 percent or more of their portfolios in corporate bonds and have no explicit restrictions on average maturity.
- **Corporate bond-intermediate-term funds** seek a high level of income with 80 percent or more of their portfolios invested at all times in corporate bonds. Their average maturity is five to ten years.
- **Corporate bond-short-term funds** seek a high level of current income with 80 percent or more of their portfolios invested at all times in corporate bonds. Their average maturity is one to five years.
- **Global bond-general funds** invest in worldwide debt securities and have no stated average maturity or an average maturity of more than five years. Up to 25 percent of their portfolios’ securities (not including cash) may be invested in companies located in the United States.
- **Global bond-short-term funds** invest in worldwide debt securities and have an average maturity of one to five years. Up to 25 percent of their portfolios’ securities (not including cash) may be invested in companies located in the United States.
- **Government bond-general funds** invest at least 80 percent of their portfolios in U.S. government securities and have no stated average maturity.
- **Government bond-intermediate-term funds** invest at least 80 percent of their portfolios in U.S. government securities and have an average maturity of five to ten years.
- **Government bond-short-term funds** invest at least 80 percent of their portfolios in U.S. government securities and have an average maturity of one to five years.
- **High-yield funds** seek a high level of current income by investing at least 80 percent of their portfolios in lower-rated corporate bonds (Baa or lower by Moody’s and BBB or lower by Standard & Poor’s rating services).
- **Mortgage-backed funds** invest at least 80 percent of their portfolios in pooled mortgage-backed securities.
- **National municipal bond-general funds** invest predominantly in municipal bonds and have an average maturity of more than five years or no stated average maturity. The funds’ bonds are usually exempt from federal income tax but may be taxed under state and local laws.
- **National municipal bond-short-term funds** invest predominantly in municipal bonds and have an average maturity of one to five years. The funds’ bonds are usually exempt from federal income tax but may be taxed under state and local laws.
- **Other world bond funds** invest at least 80 percent of their portfolios in a combination of foreign government and corporate debt. Some funds in this category invest primarily in debt securities of emerging markets.
- **State municipal bond-general funds** invest primarily in municipal bonds of a single state and have an average maturity of more than five years or no stated average maturity. The funds’ bonds are exempt from federal and state income taxes for residents of that state.
- **State municipal bond-short-term funds** invest predominantly in municipal bonds of a single state and have an average maturity of one to five years. The funds’ bonds are exempt from federal and state income taxes for residents of that state.
- **Hybrid Funds**
  - **Asset allocation funds** seek high total return by investing in a mix of equities, fixed-income securities, and money market instruments. Unlike flexible portfolio funds (defined below), these funds are required to strictly maintain a precise weighting in asset classes.
  - **Balanced funds** invest in a specific mix of equity securities and bonds with the three-part objective of conserving principal, providing income, and achieving long-term growth of both principal and income.
  - **Flexible portfolio funds** seek high total return by investing in common stock, bonds and other debt securities, and money market securities. Portfolios may hold up to 100 percent of any one of these types of securities and may easily change, depending on market conditions. Target date (or lifecycle) funds are an example of these portfolios.
  - **Income mixed funds** seek a high level of current income by investing in a variety of income-producing securities, including equities and fixed-income securities. Capital appreciation is not a primary objective.

#### Money Market Funds
- **National tax-exempt money market funds** seek income not taxed by the federal government by investing in municipal securities with relatively short maturities.
- **State tax-exempt money market funds** invest predominantly in short-term municipal obligations of a single state, which are exempt from federal and state income taxes for residents of that state.
- **Taxable money market-government funds** invest principally in short-term U.S. Treasury obligations and other short-term financial instruments issued or guaranteed by the U.S. government, its agencies, or its instrumentalities.
- **Taxable money market-nongovernment funds** invest in a variety of money market instruments, including certificates of deposit of large banks, commercial paper, and banker’s acceptances.

**Source:** Adapted from Investment Company Institute, 2010 Investment Company Fact Book
percentages. Finally, the growing desire for international diversification is reflected in the ongoing popularity of world equity funds, a trend discussed more thoroughly below.

24.3.6 Global Investment Companies

As discussed throughout this text, investors must give serious thought to global diversification of their investment portfolios. Funds that invest in non-U.S. securities are generally called either international funds or global funds. International funds often hold only non-U.S. stocks from such countries as Germany, Japan, Singapore, and Korea, while global funds contain both U.S. and non-U.S. securities. Both international and global funds fall into familiar categories: money funds, long-term government and corporate bond funds, and equity funds. In turn, an international equity fund might limit its focus to a segment of the non-U.S. market, such as the European Fund or Pacific Basin Fund, or to a single country. Given the need to invest in a diversified portfolio of emerging markets, an emerging market mutual fund that contains a number of them is an ideal vehicle for this asset allocation.

Although most global or international funds are open-end funds (either load or no load), a significant number are closed-end funds, including most of the single country and the emerging-market funds. These funds have opted to be closed end so that they are not subject to major investor liquidations that require the sale of stocks in the portfolio on an illiquid foreign stock exchange.

A final alternative that all investors—particularly those in the United States—should appreciate is the large number of non-U.S. investment companies that offer both domestic and global products in their local markets. In fact, the Investment Company Institute reported that of $23.96 trillion invested worldwide in open-end investment companies at the end of 2009, about 52 percent of these assets were controlled by firms located outside the United States. In order, the largest concentrations of these AUM occurred in Luxembourg, France, Australia, the United Kingdom, and Japan. Further, of the 65,735 investment companies in operation during 2009, less than 8,000 were domiciled in the United States. From these statistics, it is reasonable to assume that no single region of the world has a monopoly on investment management skill.

24.3.7 Mutual Fund Organization and Strategy: An Example

The Dreyfus Corporation, established in 1951 and headquartered in New York City, is one of the leading mutual fund companies in the United States. As part of BNY Mellon Financial Corporation, it helps in the management of over $1 trillion as of April 2011. The Dreyfus Appreciation Fund (DGAGX) is a one of several equity-oriented portfolios that the company offers to its institutional and retail investors. The Appreciation Fund, which follows a large-cap blend investment style, is different than many of the other funds in the Dreyfus family in that it is not managed in house by portfolio managers that it employs directly. Rather, DGAGX is managed by Fayez Sarofim, a Houston, Texas, money manager who has run his own private management firm since 1958 and serves Dreyfus as a subinvestment advisor. A description of DGAGX is shown in Exhibit 24.12. Notice that DGAGX has about $3.4 billion (Panel A) of assets under management and is a no-load fund that also does not charge a 12b-1 fee (Panel B). However, investors do pay an annual management fee of 0.55 percent of the portfolio’s assets and the expense ratio, which accounts for the total cost of running the fund, is 0.99 percent of AUM.

One of the reasons why Dreyfus chose to enter into this arrangement was to allow investors who would not otherwise have sufficient capital to gain access to a private manager with an outstanding long-term performance record. Fayez Sarofim’s investment philosophy is

percentages. Finally, the growing desire for international diversification is reflected in the ongoing popularity of world equity funds, a trend discussed more thoroughly below.

### 24.3.6 Global Investment Companies

As discussed throughout this text, investors must give serious thought to global diversification of their investment portfolios. Funds that invest in non-U.S. securities are generally called either **international funds** or **global funds**. International funds often hold only non-U.S. stocks from such countries as Germany, Japan, Singapore, and Korea, while global funds contain both U.S. and non-U.S. securities. Both international and global funds fall into familiar categories: money funds, long-term government and corporate bond funds, and equity funds. In turn, an international equity fund might limit its focus to a segment of the non-U.S. market, such as the European Fund or Pacific Basin Fund, or to a single country. Given the need to invest in a diversified portfolio of emerging markets, an emerging market mutual fund that contains a number of them is an ideal vehicle for this asset allocation.

Although most global or international funds are open-end funds (either load or no load), a significant number are closed-end funds, including most of the single country and the emerging-market funds. These funds have opted to be closed end so that they are not subject to major investor liquidations that require the sale of stocks in the portfolio on an illiquid foreign stock exchange.

A final alternative that all investors—particularly those in the United States—should appreciate is the large number of non-U.S. investment companies that offer both domestic and global products in their local markets. In fact, the Investment Company Institute reported that of $23.96 trillion invested worldwide in open-end investment companies at the end of 2009, about 52 percent of these assets were controlled by firms located outside the United States. In order, the largest concentrations of these AUM occurred in Luxembourg, France, Australia, the United Kingdom, and Japan. Further, of the 65,735 investment companies in operation during 2009, less than 8,000 were domiciled in the United States. From these statistics, it is reasonable to assume that no single region of the world has a monopoly on investment management skill.

### 24.3.7 Mutual Fund Organization and Strategy: An Example

The Dreyfus Corporation, established in 1951 and headquartered in New York City, is one of the leading mutual fund companies in the United States. As part of BNY Mellon Financial Corporation, it helps in the management of over $1 trillion as of April 2011. The Dreyfus Appreciation Fund (DGAGX) is a one of several equity-oriented portfolios that the company offers to its institutional and retail investors. The Appreciation Fund, which follows a large-cap blend investment style, is different than many of the other funds in the Dreyfus family in that it is not managed in house by portfolio managers that it employs directly. Rather, DGAGX is managed by Fayez Sarofim, a Houston, Texas, money manager who has run his own private management firm since 1958 and serves Dreyfus as a subinvestment advisor. A description of DGAGX is shown in Exhibit 24.12. Notice that DGAGX has about $3.4 billion (Panel A) of assets under management and is a no-load fund that also does not charge a 12b-1 fee (Panel B). However, investors do pay an annual management fee of 0.55 percent of the portfolio’s assets and the expense ratio, which accounts for the total cost of running the fund, is 0.99 percent of AUM.

One of the reasons why Dreyfus chose to enter into this arrangement was to allow investors who would not otherwise have sufficient capital to gain access to a private manager with an outstanding long-term performance record. Fayez Sarofim’s investment philosophy is

---

*Much of the information contained in this example is available from Dreyfus Corporation’s Web site at http://www.dreyfus.com.*
somewhat unique among mutual fund managers in that he preaches a patient approach to portfolio formation that seeks to keep turnover below 15 percent per annum. The firm describes its investment approach as follows:

Our investment philosophy leads us to construct a portfolio comprised predominantly of large capitalization, US-based, multinational companies. These companies are global leaders in structurally attractive industries. They benefit from increasing global market share, ongoing product introduction or innovation, and productivity enhancements—three key drivers of long-term earnings growth. In addition, their financial strength allows them to make profitable investments at any point in the economic cycle. We believe these businesses are most capable of generating superior growth in earnings, dividends, and cash flow over time, leading to greater capital appreciation. Investing in high quality companies at reasonable prices also produces two additional advantages for our clients—low portfolio turnover and a higher likelihood of preservation of capital.

One interesting concept implied in this statement of philosophy is that Fayez Sarofim can be considered a global portfolio manager, even though the majority of the stocks he selects are from companies domiciled in the United States. The equity holdings of DGAGX are designed to mimic the portfolios that Sarofim assembles for his own private clients, and thus follow the same philosophy. Panel A of Exhibit 24.13 shows the top 10 holdings of the fund as of January 2011. Not surprisingly, all of these stocks (e.g., ExxonMobil, Procter & Gamble, Coca-Cola) fit the profile of being large companies with dominant global franchises. Also, the DGAGX portfolio has a lower level of systematic risk than the market, with a beta coefficient of 0.82. Finally, Panel B of the exhibit shows that DGAGX outperformed Standard & Poor's 500 Index (which is a relevant comparison for a large-cap blend fund manager) by more than 7 percent during the five-year period ending in March 2011, a period marked by considerable volatility in global equity markets.

Panel B. Management & Fee Structure

The investment structures just described—private management firms and investment companies—are extremely efficient ways for investors to gain access to a number of different asset classes and strategies. This is particularly true when the desired asset class investments are in liquid markets, such as with stocks, bonds, or money market securities. Recently, individual and institutional investors have also become interested in committing their financial capital in nontraditional asset classes. These alternative asset classes can include a wide variety of investment opportunities, but the most notable ones are hedge funds, private equity, real estate, or natural resources and commodities. In this section, we will take a detailed look at hedge funds and private equity investments.

Alternative asset investing can take place either through the creation of separate accounts for each investor or through the commingling of investor capital into a single pool of assets. Thus, these structures can appear as either Panel A or Panel B in Exhibit 24.1. Most often, though, an alternative asset investment is structured as a commingled collection of assets (i.e., Panel B), with the important difference that it is usually formed as a limited partnership rather than as a mutual fund. In a limited partnership, one or more general partners are responsible for running the organization and assuming its legal obligations, while the remaining limited partners are only liable to the extent of their investments. For example, in a hedge fund or private equity partnership, the general partner develops, implements, and maintains the investment portfolio around an initial strategy, while the limited partners (e.g., high-net-worth individuals, pension funds, endowment funds) provide the majority of the capital but have no direct involvement in the actual investment process.

24.4 Investing in Alternative Asset Classes

The investment structures just described—private management firms and investment companies—are extremely efficient ways for investors to gain access to a number of different asset classes and strategies. This is particularly true when the desired asset class investments are in liquid markets, such as with stocks, bonds, or money market securities. Recently, individual and institutional investors have also become interested in committing their financial capital in nontraditional asset classes. These alternative asset classes can include a wide variety of investment opportunities, but the most notable ones are hedge funds, private equity, real estate, or natural resources and commodities. In this section, we will take a detailed look at hedge funds and private equity investments.

Alternative asset investing can take place either through the creation of separate accounts for each investor or through the commingling of investor capital into a single pool of assets. Thus, these structures can appear as either Panel A or Panel B in Exhibit 24.1. Most often, though, an alternative asset investment is structured as a commingled collection of assets (i.e., Panel B), with the important difference that it is usually formed as a limited partnership rather than as a mutual fund. In a limited partnership, one or more general partners are responsible for running the organization and assuming its legal obligations, while the remaining limited partners are only liable to the extent of their investments. For example, in a hedge fund or private equity partnership, the general partner develops, implements, and maintains the investment portfolio around an initial strategy, while the limited partners (e.g., high-net-worth individuals, pension funds, endowment funds) provide the majority of the capital but have no direct involvement in the actual investment process.

---

Note: The complete statement of the Fayez Sarofim investment philosophy can be found on the firm’s Web site (http://www.sarofim.com).
One of the reasons that investors consider hiring professional asset managers is the belief that they will be able to deliver superior investment performance relative to simple indexed investments. That is, investors feel that professional managers can consistently add alpha, which is defined as the difference between a fund’s actual and expected (e.g., CAPM, benchmark) returns.

In fact, the impressive recent development of the alternative assets market is due to the growing belief that they are better able to produce superior returns than traditional investment structures, such as mutual funds. This argument is summarized in Exhibit 24.14, which illustrates an "excess returns" form of the Security Market Line (SML) for several different asset classes. Notice that standard "long only" positions in U.S. stocks and bonds plot virtually on the SML—indicating very little possibility for adding alpha—while the alternative asset classes (i.e., hedge funds, private equity) have substantially more potential in that area.

24.4.1 Hedge Funds

One of the most significant developments in the professional asset management industry over the past 20 years has been the emergence of the global market for hedge fund investing. Exhibit 24.15 shows that the increase in both the number of hedge funds in existence and the assets under management that those funds control has been remarkable. There were about 600 funds at the start of the 1990s controlling less than $40 billion in assets; by 2010, there were more than 9,000 active funds controlling an estimated $1.7 trillion in assets. This represents AUM expansion of about 21 percent per annum over the past several years, even after accounting for the industry contraction that occurred as a result of the economic downturn in 2008.

Despite this recent surge in growth, hedge fund investing is not new. In fact, Lhabitant (2006) notes that use of the term hedge fund originated in 1949, when Alfred Winslow Jones...
tested his security selection skills by forming a portfolio that combined both long and short stock positions with the use of financial leverage to enhance returns. Jones did this using a partnership structure that avoided Security and Exchange Commission restrictions and also included an incentive fee for superior performance. The performance of this original hedge fund was spectacular—it outperformed the best mutual fund of the era by almost 90 percent over a 10-year period—but Jones’s strategy was not widely imitated for several decades. However, as indicated in Exhibit 24.15, that situation has certainly changed.

24.4.2 Characteristics of a Hedge Fund

There are several immediate consequences to creating a hedge fund as a limited partnership. Most notably, hedge fund investments are far less liquid than mutual fund (or even closed-end fund) shares; there are severe limitations on when and how often investment capital can

One of the reasons that investors consider hiring professional asset managers is the belief that they will be able to deliver superior investment performance relative to simple indexed investments. That is, investors feel that professional managers can consistently add *alpha*, which is defined as the difference between a fund’s actual and expected (e.g., CAPM, benchmark) returns. In fact, the impressive recent development of the alternative assets market is due to the growing belief that they are better able to produce superior returns than traditional investment structures, such as mutual funds. This argument is summarized in Exhibit 24.14, which illustrates an “excess returns” form of the Security Market Line (SML) for several different asset classes. Notice that standard “long only” positions in U.S. stocks and bonds plot virtually on the SML—indicating very little possibility for adding *alpha*—while the alternative asset classes (i.e., hedge funds, private equity) have substantially more potential in that area.

24.4.1 Hedge Funds

One of the most significant developments in the professional asset management industry over the past 20 years has been the emergence of the global market for hedge fund investing. Exhibit 24.15 shows that the increase in both the number of hedge funds in existence and the assets under management that those funds control has been remarkable. There were about 600 funds at the start of the 1990s controlling less than $40 billion in assets; by 2010, there were more than 9,000 active funds controlling an estimated $1.7 trillion in assets. This represents AUM expansion of about 21 percent per annum over the past several years, even after accounting for the industry contraction that occurred as a result of the economic downturn in 2008.

Despite this recent surge in growth, hedge fund investing is not new. In fact, Lhabitant (2006) notes that use of the term *hedge fund* originated in 1949, when Alfred Winslow Jones
tested his security selection skills by forming a portfolio that combined both long and short stock positions with the use of financial leverage to enhance returns. Jones did this using a partnership structure that avoided Security and Exchange Commission restrictions and also included an incentive fee for superior performance. The performance of this original hedge fund was spectacular—it outperformed the best mutual fund of the era by almost 90 percent over a 10-year period—but Jones’s strategy was not widely imitated for several decades. However, as indicated in Exhibit 24.15, that situation has certainly changed.

24.4.2 Characteristics of a Hedge Fund

There are several immediate consequences to creating a hedge fund as a limited partnership. Most notably, hedge fund investments are far less liquid than mutual fund (or even closed-end fund) shares; there are severe limitations on when and how often investment capital can
be contributed to or removed from a partnership. On the other hand, as a private partnership, hedge funds are generally less restricted in how and where they can make investments, which is perhaps the biggest reason why investors believe that these vehicles have the ability to deliver abnormally large returns. They also tend to be less correlated with traditional asset class investments, providing investors with additional diversification benefits.

Exhibit 24.16 highlights several important features related to the way hedge funds are structured. The average hedge fund only permits investors to enter or exit a few times a year (i.e., monthly and quarterly, respectively) compared to the daily ownership adjustments allowed by mutual funds. Also, most hedge funds allow managers to use leverage (71%), short sell (82%), and derivatives (69%). By contrast, Almazan et al. (2004) document that the vast majority of mutual fund managers cannot employ these investment tools. Further, as Fung and Hsieh (2006) note, it is typical for hedge fund managers to receive their compensation in two components: a regular management fee (e.g., 1 percent of AUM) and a performance allocation fee, which normally amounts to 20 percent of the fund’s profits beyond a certain prespecified return level (i.e., hurdle rate). In calculating this performance fee, investors usually require that any past losses be recouped before managers receive the additional payout; this arrangement is known as a high-water mark. Finally, as a tangible signal to investors of belief in their abilities, most hedge fund managers put a substantial amount of their own capital into the fund.

### 24.4.3 Hedge Fund Strategies

Saying you are invested in a hedge fund is a little like saying you play a sport—it is a statement that conveys some information but could actually mean a great many different things. Several investment strategies are often included under the hedge fund designation, and these
vary greatly in the risk and expected return profiles they imply. Within a given strategic category, there can be as many interpretations of how the portfolio should be designed as there are fund managers. Nevertheless, some common features define the more popular hedge fund strategies, and we will now describe them.8

I. Equity-Based Strategies

- **Long-short equity**: The original and perhaps the most basic form of hedge fund investing. Managers attempt to identify misvalued stocks and take long positions in the undervalued ones and short positions in the overvalued ones. Since investors participate in both the long and the short side of the market, one major advantage of the long-short strategy is the ability to generate “double alpha” (i.e., profit from price corrections for both undervalued and overvalued securities), unlike the long-only possibilities in the mutual fund industry. The 130/30 funds discussed in Chapter 16 can be considered as a variation of this strategy.

- **Equity market neutral**: Like the long-short strategy, returns are generated by exploiting perceived pricing inefficiencies between securities. However, equity market neutral strategies also attempt to limit the overall volatility exposure of the fund by taking offsetting risk positions on the long and short side, an effort that might also involve adopting derivative positions. Absent leverage, these portfolios are expected to produce returns of 2 to 4 percent above the risk-free rate, which has led some investors to refer to them as **absolute return** strategies.

II. Arbitrage-Based Strategies

- **Fixed-income arbitrage**: Returns are generated by taking advantage of bond pricing disparities caused by changing market events, investor preferences, or fluctuations in the fixed-income market. Because the valuation disparities between related instruments (e.g., coupon-bearing Treasury bonds and zero-coupon Treasury strips) are typically small, managers usually employ leverage to enhance their overall returns. The ability to generate alpha is driven largely by the manager’s skill at building quantitative models, as well as structuring and managing fixed-income portfolios.

- **Convertible arbitrage**: Seeks to profit from disparities in the relationship between prices for convertible bonds and the underlying common stock. A typical position involves purchasing the convertible bond and short selling the underlying stock, thereby isolating the conversion option embedded in the bond. Returns are generated in several ways, including interest income on the convertible bonds, interest on the proceeds of related equity short sales, and the price appreciation of the convertible bonds as they gradually assume the value of the equity into which they are exchangeable. Like fixed-income arbitrage, convertible arbitrage positions often utilize leverage to enhance returns.

- **Merger (risk) arbitrage**: Returns are dependent upon the magnitude of the spread on merger transactions, which are directly related to the likelihood of the deal not being completed due to regulatory, financial, or company-specific reasons. As the probability of the merger improves, the spread narrows, generating profits for the position. Merger arbitrage investors essentially bet that their subjective assessment of whether the proposed deal is ultimately completed is superior to that of the other investors in the market.

---

8This list of hedge fund strategies, which draws from the discussion in Nicholas (2003), is intended to be representative rather than exhaustive. Alternative lists of strategies can be found at the following Web sites: http://www.greenwichai.com and http://www.thefia.org.
III. Opportunistic Strategies

- **High yield and distressed:** One advantage that bond investors enjoy relative to stock investors is that, if the issuer does not default, a bond’s price will return to par at maturity. When companies are distressed, their securities can be purchased at deep discounts. If and when the turnaround materializes, security prices will approach their intrinsic value, generating profits for the distressed manager. **Emerging market** investing can be viewed as a global application of this strategy using sovereign securities instead of corporate instruments.

- **Global macro:** This broad class of strategies seeks to profit from changes in global economies, typically brought about by shifts in government policy that impact interest rates, in turn affecting currency, stock, and bond markets. Fund managers typically use a “top-down” approach to identifying opportunities and often participate in all major markets—equities, bonds, currencies, and commodities—though not always at the same time. The strategy uses leverage and derivatives to enhance returns, but also might hedge exposures on a situational basis.

- **Managed futures:** This strategy entails using long and short positions in a variety of futures contracts, both to take “directional” positions on certain economic or company-specific events (e.g., changing conditions in stock or bond markets) and to exploit pricing discrepancies between various contracts. The assets underlying these futures positions may involve commodities, equities, interest rates, or foreign currencies. These strategies frequently employ a substantial degree of financial leverage.

- **Special situations:** Special situation returns occur due to the outcomes of significant events that occur during the normal life cycle of a corporation. These strategies may involve investing in companies around the time of bankruptcies, financial restructurings or recapitalizations, spin-offs, or carve-outs. Given the underlying reason for the investment, positions are usually directional and not fully hedged. Depending on the manager’s specific strategy, event-driven returns are realized when the catalyst necessary to generate the position’s intrinsic value (e.g., the spin-off of an operating division) takes place.

IV. Multiple Strategies

- **Fund of funds:** Although not formally a separate strategic category, this investment vehicle acts like a mutual fund of hedge funds, giving investors access to managers that might otherwise be unavailable to them. The primary benefit to the investor of a fund of funds position is that it is a convenient method for achieving a well-diversified allocation to the hedge fund investment space. A fund of funds can offer a concentration in a particular strategy (e.g., long-short equity) and then either diversify across different hedge fund managers—this is a multiple manager approach—or diversify across strategies, which is the multiple strategy approach. The primary disadvantage to the fund of funds investor is that there will be an extra layer of fees necessary to compensate the fund of funds manager.

24.4.4 Risk Arbitrage Investing: A Closer Look

A popular hedge fund strategy involves taking equity positions in companies that are the target of a merger or takeover attempt. These risk arbitrage investments require managers to compare their own subjective judgment about the ultimate success of the proposed takeover with the success probability implied by the market price of the target firm’s stock following the announcement of the prospective deal. If the manager thinks the takeover is more likely to occur than the market does, she will buy shares in the target firm. Conversely, the manager might short sell the target firm shares if she thinks the proposed deal is less likely to be completed.

Consider the following hypothetical example. Suppose the shareholders of Company XYZ receive an unsolicited cash tender offer for $30 per share. At the time of the offer—which we assume was a complete surprise—XYZ’s shares traded for $20. Suppose further that shortly after
the takeover announcement—which still must be approved by regulatory authorities—the price of XYZ’s shares rises to $28. Brown and Raymond (1986) showed that a simple estimate of the market’s implied probability that the takeover bid will ultimately be successful is \((28 - 20) \div (30 - 20)\), or 80 percent. In this situation, the risk arbitrage hedge fund manager must think the deal has better than a four-in-five chance of being completed in order to justify purchasing XYZ stock for $28 in the hope of selling at the tender offer price of $30; if the deal falls apart, the manager can assume that XYZ’s shares will return to $20. Exhibit 24.17 compares the implied probabilities for a sample of proposed takeovers that were ultimately completed (both competing and non-competing) to a sample of deals that failed. Investors in the market are very good at discriminating between “good” and “bad” deals as far as three months prior to the final resolution.

Panel A of Exhibit 24.18 summarizes the relevant aspects of JPMorgan Chase (JPM) Bank’s takeover of Hambrecht & Quist (HQ), a San Francisco–based investment bank specializing in transactions involving technology firms. JPM made a tender offer of $50 per share for all of the outstanding shares of HQ, which at the time of the announcement were trading for $39.28. This represents a tender premium of $10.72, and capturing as much of this premium as possible is the goal of the risk arbitrage investor. However, Panel B indicates that within a day of the announcement, HQ shares were already trading for $48.69. This means that the market had already assessed the probability of this friendly takeover attempt to be 88 percent \((= (48.69 - 39.28) \div (50 - 39.28))\). Thus, a hedge fund manager who did not already own HQ stock would have to be extremely confident that this deal would ultimately be completed to purchase shares at that point.

### 24.4.5 Hedge Fund Performance

Nicholas (2005), as well as Ibbotson, Chen, and Zhu (2011), have studied hedge fund performance and concluded that, on average, these strategies do produce significant risk-adjusted
returns over time. This general conclusion is illustrated in Exhibit 24.19, which plots a Capital Market Line (CML) comparing total risk and return characteristics over the period from 1990 to 2010. During this time, almost all of the indicated strategies plotted above the CML, demonstrating the ability of hedge fund managers to add a positive alpha to their investors over and above the returns produced by traditional products such as Treasury bills or the S&P 500 equity index. There is also tremendous variation in the level of risk inherent in the myriad strategies; arbitrage-based strategies and those that take both long and short positions (e.g., equity market neutral) tend to exhibit far less volatility than those that adopt directional positions (e.g., macro and event-driven strategies). Clearly, not all hedge funds are the same when it comes to their risk and return profiles, a fact that participants in this market need to understand.

While these CML results are encouraging for potential hedge fund investors, keep in mind that they represent comparisons based on long-term averages over one specific time period. Investors should also be aware that the returns to these strategies show a high degree of variability on a year-to-year basis, in both an absolute and a relative sense. Exhibit 24.20, which lists the annual returns and rankings for 10 different broad hedge fund categories, documents this strategy rotation effect. Some of the swings represented in the display can be dramatic. For example, emerging markets (EM) was the worst-performing strategy in 1995, posting a loss of 16.9 percent. However, it was the best-performing strategy during the following year, returning 34.5 percent to investors. Similar patterns exist throughout the exhibit; for instance, the long/short equity (LS) strategy performed well in 2003 through 2007, but lost money in 2002 and 2008. Finally, notice that there are only two (of 16) years in which every strategy class earned positive returns.

24.4.6 Private Equity

Like hedge funds, private equity can also include a wide variety of different investment vehicles and strategies. A private equity investment refers to any ownership interest in an asset (or collection of assets) that is not tradable in a public market. This nontradeability feature has two immediate consequences. First, private equity transactions typically fund either new companies that do not have sufficient operating histories to issue common stock on a public exchange or established firms that are seeking to change their organizational structure or are
returns over time. This general conclusion is illustrated in Exhibit 24.19, which plots a Capital Market Line (CML) comparing total risk and return characteristics over the period from 1990 to 2010. During this time, almost all of the indicated strategies plotted above the CML, demonstrating the ability of hedge fund managers to add a positive alpha to their investors over and above the returns produced by traditional products such as Treasury bills or the S&P 500 equity index. There is also tremendous variation in the level of risk inherent in the myriad strategies; arbitrage-based strategies and those that take both long and short positions (e.g., equity market neutral) tend to exhibit far less volatility than those that adopt directional positions (e.g., macro and event-driven strategies). Clearly, not all hedge funds are the same when it comes to their risk and return profiles, a fact that participants in this market need to understand.

While these CML results are encouraging for potential hedge fund investors, keep in mind that they represent comparisons based on long-term averages over one specific time period. Investors should also be aware that the returns to these strategies show a high degree of variability on a year-to-year basis, in both an absolute and a relative sense. Exhibit 24.20, which lists the annual returns and rankings for 10 different broad hedge fund categories, documents this strategy rotation effect. Some of the swings represented in the display can be dramatic. For example, emerging markets (EM) was the worst-performing strategy in 1995, posting a loss of 16.9 percent. However, it was the best-performing strategy during the following year, returning 34.5 percent to investors. Similar patterns exist throughout the exhibit; for instance, the long/short equity (LS) strategy performed well in 2003 through 2007, but lost money in 2002 and 2008. Finally, notice that there are only two (of 16) years in which every strategy class earned positive returns.

### 24.4.6 Private Equity

Like hedge funds, private equity can also include a wide variety of different investment vehicles and strategies. A private equity investment refers to any ownership interest in an asset (or collection of assets) that is not tradable in a public market. This nontradeability feature has two immediate consequences. First, private equity transactions typically fund either new companies that do not have sufficient operating histories to issue common stock on a public exchange or established firms that are seeking to change their organizational structure or are
experiencing financial distress. Second, private equity investments are generally far less liquid than public stock holdings and are therefore considered to be long-term positions within an investor’s overall portfolio. The security market dynamics illustrated in Exhibit 24.14 showed that, on average, private equity commitments are among the highest-risk and highest-reward investments available. This risk-return trade-off is one of things that distinguishes private equity as a separate asset class from other forms of ownership in the public markets. Another important aspect of private equity that defines it as a unique investment category is that it is not perfectly correlated with the other traditional asset classes (e.g., U.S. and non-U.S. stocks, U.S. bonds) or alternative asset classes (e.g., hedge funds, real estate). This is shown in Exhibit 24.21, which lists expected return, standard deviation, and correlation statistics for several different asset classes based on data from a recent 10-year period. While the private and public equity markets in the United States are highly correlated (i.e., a correlation coefficient of 0.50), the same is not as true for private equity with U.S. bonds (0.05) or real estate (0.15). Thus, in addition to their potential to deliver high returns, private equity investments also serve as an important source of diversification. This combination of higher risk and less liquidity often precludes small investors from participating in the private equity market. It is not unusual for private equity funds to require minimum initial investment levels of several million dollars as well as capital "lock ups" (i.e., minimum time commitments) of one year or longer. Further, cash distributions from a fund may occur on a sporadic basis and only after an extended period of time. Thus, private equity deals are designed for those investors who can afford to have the funds committed for a lengthy period of time and be able to absorb the possibility that they may lose all of their initial capital. This best describes institutional investors, such as public and corporate pension funds or endowments, and high-net-worth individual investors.

Development and Organization of the Private Equity Market
As Hsu and Kenney (2005) discuss, organized private equity investing began in the United States with the creation of the American Research & Development Corporation (ARD) in 1946. The ARD was formed after World War II as a means of providing investment capital for new business ventures created by and for returning soldiers. The overriding premise of ARD that helped to shape the modern private equity industry was the belief that combining a pool of investment capital with skilled management could simultaneously benefit start-up companies and produce superior returns for investors. Although it was ultimately disbanded, ARD did manage to raise about $7.5 million in capital and fund at least one firm (i.e., Digital Equipment Company) that produced significant profits. It also served as the model for the limited partnership format employed by most private equity funds today, which separates the main sources of the investment capital and the source of the investment expertise (e.g., the company serving as general partner that organizes the fund).

By the late 1950s, various agencies of the government had joined the effort to help start-up companies by sponsoring Small Business Investment Companies (SBIC), in which private equity partnerships augment their capital by borrowing federal funds.

While private equity investments can be defined to include any nonpublic ownership interest, these transactions are typically classified into three different subcategories:

I. Venture Capital: Focuses on investments in start-up firms, early stage businesses, and new products and services created by established businesses. For the past two decades, venture investments have often been concentrated in the technology (e.g., Internet, telecommunications, software) and health care industries. Venture capital funds tend to specialize by stage of investing, as determined by the time frame in a company’s development:

- Seed: An entrepreneur has a new idea or product, but no established organization or operating structure. Investors at this stage (who are sometimes called “angels”) tend to provide limited financial capital and other physical resources to help the entrepreneur develop a coherent business plan.

- Early Stage: The business organization has moved beyond the planning stage and has now been formed. It has employees and products that are in the developmental stage. Early-stage investors commit capital once companies complete the business plan and have at least part of the management team in place.

- Later Stage: The firm now has an established infrastructure in place, as well as a viable product that is either ready for the market or already producing revenues. Later-stage investors usually provide financing for the expansion of a company that is already producing and shipping a product and increasing its sales volume.

II. Buyouts: Involves the acquisition of a product line, set of assets, or business from an established company. The company that is being acquired can be either a public or a private firm of virtually any size, and payment for the transaction can involve both debt and equity. (A transaction that involves the use of debt to fund the acquisition of a company is called a leveraged buyout, or LBO.) In an LBO, the assets of the acquired firm are used as collateral for the debt, which is then paid off using either the cash flow generated by the company or the sale of some of the assets. A change in the ownership control of the company being acquired is almost always a feature of a buyout transaction, which can also include recapitalizations, spin-offs, carve-outs, consolidations, and roll-ups. Firms seek buyout financing for several reasons, including a desire to expand their operations, divest themselves of a business unit that no longer fits the strategic plan, or to affect a change in management or ownership. When a public firm is bought out and taken private, there also may be less scrutiny of its operations by outside parties (e.g., regulators, financial analysts).

III. Special Situations: Includes investments in distressed companies or firms with unique opportunities that may be available on a one-time basis (e.g., an investment subsidy resulting from a change in a governmental regulation). Two important classes in this category are:

- Distressed Debt: Investors acquire multiple classes of the debt or equity of a publicly traded firm that is in or near bankruptcy. The goal of distressed investors is to create new value in the firm through an infusion of capital and a reorganization of its operations. In a reorganization, distressed investors often forgive the debt obligations of the company in exchange for equity; this is why distressed debt funds are considered equity investors. However, these funds can also profit by liquidating a firm, which is why they are sometimes called “vulture capitalists.”

These descriptions of the various types of private equity investments are adapted from Ennis Knupp (2004), who also provides an excellent overview of the industry.

Development and Organization of the Private Equity Market As Hsu and Kenney (2005) discuss, organized private equity investing began in the United States with the creation of the American Research & Development Corporation (ARD) in 1946. The ARD was formed after World War II as a means of providing investment capital for new business ventures created by and for returning soldiers. The overriding premise of ARD that helped to shape the modern private equity industry was the belief that combining a pool of investment capital with skilled management could simultaneously benefit start-up companies and produce superior returns for investors. Although it was ultimately disbanded, ARD did manage to raise about $7.5 million in capital and fund at least one firm (i.e., Digital Equipment Company) that produced significant profits. It also served as the model for the limited partnership format employed by most private equity funds today, which separates the main sources of the investment capital and the source of the investment expertise (e.g., the company serving as general partner that organizes the fund).

By the late 1950s, various agencies of the government had joined the effort to help start-up companies by sponsoring Small Business Investment Companies (SBIC), in which private equity partnerships augment their capital by borrowing federal funds.

While private equity investments can be defined to include any nonpublic ownership interest, these transactions are typically classified into three different subcategories: 9

I. **Venture Capital**: Focuses on investments in start-up firms, early stage businesses, and new products and services created by established businesses. For the past two decades, venture investments have often been concentrated in the technology (e.g., Internet, telecommunications, software) and health care industries. Venture capital funds tend to specialize by stage of investing, as determined by the time frame in a company’s development:

   • **Seed**: An entrepreneur has a new idea or product, but no established organization or operating structure. Investors at this stage (who are sometimes called “angels”) tend to provide limited financial capital and other physical resources to help the entrepreneur develop a coherent business plan.

   • **Early Stage**: The business organization has moved beyond the planning stage and has now been formed. It has employees and products that are in the developmental stage. Early-stage investors commit capital once companies complete the business plan and have at least part of the management team in place.

   • **Later Stage**: The firm now has an established infrastructure in place, as well as a viable product that is either ready for the market or already producing revenues. Later-stage investors usually provide financing for the expansion of a company that is already producing and shipping a product and increasing its sales volume.

II. **Buyouts**: Involves the acquisition of a product line, set of assets, or business from an established company. The company that is being acquired can be either a public or a private firm of virtually any size, and payment for the transaction can involve both debt and equity. (A transaction that involves the use of debt to fund the acquisition of a company is called a **leveraged buyout**, or LBO.) In an LBO, the assets of the acquired firm are used as collateral for the debt, which is then paid off using either the cash flow generated by the company or the sale of some of the assets. A change in the ownership control of the company being acquired is almost always a feature of a buyout transaction, which can also include recapitalizations, spin-offs, carve-outs, consolidations, and roll-ups. Firms seek buyout financing for several reasons, including a desire to expand their operations, divest themselves of a business unit that no longer fits the strategic plan, or to affect a change in management or ownership. When a public firm is bought out and taken private, there also may be less scrutiny of its operations by outside parties (e.g., regulators, financial analysts).

III. **Special Situations**: Includes investments in distressed companies or firms with unique opportunities that may be available on a one-time basis (e.g., an investment subsidy resulting from a change in a governmental regulation). Two important classes in this category are:

   • **Distressed Debt**: Investors acquire multiple classes of the debt or equity of a publicly traded firm that is in or near bankruptcy. The goal of distressed investors is to create new value in the firm through an infusion of capital and a reorganization of its operations. In a reorganization, distressed investors often forgive the debt obligations of the company in exchange for equity; this is why distressed debt funds are considered equity investors. However, these funds can also profit by liquidating a firm, which is why they are sometimes called “vulture capitalists.”

9These descriptions of the various types of private equity investments are adapted from Ennis Knupp (2004), who also provides an excellent overview of the industry.
• **Mezzanine Financing**: Investors provide a middle level of funding that is subordinated to senior debt but ranks above the existing equity. A typical mezzanine investment includes a subordinated loan to the company—at an interest rate higher than the yield on the senior debt—along with the receipt of some form of equity participation (e.g., warrants, common stock, preferred stock). Thus, like distressed debt investors, mezzanine financiers are providing both private debt and private equity funding.

Not all of these categories will produce investments with the same risk-return trade-offs. Venture capital commitments are generally considered to be the riskiest private equity transactions because they are often made before the organization in question has created a viable source of revenue. Buyout investments can also involve a considerable amount of risk—especially when a large amount of leverage is used in the transaction—but they have the advantage of involving companies with established product markets, which typically makes them somewhat more predictable than venture-related deals. Finally, special situation investments such as mezzanine transactions fall on the safer end of the private equity spectrum because they involve a commitment of capital with a senior claim on the firm’s resources.

Exhibit 24.22 illustrates the extent of private equity investing in the United States, in terms of the dollars committed. There has been a significant increase in private equity investments over the past 10–15 years, particularly in the amount of buyout activity. (Venture capital investing appears to have peaked during the technology-related boom in the equity market that occurred in the late 1990s.) As Acharya et al. (2007) point out, this trend reflects the simultaneous impact of several factors in place during this period: (1) the influx of a substantial amount of new investment capital as institutional investors shifted their strategic asset allocation policies toward alternative assets, (2) the availability of relatively inexpensive credit, which made debt financing a cheap source of funds, and (3) relatively high valuations in the equity market.

**The Private Equity Investment Process** To better understand the dynamics of private equity investing, consider the progression followed by the hypothetical company illustrated in Exhibit 24.23. Suppose initially that Bob and Susan, two young entrepreneurs who recently graduated from college, have developed a better and more cost-effective way to search for Web sites on the Internet. After exhausting their personal savings and bank loans to develop
the business—which is sometimes called zero-stage capital—they turn to a venture capital firm to provide the additional seed and early stage funding they need to advance their idea to the next level. Following an evaluation of Bob and Susan’s business plan, Venture Partners Fund agrees to provide financial capital and operating expertise to help launch the Internet Search Engine Company (i.e., Step 1a). In exchange for these resources, Venture Partners receives an equity stake in the new company.

Venture capital investing is extremely risky because the enterprise in question is unlikely to have an established stream of revenues or profits. Thus, investors like Venture Partners Fund must evaluate firms like Internet Search Engine Company on the basis of their potential for future success. Typically, only two or three out of ten first-stage ventures become profitable and only one in ten becomes a huge success (e.g., Apple Computer, Genentech, Federal Express). One consequence of this high failure rate is that venture capital firms usually mitigate their risk by diversifying their investments across a portfolio of start-up companies. Another is that venture funds limit their exposure to a given start-up by providing funding in stages as the company demonstrates its capacity for success. Thus, Venture Partners Fund will only provide later-stage equity capital to help Internet Search Engine Company expand its operations once the firm has established a viable product (i.e., Step 1b).

While venture capital funds help companies develop and grow, they will ultimately want to liquidate their equity holdings in order to create a return on their investment and provide capital to fund new ventures. A typical holding period for their successful investments is between three and seven years. Generally, there are two ways that a venture fund can “exit” one of the companies in their investment portfolio: (1) through a buyout arranged with another private
**Returns to Private Equity Funds** Private equity commitments should be viewed as long-term, highly illiquid investments, regardless of the stage of a company’s development in which the partnership fund specializes. Although average annual returns for these investments tend to be quite high over time, the initial years of a new private equity commitment usually produce negative returns. This is because the organizational expenses incurred by the fund’s general partner are drawn from invested capital, as well as the fact that the less-successful investments in the portfolio tend to be recognized quickly and written down. However, as the better-performing investments increase in value over time and are sold at a profit, the returns to the private equity fund tend to increase dramatically. This return pattern is known as the **J-curve effect** and is illustrated in Exhibit 24.24. The performance measure in this exhibit is the internal rate of return (IRR), which is the most widely used statistic for private market investments. In the early years of a fund’s operations, these IRR calculations are usually based on valuation estimates, since the portfolio companies are themselves illiquid assets that trade infrequently. As these assets are sold over time, the IRR statistics become based on the actual cash distributions to the investors.
The issue of ethical behavior arises any time one person is hired to look after the interests of another. Economists often refer to this potential conflict as the principal-agent problem, which can be summarized as follows: A principal (owner of the assets) hires an agent (manager) to manage her assets. She rightfully expects that the manager will make decisions that are in her best interest. Although he is being paid to protect the owner’s assets, the manager also has the incentive to take actions that may be in his best interest instead. For instance, the manager might misuse the owner’s assets in both subtle ways (e.g., generating unnecessary expenses for first-class travel or office furnishings) and more blatant ways (e.g., expropriation of resources). This sort of agency conflict occurs frequently in financial relationships. The stockholders of a corporation (i.e., principals) are the owners of the firm’s assets, but they usually hire professional managers (i.e., agents) to run the company. Thus, the stockholders face the constant challenge of how they can keep the managers’ incentives aligned with theirs. This topic is particularly important for the investment management business because the entire industry is based on handling someone else’s money, meaning that agency issues are always present. In this section, we consider how the industry addresses these conflicts, from both a legal (i.e., regulatory) and an ethical standpoint.

### 24.5.1 Regulation in the Asset Management Industry

Professional portfolio managers are entrusted with the management of trillions of dollars. It is therefore not surprising that the investment industry is highly regulated to ensure a minimum level of acceptable practice. These regulations, which often involve a complex interaction between state and federal laws, are designed for the primary purpose of ensuring that portfolio managers act in the best interests of their investors. At their most basic level, regulations are written to promote adequate disclosure of information related to the investment process and to provide various antifraud protections. Exhibit 24.26 describes seven principal securities laws that govern the investment management industry: the Securities Act of 1933 (primary regulatory target: security issuers), the Securities Exchange Act of 1934 (security brokers), the Investment Company Act of 1940 (mutual funds), the Investment Advisers Act of 1940 (advisors and private managers), the Employee Retirement Income Security Act of 1974 (retirement asset managers and fiduciaries), the Pension Protection Act of 2006 (pension fund sponsors and managers), and the Dodd-Frank Wall Street Reform and Consumer Protection Act of 2010.

One of the main intentions of these regulations is to guarantee that investment professionals keep accurate and detailed transaction records and that account information is reported to investors in a fair and timely manner. As the Investment Company Institute notes, the U.S. Securities and Exchange Commission (SEC) is the main federal agency responsible for regulating professional asset management activities in the United States. In addition to monitoring compliance with existing statutes, the SEC performs the following functions:

- Maintains strict standards on the use of leverage so that funds do not take undue risk;
- Ensures that funds maintain effective governance systems;
- Requires understandable reporting and full disclosure to investors and works to eliminate fraud and abuse;
- Reviews required filings of investment companies; and
- Develops and revises rules to adapt regulations to new circumstances.

Other regulatory agencies that help to govern behavior in the investment industry include the U.S. Department of Labor (protection of pension plans, including 401(k) plans), the Financial...

### Exhibit 24.24 The J-Curve Effect

Beyond the historical data summarized in Exhibit 24.14 and Exhibit 24.21, another way to think about the performance of private equity investments relative to other asset classes is to compare the dispersion of outcomes that investors experience over time. Exhibit 24.25 lists returns for several different asset class categories when the investment was made with (1) a “good” fund manager (i.e., a manager with performance in the top quartile of all available managers), (2) an “average” manager (i.e., the median performer), and (3) a “bad” manager (i.e., a bottom-quartile performer). The return data reflect historical performance over a recent 10-year period. The last row of the exhibit lists the interquartile range for each asset class, which is the difference in the returns between the top- and bottom-quartile managers. This statistic serves as a measure of the dispersion in returns for a given asset category because it reflects the opportunity cost of placing capital with a low-performing manager instead of a top performer. For instance, in large-cap U.S. public equities, the difference between the performance of a good and bad manager is only 1.26 percent. However, in private equity, this difference is 11.38 percent, almost 10 times as large! Thus, in addition to its higher overall risk level, investors also need to realize that the selection of the right private equity fund manager is critical to the success of the investment.

24.5 Ethics and Regulation in the Professional Asset Management Industry

The issue of ethical behavior arises any time one person is hired to look after the interests of another. Economists often refer to this potential conflict as the principal-agent problem, which can be summarized as follows: A principal (owner of the assets) hires an agent (manager) to manage her assets. She rightfully expects that the manager will make decisions that are in her best interest. Although he is being paid to protect the owner’s assets, the manager also has the incentive to take actions that may be in his best interest instead. For instance, the manager might misuse the owner’s assets in both subtle ways (e.g., generating unnecessary expenses for first-class travel or office furnishings) and more blatant ways (e.g., expropriation of resources).

This sort of agency conflict occurs frequently in financial relationships. The stockholders of a corporation (i.e., principals) are the owners of the firm’s assets, but they usually hire professional managers (i.e., agents) to run the company. Thus, the stockholders face the constant challenge of how they can keep the managers’ incentives aligned with theirs. This topic is particularly important for the investment management business because the entire industry is based on handling someone else’s money, meaning that agency issues are always present. In this section, we consider how the industry addresses these conflicts, from both a legal (i.e., regulatory) and an ethical standpoint.

24.5.1 Regulation in the Asset Management Industry

Professional portfolio managers are entrusted with the management of trillions of dollars. It is therefore not surprising that the investment industry is highly regulated to ensure a minimum level of acceptable practice. These regulations, which often involve a complex interaction between state and federal laws, are designed for the primary purpose of ensuring that portfolio managers act in the best interests of their investors. At their most basic level, regulations are written to promote adequate disclosure of information related to the investment process and to provide various antifraud protections. Exhibit 24.26 describes seven principal securities laws that govern the investment management industry: the Securities Act of 1933 (primary regulatory target: security issuers), the Securities Exchange Act of 1934 (security brokers), the Investment Company Act of 1940 (mutual funds), the Investment Advisers Act of 1940 (advisors and private managers), the Employee Retirement Income Security Act of 1974 (retirement asset managers and fiduciaries), the Pension Protection Act of 2006 (pension fund sponsors and managers), and the Dodd-Frank Wall Street Reform and Consumer Protection Act of 2010.

One of the main intentions of these regulations is to guarantee that investment professionals keep accurate and detailed transaction records and that account information is reported to investors in a fair and timely manner. As the Investment Company Institute notes, the U.S. Securities and Exchange Commission (SEC) is the main federal agency responsible for regulating professional asset management activities in the United States. In addition to monitoring compliance with existing statutes, the SEC performs the following functions:

- Maintains strict standards on the use of leverage so that funds do not take undue risk;
- Ensures that funds maintain effective governance systems;
- Requires understandable reporting and full disclosure to investors and works to eliminate fraud and abuse;
- Reviews required filings of investment companies; and
- Develops and revises rules to adapt regulations to new circumstances.

Other regulatory agencies that help to govern behavior in the investment industry include the U.S. Department of Labor (protection of pension plans, including 401(k) plans), the Financial
fund managers to employ certain strategic tools (e.g., leverage, short selling) that were not available to traditional fund managers. However, the Dodd-Frank Reform Act of 2010 made registration mandatory for hedge fund advisers with more than US$150 million in assets under management. A hedge fund qualifies for an exemption from the Investment Company Act if it has fewer than 100 investors, while hedge fund managers are exempt from the Investment Advisers Act if they manage less than $25 million in assets. On the other hand, if a quarter of a hedge fund’s assets consist of retirement plan assets, the fund must comply with the restrictions set forth under ERISA.

24.5.2 Standards for Ethical Behavior

Many developed economies like that in the United States are founded on the notion of financial market discipline. In such a system, government intervention is necessary to remedy situations when market forces fail to adequately protect investor interests. Unfortunately, as Boatright (2008) points out, such failures do occur. Investors are well aware of the securities scandals of the 1980s that made Ivan Boesky and Michael Milken household names. Further, the market timing trading scandals that tainted the mutual fund industry in 2003 as well as the subprime loan crisis of 2008 proved that lapses in ethical judgment could take place at the company level as well. The financial rescue of Long Term Capital Management that occurred in the 1990s created considerable interest in increasing governmental oversight of the hedge fund industry.

Transgressions of this nature attest to the fact that although regulations can punish those violating the law, they cannot prevent all such abuses from occurring in the first place. Absolute prevention requires self-regulation on the part of the asset manager in the form of a strict set of personal ethical standards. Prentice (2007) and Jennings (2000) have stressed that the desire of individuals and firms in the investment management business to maintain their reputation with clients is a major motivating factor in the practice of self-regulation. Avera (1994) has outlined four general principles that should form the cornerstone of the standards of conduct in the profession. First, managers must conduct themselves with integrity and act in an ethical manner in all dealings. Second, they should perform financial analysis in a professional and ethical manner. Third, managers should act with competence and strive to maintain and improve their competence. Finally, they should always use proper care and exercise independent professional judgment.

The CFA (Chartered Financial Analysts) Institute has developed for its worldwide membership of security analysts and money managers a rigorous Code of Ethics and Standards of Professional Conduct based on these principles. (These are available online at www.cfainstitute.org and in Appendix B at the back of this book.) The Code of Ethics contains an expanded version of the four themes listed previously and can be stated as follows:

Members of the CFA Institute must:

1. Act with integrity, competence, diligence, respect, and in an ethical manner with the public, clients, prospective clients, employers, employees, colleagues in the investment profession, and other participants in the global capital markets.
2. Place the integrity of the investment profession and the interests of clients above their own personal interests.
3. Use reasonable care and exercise independent professional judgment when conducting investment analysis, making investment recommendations, taking investment actions, and engaging in other professional activities.

Industry Regulatory Authority (or FINRA, the largest independent regulator for all securities firms doing business in the United States), the U.S. Commodity Futures Trading Commission (monitoring of futures and commodities trading activities), and the U.S. Internal Revenue Service (setting and enforcing of tax policies).

The main federal regulation governing the management of private pension funds is the Employee Retirement Income Security Act (ERISA), which was enacted in 1974 and primarily impacts the activities of private management companies as well as mutual funds. ERISA clearly states that pension funds are to be managed to the needs of the plan participants and their beneficiaries—as opposed to the corporation sponsoring the plan—and that managers should diversify plan assets so as to minimize the risk of large losses. As Del Guercio (1996) discusses, a key feature of ERISA is the prudent man statute, which outlines the level of fiduciary care that the manager must provide to the investor. This definition of the manager’s required level of “care, skill, prudence, and diligence” was the first legal recognition of prudence involving the entire portfolio, rather than the individual securities on a case-by-case basis.

One of the advantages that the hedge fund industry has enjoyed historically is being relatively free from regulatory prohibitions that might otherwise impede the investment process. These funds tended to adopt a limited liability format (e.g., limited partnership, limited liability company) purposely to avoid having to register with the SEC. This freedom allowed hedge
fund managers to employ certain strategic tools (e.g., leverage, short selling) that were not available to traditional fund managers. However, the Dodd-Frank Reform Act of 2010 made registration mandatory for hedge fund advisers with more than US$150 million in assets under management. A hedge fund qualifies for an exemption from the Investment Company Act if it has fewer than 100 investors, while hedge fund managers are exempt from the Investment Advisers Act if they manage less than $25 million in assets. On the other hand, if a quarter of a hedge fund’s assets consist of retirement plan assets, the fund must comply with the restrictions set forth under ERISA.

24.5.2 Standards for Ethical Behavior

Many developed economies like that in the United States are founded on the notion of financial market discipline. In such a system, government intervention is necessary to remedy situations when market forces fail to adequately protect investor interests. Unfortunately, as Boatright (2008) points out, such failures do occur. Investors are well aware of the securities scandals of the 1980s that made Ivan Boesky and Michael Milken household names. Further, the market timing trading scandals that tainted the mutual fund industry in 2003 as well as the subprime loan crisis of 2008 proved that lapses in ethical judgment could take place at the company level as well. The financial rescue of Long Term Capital Management that occurred in the 1990s created considerable interest in increasing governmental oversight of the hedge fund industry.

Transgressions of this nature attest to the fact that although regulations can punish those violating the law, they cannot prevent all such abuses from occurring in the first place. Absolute prevention requires self-regulation on the part of the asset manager in the form of a strict set of personal ethical standards. Prentice (2007) and Jennings (2000) have stressed that the desire of individuals and firms in the investment management business to maintain their reputation with clients is a major motivating factor in the practice of self-regulation. Avera (1994) has outlined four general principles that should form the cornerstone of the standards of conduct in the profession. First, managers must conduct themselves with integrity and act in an ethical manner in all dealings. Second, they should perform financial analysis in a professional and ethical manner. Third, managers should act with competence and strive to maintain and improve their competence. Finally, they should always use proper care and exercise independent professional judgment.10

The CFA (Chartered Financial Analysts) Institute has developed for its worldwide membership of security analysts and money managers a rigorous Code of Ethics and Standards of Professional Conduct based on these principles. (These are available online at www.cfainstitute.org and in Appendix B at the back of this book.) The Code of Ethics contains an expanded version of the four themes listed previously and can be stated as follows:

* Members of the CFA Institute must:
  * Act with integrity, competence, diligence, respect, and in an ethical manner with the public, clients, prospective clients, employers, employees, colleagues in the investment profession, and other participants in the global capital markets.
  * Place the integrity of the investment profession and the interests of clients above their own personal interests.
  * Use reasonable care and exercise independent professional judgment when conducting investment analysis, making investment recommendations, taking investment actions, and engaging in other professional activities.

10For interesting discussions of the investing public’s perception of ethics in the asset management industry, see Lummer (1994) and Ware (2000).
• Practice and encourage others to practice in a professional and ethical manner that will reflect credit on themselves and the profession.
• Promote the integrity of, and uphold the rules governing, capital markets.
• Maintain and improve their professional competence and strive to maintain and improve the competence of other investment professionals.

The specific standards of practice suggested by these ethical mandates are summarized at the back of the book in Appendix B. These standards provide asset managers with precisely defined conduct and actions that are acceptable (or, more to the point, unacceptable) in daily practice. For example, the general principle that managers should use proper care becomes a specific requirement that they must be able to justify the suitability of any investment decision made on behalf of a particular client. The CFA Institute expects all of its members, which includes everyone holding the CFA designation, to uphold these standards on a voluntary basis. Violations deemed severe enough can result in the loss of a manager’s charter.

In recognition of the unique place of trust that portfolio managers enjoy, one recent initiative that the CFA Institute has undertaken on behalf of its worldwide constituency has been the creation of a comprehensive Asset Manager Code of Professional Conduct. In the 2010 edition, the Asset Manager Code sets forth minimum standards for providing asset management services to clients, based on the following general principles of conduct:

Managers have the following responsibilities to their clients. Managers must:

1. Act in a professional and ethical manner at all times.
2. Act for the benefit of clients.
3. Act with independence and objectivity.
4. Act with skill, competence, and diligence.
5. Communicate with clients in a timely and accurate manner.
6. Uphold the applicable rules governing capital markets.

The Code seeks to extend the voluntary standards of practice governing individual conduct to a set of rules that pertains to entire investment management firms. Although many firms already have such standards in place, others (including both traditional managers and hedge fund managers) do not, and this is the niche the Code is designed to fill.

24.5.3 Examples of Ethical Conflicts

Many ethical breaches, such as plagiarizing research reports or falsifying performance statements, are unambiguously wrong. Other lapses are not as clear-cut. We will conclude this section with a discussion of three examples of how possible conflicts between the manager and the investor can arise from accepted business practices.

Incentive Compensation Schemes The first example is related to the way in which managers are compensated for their services. We saw earlier in the chapter that traditional asset management companies—both public and private—typically receive fees based on AUM. Further, hedge fund and private equity managers also receive a performance allocation fee that is tied directly to the portfolio’s performance. The managers at these companies, in turn, are often compensated with a base salary and bonus that depends on the performance of their portfolios relative to those of their peers. Brown, Harlow, and Starks (1996) argued that this arrangement is analogous to a golf or tennis tournament where the players with the best relative performance at the end of the competition receive the largest payoffs. They documented that mutual fund managers with the worst relative performance midway through a compensation period were more likely to increase the risk of the portfolio in an effort to increase their final standing. Of course, altering fund risk to enhance their own compensation suggests that some managers may not always act in their clients’ best interests.
5. Administer the account, keep records of costs and transactions, provide timely information for tax purposes, and reinvest dividends if desired.

6. Maintain ethical standards of behavior at all times.

Not all of the types of asset management organizations we have discussed in this chapter address each of these goals. For instance, mutual funds do not determine your risk preference for you, while alternative asset investments are seldom well diversified. However, once you determine your risk-return preferences, you can choose a mutual fund designed to achieve almost any investment goal. In general, these types of managers are consistent in meeting their stated goals for investment strategies, risk, and returns. Private asset management companies are oriented toward providing similar services (including investment policy development) for clients who have larger amounts of investable capital.

Diversifying your portfolio to eliminate unsystematic risk is one of the major benefits of both private management companies and mutual funds. Many mutual funds provide instant diversification, which is especially beneficial to small investors who do not have the resources to form their own large-scale portfolios. Although diversification varies among funds, many existing portfolios have a correlation with the market above 0.80. Therefore, most mutual funds provide excellent diversification, especially if they state this goal as an explicit objective.

The third function your portfolio manager might perform for you is to maintain the diversification of your portfolio within your desired risk class. Both types of traditional asset managers (i.e., private management companies and mutual funds) generally maintain the stability of their correlation with the market over time because few managers change the makeup of reasonably well-diversified portfolios very much. Strong evidence exists regarding the consistency of the risk class mandates for portfolios regardless of whether the overall performance is better or worse than average. On the other hand, hedge fund portfolios often vary significantly within the broad context of their designated strategy as managers attempt to add the maximum amount of alpha.

Mutual funds have met the desire for flexibility to change investment instruments by creating numerous funds within a given management company. Typically, investment groups—such as T. Rowe Price, Vanguard, or Fidelity Investments—will allow you to shift between portfolios in their family of funds without a charge simply by calling the company. Therefore, you can shift between an aggressive stock fund, a money market fund, and a bond fund for much less than it would cost you in time and money to buy and sell numerous individual issues. By their nature, private management companies, hedge funds, and private equity firms tend to restrict an investor’s ability to make these sorts of changes; accordingly, these management types are considered to be less liquid than mutual funds.

The fourth function of your portfolio manager is to provide risk-adjusted performance that is superior to your benchmark, which implies that it is superior to a naive buy-and-hold investment policy. The rapid development of the alternative asset industry over the past several years suggests two things in this regard. First, investors increasingly view these managers as being better suited to produce positive and consistent alphas than traditional managers. Second, it is becoming more and more difficult for many traditional asset managers to generate superior risk-adjusted returns because of the many constraints imposed on their investment process (e.g., short sale prohibitions, leverage restrictions).

The fifth function of a portfolio manager is account administration. All managers provide this service to some degree. However, private management companies are the most likely to see all (or substantially all) of a client’s assets, and so these firms are in the best position to administer the account most effectively. Most mutual funds also provide many valuable administrative services. For instance, they allow automatic reinvestment of dividends at no charge and supply annual statements of dividend income and capital gain distribution that can be used to prepare tax returns. Given their partnership format, hedge funds and private equity firms...

### Soft Dollar Arrangements
A second potential ethical dilemma for professional asset managers involves the use of soft dollars. Soft dollars are generated when a manager commits the investor to paying a brokerage commission that is higher than the simple cost of executing a security trade in exchange for the manager receiving additional bundled services from the broker. A typical example of this practice would be for a manager to route her equity trades through a nondiscount broker in order to receive security research reports that the brokerage firm produces. It may not be hard for the manager to justify how this additional research benefits the investor—who ultimately pays for the service—but the story is quite different if, instead of research, the manager receives from the broker “perks,” such as office equipment, secretarial services, or even payment for personal travel. Blume (1993) and Bogle (2009) have argued that this practice can result in a misallocation of resources or an expropriation of investor wealth by the manager, although Horan and Johnsen (2000) document that the use of soft dollars is actually a cost-effective way for investors to monitor a manager’s behavior. In 1998, the CFA Institute adopted a comprehensive set of voluntary standards designed to give its members guidance on the permissible uses of soft dollar arrangements.

### Marketing Investment Management Services
A final example of an ethical dilemma that confronts professional asset management organizations is how and when to advertise their services. Conventional wisdom holds that it would be in the investors’ best interests for any particular investment management company to build a steady awareness over time of its relative merits. However, in their survey of the mutual fund market, Capon, Fitzsimons, and Prince (1996) documented that the main factor in the decision of which fund’s shares to buy was the immediate past total return performance of the portfolio. Zweig (2000) observed that a consequence of this tendency has been that mutual funds time their advertisements around relative peaks in their performance. Further, firms that run a family of funds can choose which portfolio or manager they want to promote on a situational basis, while still maintaining continuous brand awareness for the entire complex. Despite the usual disclaimers to the effect that “past returns are not an indication of future performance,” the decision to always promote the “hot hand” is likely to be effective, but it is also likely to result in a misallocation of investor capital.

In summary, it is important for investors to recognize that potential ethical conflicts will exist any time they hire professional investment managers. Investors are protected by the series of regulations that oversee the security industry as well as the strict standards imposed by trade associations such as the CFA Institute. Of course, perhaps the best protection that investors have is the vast majority of the thousands of investment advisors and managers throughout the world who are unwilling to do anything that would jeopardize their personal and professional reputations.

### 24.6 What Do You Want from a Professional Asset Manager?
What functions do you want your portfolio manager to perform for you? The list probably includes some or all of the following:

1. Help determine your investment objectives and constraints (e.g., return goals, risk tolerance), and develop a portfolio that is consistent with them.
2. Diversify your portfolio to eliminate unsystematic risk.
3. Maintain your portfolio diversification within your desired risk class, while allowing flexibility so that you can shift between alternative investment instruments as desired.
4. Attempt to achieve a risk-adjusted performance level that is superior to that of your relevant benchmark; some investors may be willing to sacrifice diversification for superior returns in limited segments of their portfolios.
5. Administer the account, keep records of costs and transactions, provide timely information for tax purposes, and reinvest dividends if desired.

6. Maintain ethical standards of behavior at all times.

Not all of the types of asset management organizations we have discussed in this chapter address each of these goals. For instance, mutual funds do not determine your risk preference for you, while alternative asset investments are seldom well diversified. However, once you determine your risk-return preferences, you can choose a mutual fund designed to achieve almost any investment goal. In general, these types of managers are consistent in meeting their stated goals for investment strategies, risk, and returns. Private asset management companies are oriented toward providing similar services (including investment policy development) for clients who have larger amounts of investable capital.

Diversifying your portfolio to eliminate unsystematic risk is one of the major benefits of both private management companies and mutual funds. Many mutual funds provide instant diversification, which is especially beneficial to small investors who do not have the resources to form their own large-scale portfolios. Although diversification varies among funds, many existing portfolios have a correlation with the market above 0.80. Therefore, most mutual funds provide excellent diversification, especially if they state this goal as an explicit objective.

The third function your portfolio manager might perform for you is to maintain the diversification of your portfolio within your desired risk class. Both types of traditional asset manager (i.e., private management companies and mutual funds) generally maintain the stability of their correlation with the market over time because few managers change the makeup of reasonably well-diversified portfolios very much. Strong evidence exists regarding the consistency of the risk class mandates for portfolios regardless of whether the overall performance is better or worse than average. On the other hand, hedge fund portfolios often vary significantly within the broad context of their designated strategy as managers attempt to add the maximum amount of alpha.

Mutual funds have met the desire for flexibility to change investment instruments by creating numerous funds within a given management company. Typically, investment groups—such as T. Rowe Price, Vanguard, or Fidelity Investments—will allow you to shift between portfolios in their family of funds without a charge simply by calling the company. Therefore, you can shift between an aggressive stock fund, a money market fund, and a bond fund for much less than it would cost you in time and money to buy and sell numerous individual issues. By their nature, private management companies, hedge funds, and private equity firms tend to restrict an investor’s ability to make these sorts of changes; accordingly, these management types are considered to be less liquid than mutual funds.

The fourth function of your portfolio manager is to provide risk-adjusted performance that is superior to your benchmark, which implies that it is superior to a naive buy-and-hold investment policy. The rapid development of the alternative asset industry over the past several years suggests two things in this regard. First, investors increasingly view these managers as being better suited to produce positive and consistent alphas than traditional managers. Second, it is becoming more and more difficult for many traditional asset managers to generate superior risk-adjusted returns because of the many constraints imposed on their investment process (e.g., short sale prohibitions, leverage restrictions).

The fifth function of a portfolio manager is account administration. All managers provide this service to some degree. However, private management companies are the most likely to see all (or substantially all) of a client’s assets, and so these firms are in the best position to administer the account most effectively. Most mutual funds also provide many valuable administrative services. For instance, they allow automatic reinvestment of dividends at no charge and supply annual statements of dividend income and capital gain distribution that can be used to prepare tax returns. Given their partnership format, hedge funds and private...
equity funds also provide investors with necessary tax information, as well as periodic accounting of investment activity.

The final function that you should expect from your portfolio manager is ethical behavior that follows the prevailing regulations and standards of conduct in the industry. For all investors, this is—and should be—a nonnegotiable requirement, regardless of the organizational form of the company. As we have seen, professional asset management is a fiduciary business, and those managers whose conduct violates the trust of those whose wealth they protect and grow will not last long. In extreme cases, they may even suffer legal consequences.

In summary, as an investor, you want your portfolio manager to perform a broad array of functions. Typically, however, no single manager is equipped to provide all of the services that you may require. Therefore, it is quite common for investors to form a “portfolio” of managers with different talents and capabilities (e.g., a hedge fund manager to provide superior risk-adjusted returns, an index mutual fund manager to provide diversification for the majority of your assets). Given what we know about the value of diversifying financial capital across different asset classes and securities, it should come as no surprise that the same principle holds for portfolio management skills as well.

**SUMMARY**

- There are two primary types of professional asset management companies. Management and advisory firms hold the assets of individual and institutional investors in separate accounts. Investment companies are pools of assets that are managed collectively. Investors in these funds receive shares representing their proportional ownership in the underlying portfolio of stocks, bonds, or other securities. These fund shares can be either traded in the secondary market (closed-end) or sold directly back to the investment company (mutual fund) at the prevailing net asset value. A wide variety of funds are available, so you can find one to match almost any investment objective or combination of investment objectives.

- In recent years, the professional asset management industry has undergone considerable structural change. Among traditional “long-only” asset management firms, there has been a trend toward consolidating assets under management (AUM) in large, multiproduct companies. This has had a beneficial effect for investors of reducing management fees, which are usually charged on a declining percentage of AUM. Investment companies also often charge fees for marketing their shares, in the form of front-end fees, annual 12b-1 fees, or back-end load fees. Publicly available information exists on mutual fund investment practices and performance, to help investors make decisions that are appropriate for their circumstances.

- A second trend that has marked the professional asset management industry in recent years has been the rapid development of vehicles to invest in alternative asset classes, such as hedge funds and private equity. One of the main advantages that these funds enjoy is that they are generally less restricted in what strategies they can follow and investment techniques they can employ, such as the use of both leverage and short selling. As a consequence of this additional level of flexibility, many investors have come to regard alternative asset managers as being in a unique position to produce superior risk-adjusted returns.

- Issues of ethical behavior arise any time one person is hired to perform a service for another. The professional asset management industry protects investors through a series of government regulations and voluntary standards of practice imposed by trade associations on their members. The primary purpose of these regulations and standards is to ensure that managers deal with all investors fairly and equitably and that information about investment performance is accurately reported. Two areas of particular concern in the investment community involve manager compensation arrangements and the use of soft dollars.
Chapter 24: Professional Money Management, Alternative Assets, and Industry Ethics

**SUGGESTED READINGS**

**QUESTIONS**

1. What are the differences between a management and advisory firm and an investment company? Describe the approach toward portfolio management adopted by each organization.

2. It has been suggested that the professional asset management community is rapidly becoming dominated by a fairly small number of huge, multiproduct firms. Discuss whether the data presented in Exhibit 24.2 support that view.

3. Closed-end funds generally invest in securities and financial instruments that are relatively illiquid, whereas most mutual funds invest in widely traded stocks and bonds. Explain the difference between closed-end and open-end funds and why this liquidity distinction matters.

4. What is the difference between a load fund and a no-load fund?

5. Should you care about how well a mutual fund is diversified? Why or why not?

6. As an investigator evaluating how well mutual fund managers select undervalued stocks or project market returns, discuss whether net or gross returns are more relevant.

7. You are told that Fund X experienced above-average performance over the past two years. Do you think it will continue over the next two years? Why or why not?

8. Catherine Marco is a portfolio manager with Mouton Investments, Inc., a regional money management firm. She is considering investments in alternative assets and decides to research the following three questions about long-short strategies and hedge funds:

   (1) How can the alpha generated from a long-short strategy in one asset class be transported to another asset class?

   (2) What are the three major quantifiable sources of risk that a fund of hedge funds manager must consider in risk monitoring?

   (3) For a fund of hedge funds, how does risk-based leverage differ from accounting-based leverage?

   a. Formulate one correct response to each of Marco’s three questions.

Marco decides to explore various hedge fund investment strategies and reviews the following three strategy components:

i. Buy stocks after positive earnings surprise announcements, anticipating that the stock price will rise in the short term.

ii. Establish appropriate long and short positions in stocks of companies that have announced a merger or acquisition or are rumored to be considering such a transaction.

iii. Use neural networks to detect patterns in historical data.

b. Identify the hedge fund investment strategy that is best characterized by each of the three strategy components reviewed by Marco.

Following her research, Marco applies her findings to the situation of an individual client. This client currently holds only traditional equity and fixed income investments and is willing to consider investing in alternative assets to lower the risk of his portfolio.
Marco forms the following five conclusions about investing in alternative assets for this client:

i. Investing in a fund of hedge funds is likely to increase the client’s portfolio diversification and allow the client’s portfolio to have exposure to a wide variety of hedge funds that may not otherwise be available to the client.

ii. A lack of transparency and the fund manager’s inability to add value through portfolio construction are both disadvantages of investing in a fund of hedge funds.

iii. Because a directional hedge fund is expected to exhibit a lower dispersion of returns than a nondirectional hedge fund, a directional hedge fund is a more appropriate investment for this client.

iv. One appropriate hedge fund investment strategy for this client is a macro hedge fund, which is likely to provide increased returns with a relatively low standard deviation of returns.

v. Another approach that is consistent with the client’s objectives is to use an equitized long-short strategy, which can be expected to neutralize market risk.

c. Judge whether each of Marco’s five conclusions is correct or incorrect. If incorrect, give one reason why the conclusion is incorrect.

9. Most money managers have a portion of their compensation tied to the performance of the portfolios they manage. Explain how this arrangement can create an ethical dilemma for the manager.

10. What are soft dollar arrangements? Describe one potential way they can be used to transfer wealth from the investor to the manager.

---

**PROBLEMS**

1. Suppose ABC Mutual Fund had no liabilities and owned only four stocks as follows:

<table>
<thead>
<tr>
<th>Stock</th>
<th>Shares</th>
<th>Price</th>
<th>Market Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>W</td>
<td>1,000</td>
<td>$12</td>
<td>$12,000</td>
</tr>
<tr>
<td>X</td>
<td>1,200</td>
<td>15</td>
<td>18,000</td>
</tr>
<tr>
<td>Y</td>
<td>1,500</td>
<td>22</td>
<td>33,000</td>
</tr>
<tr>
<td>Z</td>
<td>800</td>
<td>16</td>
<td>12,800</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>$75,800</td>
</tr>
</tbody>
</table>

The fund began by selling $50,000 of stock at $8.00 per share. What is its NAV?

2. Suppose you are considering investing $1,000 in a load fund that charges a fee of 8 percent, and you expect your investment to earn 15 percent over the next year. Alternatively, you could invest in a no-load fund with similar risk that charges a 1 percent redemption fee. You estimate that this no-load fund will earn 12 percent. Given your expectations, which is the better investment and by how much?

3. Consider the recent performance of the Closed Fund, a closed-end fund devoted to finding undervalued, thinly traded stocks:

<table>
<thead>
<tr>
<th>Period</th>
<th>NAV</th>
<th>Premium/Discount</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>$10.00</td>
<td>0.0%</td>
</tr>
<tr>
<td>1</td>
<td>11.25</td>
<td>-5.0%</td>
</tr>
<tr>
<td>2</td>
<td>9.85</td>
<td>+2.3%</td>
</tr>
<tr>
<td>3</td>
<td>10.50</td>
<td>-3.2%</td>
</tr>
<tr>
<td>4</td>
<td>12.30</td>
<td>-7.0%</td>
</tr>
</tbody>
</table>
The Focus Fund is a mutual fund that holds long-term positions in a small number of nondividend-paying stocks. Its holdings at the end of two recent years are as follows:

<table>
<thead>
<tr>
<th>Year 1</th>
<th>Year 2</th>
</tr>
</thead>
<tbody>
<tr>
<td>Stock</td>
<td>Shares</td>
</tr>
<tr>
<td>A</td>
<td>100,000</td>
</tr>
<tr>
<td>B</td>
<td>225,000</td>
</tr>
<tr>
<td>C</td>
<td>375,000</td>
</tr>
<tr>
<td>D</td>
<td>115,000</td>
</tr>
<tr>
<td>E</td>
<td>154,000</td>
</tr>
<tr>
<td>F</td>
<td>175,000</td>
</tr>
<tr>
<td>G</td>
<td>212,000</td>
</tr>
<tr>
<td>H</td>
<td>275,000</td>
</tr>
<tr>
<td>I</td>
<td>450,000</td>
</tr>
<tr>
<td>J</td>
<td>90,000</td>
</tr>
<tr>
<td>K</td>
<td>87,000</td>
</tr>
<tr>
<td>L</td>
<td>137,000</td>
</tr>
<tr>
<td>M</td>
<td>150,000</td>
</tr>
<tr>
<td>Cash</td>
<td></td>
</tr>
<tr>
<td>Expenses</td>
<td>730,000</td>
</tr>
</tbody>
</table>

At the end of both years, Focus Fund had 5,430,000 shares outstanding.

a. Calculate the net asset value for a share of the Focus Fund at the end of Year 1, being sure to include the cash position in the net total portfolio value.

b. Immediately after calculating its Year 1 NAV, Focus Fund sold its position in Stock L and purchased its position in Stock M (both transactions were done at Year 1 prices). Calculate the Year 2 NAV for Focus Fund, and compute the growth rate in the fund share value on a percentage basis.

c. At the end of Year 2, how many fund shares of the Focus Fund could the manager redeem without having to liquidate her stock positions (i.e., using only the cash account)?

d. If immediately after calculating the Year 2 NAV the manager received investor redemption requests for 500,000 shares, how many shares of each stock would she have to sell in order to maintain the same proportional ownership position in each stock? Assume that she liquidates the entire cash position before she sells any stock holdings.

4. CMD Asset Management has the following fee structure for clients in its equity fund:

<table>
<thead>
<tr>
<th>Fee Structure</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.00% of first $5 million invested</td>
</tr>
<tr>
<td>0.75% of next $5 million invested</td>
</tr>
<tr>
<td>0.60% of next $10 million invested</td>
</tr>
<tr>
<td>0.40% above $20 million</td>
</tr>
</tbody>
</table>

a. Calculate the annual dollar fees paid by Client 1, who has $27 million under management, and Client 2, who has $97 million under management.

b. Calculate the fees paid by both clients as a percentage of their assets under management.

c. What is the economic rationale for a fee schedule that declines (in percentage terms) with increases in assets under management?

5. Describe a potential conflict of interest in each of the following four situations:

a. An investment advisor whose compensation is based on commissions from client trades

b. An investment manager’s use of client brokerage (“soft dollars”) to purchase research or other services

c. A portfolio manager of a mutual fund who purchases, for the fund, a substantial amount of stock in a small-capitalization company whose warrants the manager owns

d. A research analyst who accepts reimbursement for food, lodging, and air transportation expenses for a site visit from the company on which she is writing a research report

Note: In formulating your answers, you should consider CFA Institute’s Code of Ethics and Standards of Professional Conduct, located in Appendix B in the back of this book.

6. Suppose that at the start of the year, a no-load mutual fund has a net asset value of $27.15 per share. During the year, it pays its shareholders a capital gain and dividend distribution of $1.12 per share and finishes the year with an NAV of $30.34.

a. What is the return to an investor who holds 257,876 shares of this fund in his (non-taxable) retirement account?
b. What is the after-tax return for the same investor if these shares were held in an ordinary savings account? Assume that the investor is in the 30 percent tax bracket.
c. If the investment company allowed the investor to automatically reinvest his cash distribution in additional fund shares, how many additional shares could the investor acquire? Assume that the distribution occurred at year end and that the proceeds from the distribution can be reinvested at the year-end NAV.
7. The Focus Fund is a mutual fund that holds long-term positions in a small number of nondividend-paying stocks. Its holdings at the end of two recent years are as follows:

<table>
<thead>
<tr>
<th>Stock</th>
<th>Year 1</th>
<th>Year 2</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Shares</td>
<td>Price</td>
</tr>
<tr>
<td>A</td>
<td>100,000</td>
<td>45.25</td>
</tr>
<tr>
<td>B</td>
<td>225,000</td>
<td>25.38</td>
</tr>
<tr>
<td>C</td>
<td>375,000</td>
<td>14.50</td>
</tr>
<tr>
<td>D</td>
<td>115,000</td>
<td>87.13</td>
</tr>
<tr>
<td>E</td>
<td>154,000</td>
<td>56.50</td>
</tr>
<tr>
<td>F</td>
<td>175,000</td>
<td>63.00</td>
</tr>
<tr>
<td>G</td>
<td>212,000</td>
<td>32.00</td>
</tr>
<tr>
<td>H</td>
<td>275,000</td>
<td>15.25</td>
</tr>
<tr>
<td>I</td>
<td>450,000</td>
<td>9.63</td>
</tr>
<tr>
<td>J</td>
<td>90,000</td>
<td>71.25</td>
</tr>
<tr>
<td>K</td>
<td>87,000</td>
<td>42.13</td>
</tr>
<tr>
<td>L</td>
<td>137,000</td>
<td>19.88</td>
</tr>
<tr>
<td>M</td>
<td>0</td>
<td>17.75</td>
</tr>
<tr>
<td>Cash</td>
<td>$3,542,000</td>
<td></td>
</tr>
<tr>
<td>Expenses</td>
<td>$730,000</td>
<td></td>
</tr>
</tbody>
</table>

At the end of both years, Focus Fund had 5,430,000 shares outstanding.

a. Calculate the net asset value for a share of the Focus Fund at the end of Year 1, being sure to include the cash position in the net total portfolio value.

b. Immediately after calculating its Year 1 NAV, Focus Fund sold its position in Stock L and purchased its position in Stock M (both transactions were done at Year 1 prices). Calculate the Year 2 NAV for Focus Fund, and compute the growth rate in the fund share value on a percentage basis.

c. At the end of Year 2, how many fund shares of the Focus Fund could the manager redeem without having to liquidate her stock positions (i.e., using only the cash account)?

d. If immediately after calculating the Year 2 NAV the manager received investor redemption requests for 500,000 shares, how many shares of each stock would she have to sell in order to maintain the same proportional ownership position in each stock? Assume that she liquidates the entire cash position before she sells any stock holdings.

8. Mutual funds can effectively charge sales fees in one of three ways: front-end load fees, 12b-1 (i.e., annual) fees, or deferred (i.e., back-end) load fees. Assume that the SAS Fund offers its investors the choice of the following sales fee arrangements: (1) a 3 percent front-end load, (2) a 0.50 percent annual deduction, or (3) a 2 percent back-end load, paid at the liquidation of the investor’s position. Also, assume that SAS Fund averages NAV growth of 12 percent per year.

a. If you start with $100,000 in investment capital, calculate what an investment in SAS would be worth in three years under each of the proposed sales fee schemes. Which scheme would you choose?

b. If your investment horizon were 10 years, would your answer in Part a change? Demonstrate.

c. Explain the relationship between the timing of the sales charge and your investment horizon. In general, if you intend to hold your position for a long time, which fee arrangement would you prefer?
9. Clark & Kerns (C&K), a U.S. pension fund manager for more than 20 years, plans to establish offices in a European and a Pacific Rim country in order to manage pension funds located in those countries and invest in their local stock markets. Tony Clark, CFA, managing partner, learns that investment organizations and their affiliates in the European country perform three functions:

- Consult with corporate pension sponsors on how the pension fund should be managed and by whom
- Manage their portfolios
- Execute securities transactions as a broker for the funds

Common practice in this country is to withhold disclosure of the ownership of business organizations. Clark believes that C&K must provide all three functions to compete effectively. He therefore decides to establish offices in Europe to offer all three services to prospective pension fund clients, through local organizations owned by C&K. The pension consulting organization will be Europension Group; the portfolio management firm will be C&K International; and the broker-dealer operation will be Alps Securities.

a. Briefly describe two CFA Institute Standards of Professional Conduct that apply to Clark, if C&K provides all three functions on a combined basis. Describe the specific duty Clark is required to perform to comply with these standards.

b. Identify and briefly explain two CFA Institute Standards of Professional Conduct that apply to this situation.

c. Identify and briefly explain two CFA Institute Standards of Professional Conduct that apply to this situation.

10. Peter and Andrea Mueller have built up their $600,000 investment portfolio over many years through regular purchases of mutual funds holding only U.S. securities. Each purchase was based on personal research but without consideration of their other holdings. They would now like advice on their total portfolio, which follows:

<table>

Evaluate the Muellers’ portfolio in terms of the following criteria:

a. Preference for “minimal volatility”

b. Equity diversification

c. Asset allocation (including cash flow needs)
After you read this chapter, you should be able to answer the following questions:

1. What major requirements do clients expect from their portfolio managers?
2. What is the peer group comparison method of evaluating an investor's performance?
3. What is the Treynor portfolio performance measure?
4. What is the Sharpe portfolio performance measure?
5. What is the Jensen portfolio performance measure, and how can it be adapted to include multifactor models of risk and expected return?
6. What is the information ratio, and how is it related to the other performance measures?
7. When evaluating a sample of portfolios, how do you determine how well diversified they are?
8. What are the Fama and Sortino portfolio performance measures, and what information do they provide beyond other measures?
9. How can investment performance be measured by analyzing the security holdings of a portfolio?
10. What is attribution analysis, and how can it be used to distinguish between a portfolio manager's market timing and security selection skills?
11. What are customized benchmarks, and what are the important characteristics that any benchmark should possess?
12. How do bond portfolio performance measures differ from equity portfolio performance measures?
13. What are time-weighted and dollar-weighted returns, and which should be reported under the CFA Institute's Performance Presentation Standards?

This chapter outlines the theory and practice of evaluating the performance of an investment portfolio. We begin by considering what an investor should require of a portfolio manager. We also briefly discuss how investment performance was evaluated before asset pricing models were developed and examine an assessment technique—called a peer group comparison—still widely used today that does not require an explicit adjustment for the risk exposure of the portfolio.

Comparing a portfolio's historical returns to those produced by other managers or indexes can be instructive, but it does not produce a complete picture of the portfolio's performance. The central tenet of modern performance measurement is that it is impossible to make a thorough evaluation of an investment without explicitly controlling for the risk of the portfolio. Given the complexity of the issues involved, it should not be surprising to learn that there is not a single universally accepted procedure for risk-adjusting portfolio returns. Instead, there are several techniques that are commonly employed in practice, and we will consider the most prominent of these in detail. There are four portfolio performance evaluation techniques (referred to as composite performance measures) that comprise the basic "toolkit" for measuring risk-adjusted performance.
CHAPTER 25
Evaluation of Portfolio Performance

After you read this chapter, you should be able to answer the following questions:

- What major requirements do clients expect from their portfolio managers?
- What is the peer group comparison method of evaluating an investor’s performance?
- What is the Treynor portfolio performance measure?
- What is the Sharpe portfolio performance measure?
- What is the Jensen portfolio performance measure, and how can it be adapted to include multifactor models of risk and expected return?
- What is the information ratio, and how is it related to the other performance measures?
- When evaluating a sample of portfolios, how do you determine how well diversified they are?
- What are the Fama and Sortino portfolio performance measures, and what information do they provide beyond other measures?
- How can investment performance be measured by analyzing the security holdings of a portfolio?
- What is attribution analysis, and how can it be used to distinguish between a portfolio manager’s market timing and security selection skills?
- What are customized benchmarks, and what are the important characteristics that any benchmark should possess?
- How do bond portfolio performance measures differ from equity portfolio performance measures?
- What are time-weighted and dollar-weighted returns, and which should be reported under the CFA Institute’s Performance Presentation Standards?

This chapter outlines the theory and practice of evaluating the performance of an investment portfolio. We begin by considering what an investor should require of a portfolio manager. We also briefly discuss how investment performance was evaluated before asset pricing models were developed and examine an assessment technique—called a peer group comparison—still widely used today that does not require an explicit adjustment for the risk exposure of the portfolio.

Comparing a portfolio’s historical returns to those produced by other managers or indexes can be instructive, but it does not produce a complete picture of the portfolio’s performance. The central tenet of modern performance measurement is that it is impossible to make a thorough evaluation of an investment without explicitly controlling for the risk of the portfolio. Given the complexity of the issues involved, it should not be surprising to learn that there is not a single universally accepted procedure for risk-adjusting portfolio returns. Instead, there are several techniques that are commonly employed in practice, and we will consider the most prominent of these in detail. There are four portfolio performance evaluation techniques (referred to as composite performance measures) that comprise the basic “toolkit” for measuring risk-adjusted performance.
Although some redundancy exists among the measures, each of them provides unique perspectives, so they are best viewed as a complementary set.

Following this discussion, we consider some additional techniques that measure different aspects of investment performance. We demonstrate how an investor can evaluate a manager’s performance by looking at the underlying security holdings of the portfolio and examine attribution analysis, a measurement technique designed to establish the source of a portfolio manager’s skill. We will also discuss how measuring the performance of a bond portfolio differs from that of a collection of stocks.

The chapter concludes with a discussion of a number of factors to consider when applying these various measures. We examine the controversy surrounding the selection of the proper benchmark to use in the risk-adjustment process and discuss why this benchmark problem becomes larger when you begin investing globally. The characteristics of a good benchmark are also described. Finally, we examine industry standards for calculating returns and reporting portfolio performance to investors.

### 25.1 What Is Required of a Portfolio Manager?

There are two desirable attributes of a portfolio manager’s performance:

1. The ability to derive above-average returns for a given risk class.
2. The ability to diversify the portfolio completely to eliminate all unsystematic risk, relative to the portfolio’s benchmark.

In terms of return performance, the first requirement is obvious, but the need to consider risk in this context was generally not apparent before the 1960s, when work in portfolio theory became widely accepted. As we have seen, superior risk-adjusted returns can be derived through either superior timing or superior security selection.

For example, an equity portfolio manager who can do a superior job of predicting the peaks or troughs in the market can adjust the portfolio’s composition to anticipate these trends, holding a completely diversified portfolio of high-beta stocks through rising markets and favoring low-beta stocks and money market instruments during declining markets. Bigger gains in rising markets and smaller losses in declining markets give the portfolio manager above-average risk-adjusted returns. Similarly, a fixed-income portfolio manager with superior timing ability might change the portfolio’s duration in anticipation of interest rate changes by increasing the duration of the portfolio in anticipation of failing interest rates and reducing it when rates are expected to rise.

As an alternative strategy, a portfolio manager may try consistently to select undervalued stocks or bonds for a given risk class. Even without superior market timing, such a portfolio would likely experience above-average risk-adjusted returns.

The second factor to consider in evaluating a manager is the ability to diversify the portfolio completely. We have seen that, on average, the market rewards investors only for bearing systematic (market) risk. Unsystematic risk is often not even considered when determining required returns because it can be eliminated in a diversified market portfolio. Because they can expect no reward for bearing this uncertainty, investors typically want their portfolios completely to be diversified. The level of diversification can be judged on the basis of the correlation between the portfolio returns and the returns for a market portfolio or some other benchmark index. A completely diversified portfolio is perfectly correlated with the fully diversified benchmark portfolio.

These two requirements of a portfolio manager are important because some portfolio evaluation techniques take into account one requirement but not the other. Other techniques implicitly consider both factors but do not differentiate between them.
25.2 Early Performance Measurement Techniques

25.2.1 Portfolio Evaluation before 1960
At one time, investors evaluated portfolio performance almost entirely on the basis of the rate of return. They were aware of the concept of risk but did not know how to measure it, so they could not consider it explicitly. Developments in portfolio theory in the early 1960s showed investors how to quantify risk in terms of the variability of returns. Still, because no single measure combined both return and risk, the two factors had to be considered separately, as Friend, Blume, and Crockett (1970) did by grouping portfolios into similar risk classes based on return variance and then comparing the rates of return for alternative portfolios directly within these risk classes.

25.2.2 Peer Group Comparisons
A peer group comparison, which Kritzman (1990) describes as the most common manner of evaluating portfolio managers, collects the returns produced by a representative universe of investors over a specific period of time and displays them in a simple boxplot format. The universe is typically divided into percentiles, showing the relative ranking of a given investor. For instance, a portfolio manager who produced a one-year return of 12.4 percent would be in the 10th percentile if only 9 other portfolios in a universe of 100 produced a higher return. Although these comparisons can get quite detailed, it is common for the boxplot graphic to include the maximum and minimum returns, as well as the returns falling at the 25th, 50th (i.e., the median), and 75th percentiles.

Exhibit 25.1 shows the returns from periods of varying length for a representative investor—labeled here as “U.S. Equity with Cash”—relative to its peer universe of other U.S. domestic equity managers.\(^1\) Also included in the comparison are the periodic returns to three indexes of the overall market: Standard and Poor’s 500, Russell 1000, and Russell 3000. The display shows return quartiles for investment periods ranging from 5 to 10 years. The investor in question (indicated by the large dot) performed admirably, finishing above the median in each of the comparison periods. The manager of this portfolio produced the largest 9-year return (16.5 percent), well above the median return of 13.0 percent. Notice that although the investor’s 10-year average return exceeds the 9-year level (16.6 percent), it falls below the fifth percentile, which is no longer the best.

There are several potential problems with the peer group comparison method of evaluating an investor’s performance. First, the boxplots shown in Exhibit 25.1 do not make any explicit adjustment for the risk level of the portfolios in the universe. Investment risk is only implicitly considered to the extent that all the portfolios in the universe have essentially the same level of volatility. This is not likely to be the case for any sizable peer group, particularly if the universe mixes portfolios with different investment styles. Second, it is almost impossible to form a truly comparable peer group that is large enough to make the percentile rankings valid and meaningful. Finally, by focusing on nothing more than relative returns, such a comparison loses sight of whether the investor in question has accomplished his individual objectives and satisfied his investment constraints.

25.3 Composite Portfolio Performance Measures
This section describes in detail the four major composite equity portfolio performance measures that combine risk and return performance into a single value. We also compare the measures and discuss how they differ and why they rank portfolios differently.

\(^1\)This example comes from Singer (1996) and was based on data from the Frank Russell Company.
25.3.1 Treynor Portfolio Performance Measure

Treynor (1965) developed the first composite measure of portfolio performance that included risk. He postulated two components of risk: (1) risk produced by general market fluctuations, and (2) risk resulting from unique fluctuations in the portfolio securities. To identify risk due to market fluctuations, he introduced the characteristic line, which defines the relationship between the returns to a managed portfolio and the market portfolio. As we know from Chapter 8, the slope of this line is the portfolio's beta coefficient. A higher slope (beta) characterizes a portfolio that is more sensitive to market returns and has greater market risk. Deviations from the characteristic line indicate unique return components for the portfolio relative to the market. In a completely diversified portfolio, these unique returns should cancel out. As the correlation of the portfolio with the market increases, unique risk declines and diversification improves. Because Treynor was not concerned about this aspect of portfolio performance, he gave no further consideration to the diversification measure.

Treynor's Composite Performance Measure

Treynor was interested in a measure of performance that would apply to all investors, regardless of their risk preferences. Building on capital market theory, he introduced a risk-free asset that could be combined with different portfolios to form a portfolio possibility line. He showed that rational, risk-averse investors would always prefer the portfolio line with the largest slope because this would place them on the highest indifference curve. The slope of this portfolio possibility line (designated $T_i$) is equal to:

$$T_i = \frac{R_i - R_{FR}}{\beta_i}$$

where:

- $R_i$ = the average rate of return for Portfolio $i$ during a specified time period
- $R_{FR}$ = the average rate of return on a risk-free investment during the same time period
- $\beta_i$ = the slope of the fund's characteristic line during that time period

As noted, a larger $T$ value indicates a better portfolio for all investors, regardless of their risk preferences. Because the numerator of this ratio is the risk premium and the denominator is a measure of risk, the total expression indicates the portfolio's risk premium return per unit of risk. All risk-averse investors would prefer to maximize this value. The risk variable beta measures systematic risk and tells us nothing about the diversification of the portfolio. It implicitly assumes a completely diversified portfolio.

Comparing a portfolio's $T$ value to a similar measure for the market portfolio indicates whether the portfolio would plot above the SML. Calculate the $T$ value for the aggregate market as follows:

$$T_M = R_M - R_{FR}$$

In this expression, $\beta_M$ equals 1.0 (the market's beta) and $T_M$ indicates the slope of the SML. Therefore, a portfolio with a higher $T$ value than the market portfolio plots above the SML, indicating superior risk-adjusted performance.

Demonstration of Comparative Treynor Measures

Suppose that during the most recent 10-year period, the average annual total rate of return (including dividends) on an aggregate market portfolio, such as the S&P 500, was 14 percent ($R_M = 0.14$) and the average nominal rate of return on government T-bills was 8 percent ($R_{FR} = 0.08$). As administrator of a large

The terms used in the formula differ from those used by Treynor but are consistent with our earlier discussion.

25.3.1 Treynor Portfolio Performance Measure

Treynor (1965) developed the first composite measure of portfolio performance that included risk. He postulated two components of risk: (1) risk produced by general market fluctuations, and (2) risk resulting from unique fluctuations in the portfolio securities. To identify risk due to market fluctuations, he introduced the characteristic line, which defines the relationship between the returns to a managed portfolio and the market portfolio. As we know from Chapter 8, the slope of this line is the portfolio’s beta coefficient. A higher slope (beta) characterizes a portfolio that is more sensitive to market returns and has greater market risk.

Deviations from the characteristic line indicate unique return components for the portfolio relative to the market. In a completely diversified portfolio, these unique returns should cancel out. As the correlation of the portfolio with the market increases, unique risk declines and diversification improves. Because Treynor was not concerned about this aspect of portfolio performance, he gave no further consideration to the diversification measure.

Treynor’s Composite Performance Measure Treynor was interested in a measure of performance that would apply to all investors, regardless of their risk preferences. Building on capital market theory, he introduced a risk-free asset that could be combined with different portfolios to form a portfolio possibility line. He showed that rational, risk-averse investors would always prefer the portfolio line with the largest slope because this would place them on the highest indifference curve. The slope of this portfolio possibility line (designated T) is equal to:

\[ T_i = \frac{R_i - R_{FR}}{\beta_i} \]

where:

- \( R_i \) = the average rate of return for Portfolio i during a specified time period
- \( R_{FR} \) = the average rate of return on a risk-free investment during the same time period
- \( \beta_i \) = the slope of the fund’s characteristic line during that time period

As noted, a larger T value indicates a better portfolio for all investors, regardless of their risk preferences. Because the numerator of this ratio \((R_i - R_{FR})\) is the risk premium and the denominator is a measure of risk, the total expression indicates the portfolio’s risk premium return per unit of risk. All risk-averse investors would prefer to maximize this value. The risk variable beta measures systematic risk and tells us nothing about the diversification of the portfolio. It implicitly assumes a completely diversified portfolio.

Comparing a portfolio’s T value to a similar measure for the market portfolio indicates whether the portfolio would plot above the SML. Calculate the T value for the aggregate market as follows:

\[ T_M = \frac{R_M - R_{FR}}{\beta_M} \]

In this expression, \( \beta_M \) equals 1.0 (the market’s beta) and \( T_M \) indicates the slope of the SML. Therefore, a portfolio with a higher T value than the market portfolio plots above the SML, indicating superior risk-adjusted performance.

Demonstration of Comparative Treynor Measures Suppose that during the most recent 10-year period, the average annual total rate of return (including dividends) on an aggregate market portfolio, such as the S&P 500, was 14 percent \((R_M = 0.14)\) and the average nominal rate of return on government T-bills was 8 percent \((R_{FR} = 0.08)\). As administrator of a large

---

The terms used in the formula differ from those used by Treynor but are consistent with our earlier discussion.
pension fund that has been divided among three money managers during the past 10 years, you must decide whether to renew their investment management contracts based on the following results:

<table>
<thead>
<tr>
<th>Investment Manager</th>
<th>Average Annual Rate of Return</th>
<th>Beta</th>
</tr>
</thead>
<tbody>
<tr>
<td>W</td>
<td>0.12</td>
<td>0.90</td>
</tr>
<tr>
<td>X</td>
<td>0.16</td>
<td>1.05</td>
</tr>
<tr>
<td>Y</td>
<td>0.18</td>
<td>1.20</td>
</tr>
</tbody>
</table>

You compute $T$ values for the market portfolio and for each of the individual portfolio managers as follows:

$$T_M = \frac{0.14 - 0.08}{1.00} = 0.060$$

$$T_W = \frac{0.12 - 0.08}{0.90} = 0.044$$

$$T_X = \frac{0.16 - 0.08}{1.05} = 0.076$$

$$T_Y = \frac{0.18 - 0.08}{1.20} = 0.083$$

These results indicate that Investment Manager W not only ranked the lowest of the three managers but did not perform as well as the aggregate market on a risk-adjusted basis. In contrast, both X and Y beat the market portfolio, and Manager Y performed somewhat better than Manager X. Both of their portfolios plotted above the SML, as shown in Exhibit 25.2.

Very poor return performance or very good performance with very low risk may yield negative $T$ values. An example of poor performance is a portfolio with both an average rate of
return below the risk-free rate and a positive beta. Assume that a fourth portfolio manager, Z, had a portfolio beta of 0.50 but an average rate of return of only 0.07. The $T$ value would be:

$$T_z = \frac{0.07 - 0.08}{0.50} = -0.02$$

Obviously, this performance would plot below the SML in Exhibit 25.2.

A portfolio with a negative beta and an average rate of return above the risk-free rate of return would likewise have a negative $T$ value. In this case, however, it indicates exemplary performance. Suppose Portfolio Manager G invested heavily in gold mining stocks during a period of great political and economic uncertainty. Because gold often has a negative correlation with most stocks, this portfolio had a beta of $-0.20$ and yet experienced an average rate of return of 10 percent. The $T$ value for this portfolio would then be:

$$T_g = \frac{0.10 - 0.08}{-0.20} = -0.100$$

Although the $T$ value is negative, if you plotted these results on a graph, it would indicate a position substantially above the SML in Exhibit 25.2.

Because negative betas can yield $T$ values that give confusing results, it is preferable either to plot the portfolio on an SML graph or to compute the expected return for this portfolio using the SML equation and then compare this expected return to the actual return. For Portfolio G, the expected return would be:

$$E(R_G) = R_{FR} + \beta_G (R_M - R_{FR})$$

$$= 0.08 + (-0.20)(0.06)$$

$$= 0.08 - 0.012$$

$$= 0.068$$

Comparing this expected return of 6.8 percent to the actual return of 10 percent shows that Portfolio Manager G has done a superior job.

### 25.3.2 Sharpe Portfolio Performance Measure

Sharpe (1966) likewise conceived of a composite measure to evaluate the performance of mutual funds. The measure followed closely his earlier work on the capital asset pricing model (CAPM), dealing specifically with the capital market line (CML).

The **Sharpe measure** of portfolio performance (designated $S$) is stated as follows:

$$S_i = \frac{R_i - R_{FR}}{\sigma_i}$$

where in addition to the earlier notation:

- $\sigma_i$ = the standard deviation of the rate of return for Portfolio $i$ during the time period

This performance measure clearly is similar to the Treynor measure; however, it seeks to measure the total risk of the portfolio by using the standard deviation of returns rather than considering only the systematic risk summarized by beta. Because the numerator is the portfolio’s risk premium, this measure indicates the risk premium return earned per unit of total risk. As such, this portfolio performance measure uses the CML to compare portfolios, whereas the Treynor measure examines portfolio performance in relation to the SML. Finally, the standard deviation in $S_i$ can be calculated using either (1) total portfolio returns or (2) portfolio returns in excess of the risk-free rate.\(^3\)

\(^3\)The Sharpe measure was formulated using the total risk (i.e., $\sigma$) of a portfolio, but recently Sharpe (1994, 2007) and Lo (2002) have suggested using the standard deviation of the excess portfolio return (i.e., $\sigma_{ex}$) instead. With this adjustment, the measure becomes $S_i = \frac{R_i - R_{FR}}{\sigma_{ex}}$. The advantage of this approach will be clear shortly when we discuss the information ratio performance measure.
Demonstration of Comparative Sharpe Measures  Again, assume that $\bar{R}_M = 0.14$ and $R_{FR} = 0.08$. Suppose you are told that the standard deviation of the annual rate of return for the market portfolio over the past 10 years was 20 percent ($\sigma_M = 0.20$). You want to examine the risk-adjusted performance of the following portfolios:

<table>
<thead>
<tr>
<th>Portfolio</th>
<th>Average Annual Rate of Return</th>
<th>Standard Deviation of Return</th>
</tr>
</thead>
<tbody>
<tr>
<td>D</td>
<td>0.13</td>
<td>0.18</td>
</tr>
<tr>
<td>E</td>
<td>0.17</td>
<td>0.22</td>
</tr>
<tr>
<td>F</td>
<td>0.16</td>
<td>0.23</td>
</tr>
</tbody>
</table>

The Sharpe measures for these portfolios are as follows:

\[
S_M = \frac{0.14 - 0.08}{0.20} = 0.300
\]

\[
S_D = \frac{0.13 - 0.08}{0.18} = 0.278
\]

\[
S_E = \frac{0.17 - 0.08}{0.22} = 0.409
\]

\[
S_F = \frac{0.16 - 0.08}{0.23} = 0.348
\]

Portfolio D had the lowest risk premium return per unit of total risk, failing to perform as well as the market portfolio. In contrast, Portfolios E and F performed better than the aggregate market: Portfolio E did better than Portfolio F.

Given the market portfolio performance, it is possible to draw the CML. If we plot the results for Portfolios D, E, and F on this graph, as shown in Exhibit 25.3, we see that Portfolio D
Therefore, the $\alpha$ coefficient represents how much of the managed portfolio's return is attributable to the manager's ability to derive above-average returns adjusted for risk. Superior risk-adjusted returns indicate that the manager is good at either predicting market turns or selecting undervalued issues for the portfolio, or both.

### 25.3.3 Jensen Portfolio Performance Measure

Like the $T$ and $S$ measures just discussed, the Jensen measure (Jensen, 1968) was originally based on the capital asset pricing model (CAPM), which calculates the expected one-period return on any security or portfolio by the following expression:

\[
E(R_j) = RFR + \beta_j [E(R_M) - RFR]
\]

where:

- $E(R_j)$ = the expected return on security or Portfolio $j$
- $RFR$ = the one-period risk-free interest rate
- $\beta_j$ = the systematic risk (beta) for security or Portfolio $j$
- $E(R_M)$ = the expected return on the market portfolio of risky assets

The expected return and the risk-free return vary for different periods. Consequently, we are concerned with the time series of expected rates of return for Security or Portfolio $j$. Moreover, you can express Equation 25.3 in terms of realized rates of return as follows:

\[
R_j = RFR_i + \beta_j [R_{mt} - RFR_i] + e_{jt}
\]

This equation states that the realized rate of return on a security or portfolio during a given time period should be a linear function of the risk-free rate of return during the period, plus a risk premium that depends on the systematic risk of the security or portfolio during the period plus a random error term ($e_{jt}$).

Subtracting the risk-free return from both sides, we have:

\[
R_j - RFR_i = \beta_j [R_{mt} - RFR_i] + e_{jt}
\]

so that the risk premium earned on the $j$th portfolio is equal to $\beta_j$ times a market risk premium plus a random error term. An intercept for the regression is not expected if all assets and portfolios were in equilibrium.

Alternatively, superior portfolio managers who forecast market turns or consistently select undervalued securities earn higher risk premiums over time than those implied by this model. Such managers have mostly positive random error terms because the actual returns for their portfolios consistently exceed their expected returns. To detect this superior performance, you must allow for an intercept (a nonzero constant) that measures any positive or negative difference from the model. Consistent positive differences cause a positive intercept, whereas consistent negative differences (inferior performance) cause a negative intercept. With an intercept included, the earlier equation becomes:

\[
R_j - RFR_i = \alpha_j + \beta_j [R_{mt} - RFR_i] + e_{jt}
\]

In Equation 25.4, the $\alpha_j$ value indicates whether the portfolio manager is superior or inferior in her investment ability. A superior manager has a significant positive $\alpha$ (or "alpha") value, while an inferior manager’s returns consistently fall short of expectations based on the CAPM model producing a significant negative value for $\alpha$.

The performance of a portfolio manager with no forecasting ability but not clearly inferior equals that of a naive buy-and-hold policy. Because returns on such a portfolio typically match the returns you expect, the residual returns generally are randomly positive and negative. This gives a constant term that differs insignificantly from zero, indicating that the portfolio manager basically matched the market on a risk-adjusted basis.
To see how \textit{IR} can be computed and interpreted, consider the returns produced by an active portfolio manager over the past eight quarters, along with the returns to her benchmark index:

<table>

Average: 3.0% 2.8% 0.2%

Std Dev. (TE): —— 1.0%

In this case, the manager’s outperformed her benchmark by an average of 20 basis points per quarter, but did so with a periodic tracking error of 1.0 percent. Thus, her quarterly information ratio is 0.20 (= 0.2% ÷ 1.0%). This represents the manager’s average alpha (relative to the index) per unit of incremental risk incurred in the pursuit of those active returns. Notice that \textit{IR} will only be positive when the investor outperforms her benchmark.

Goodwin (1998) noted that the Sharpe ratio is a special case of the \textit{IR} where the risk-free asset is the benchmark portfolio, although this interpretation violates the spirit of a statistic that should have a value of zero for any passively managed portfolio. He also showed that if excess portfolio returns are estimated with historical data using the same single-factor regression equation used to compute Jensen’s alpha, the \textit{IR} simplifies to:

\[
\text{IR}_j = \frac{\alpha_j}{\sigma_{ER}}
\]

where:

- \(\sigma_{ER}\) is the standard error of the regression

Finally, he showed that an information ratio based on periodic returns measured \(T\) times per year could be annualized as follows:

\[
\text{Annualized IR} = \frac{\alpha_j}{\sqrt{T}}
\]

For instance, the investor from the preceding example that generated a quarterly ratio of 0.200 would have an annualized \textit{IR} of 0.40 = \(\sqrt{4} \times 0.20\).

Grinold and Kahn (2000) argued that reasonable information ratio levels should range from 0.50 to 1.00, with an investor having an \textit{IR} of 0.50 being good, and one with an \textit{IR} of 1.00 being exceptional. These appear to be difficult hurdles to clear. Goodwin (1998) studied the performance of more than 200 professional equity and fixed-income portfolio managers with various investment styles over a 10-year period. He found that the \textit{IR} of the median manager in each style group was positive but never exceeded 0.50. Thus, although the average manager added value to investors (and hence \textit{IR}) is greater than zero—she doesn’t qualify as “good.” Further, no style group had more than 3 percent of its managers deliver an \textit{IR} in excess of 1.00. Information ratio histograms summarizing this research are shown in Exhibit 25.4.

The development of this form of the information ratio is credited to Treynor and Black (1973).
To see how IR can be computed and interpreted, consider the returns produced by an active portfolio manager over the past eight quarters, along with the returns to her benchmark index:

### 25.3.5 Comparing the Composite Performance Measures

Each of the portfolio performance statistics just described is widely used in practice and has its own strengths and weaknesses. The primary advantages and disadvantages of the $T$, $S$, $\alpha$, and $IR$ measures are listed in Exhibit 25.5. The important thing to recognize is that no one of these measures dominates the others, and they all provide at least slightly different information
A disadvantage of the Treynor and Sharpe measures is that they only produce relative, not absolute, performance rankings. For example, the Sharpe values for Portfolios E and F in Exhibit 25.3 show that both managers generated risk-adjusted returns above the market. Further, E’s risk-adjusted performance measure (0.409) is larger than F’s (0.348). What we cannot say with certainty, however, is whether this difference is statistically significant. The same dilemma exists when comparing the performance of Portfolio X and Y using the Treynor measure illustrated in Exhibit 25.2.

The Jensen’s alpha measure is typically the most difficult to compute because it requires a formal regression analysis. Offsetting that drawback are three substantial advantages relative to the T and S measures. First, it is easier to understand: An alpha value of 0.02 indicates that the manager generated a return of 2 percent per period more than what was expected given the portfolio’s risk level. On the other hand, a Sharpe ratio of 0.409 means that the portfolio manager generated 0.409 units of excess return per unit of total risk, which is more challenging language to interpret. Second, because α is estimated from a formal statistical process, it is possible to make statements about the statistical significance of the manager’s skill level, or the difference in skill between two different managers. Third, Jensen’s alpha can be computed relative to any risk-return model, in contrast to S, which focuses on total risk and ignores the return-generating process altogether, and T, which is locked into beta as the specific estimate of systematic risk. Finally, because the information ratio is similar in form to T and S, it shares many of the same strengths and weakness of those two ratios. The primary advantage that differentiates IR from the other composite measures is that it provides a direct comparison between the return performance of the portfolio manager and that of the specific benchmark index against which she is competing. Since investors can often own this benchmark portfolio directly—either through index mutual funds or exchange-traded funds—the IR measure calculates the risk-adjusted value added by the active portfolio manager relative to a passive investment alternative. However, Baker, Bradley, and Wurgler (2011) note that tying performance to a single benchmark could lead to missed investment opportunities.

25.4 APPLICATION OF PORTFOLIO PERFORMANCE MEASURES

To apply these measures, we selected 30 open-end mutual funds from the nine investment-style classes described in Chapter 16 and used monthly data for the five-year period from July 2005 to June 2010. The monthly rates of return for one of these funds—Janus Twenty (JAVLX)—and the S&P 500 are contained in Exhibit 25.6. The total rate of return for each month is computed as follows:

\[ R_{it} = EP_{it} + Div_{it} + Cap_{it\cdot Dist}_{it} - BP_{it} \]

where:

- \( R_{it} \) = the total rate of return on Fund \( i \) during month \( t \)
- \( EP_{it} \) = the ending price for Fund \( i \) during month \( t \)
- \( Div_{it} \) = the dividend payments made by Fund \( i \) during month \( t \)
- \( Cap_{it\cdot Dist}_{it} \) = the capital gain distributions made by Fund \( i \) during month \( t \)
- \( BP_{it} \) = the beginning price for Fund \( i \) during month \( t \)

These return computations do not take into account any sales charges by the funds.

The arithmetic average annual rate of return for JAVLX was 6.50 percent versus 0.64 percent for the market, and the fund’s beta was slightly greater than 1.00 (1.062). Using the average annual rate of T-bills of 2.54 percent as the RFR, the Treynor measure for JAVLX (\( T_i \)) was substantially bigger than the comparable measure for the market \( T_M \) (3.725 vs. −1.899), with the latter being negative since the overall market produced returns less than the risk-free asset.
A disadvantage of the Treynor and Sharpe measures is that they only produce relative, not absolute, performance rankings. For example, the Sharpe values for Portfolios E and F in Exhibit 25.3 show that both managers generated risk-adjusted returns above the market. Further, E’s risk-adjusted performance measure (0.409) is larger than F’s (0.348). What we cannot say with certainty, however, is whether this difference is statistically significant. The same dilemma exists when comparing the performance of Portfolio X and Y using the Treynor measure illustrated in Exhibit 25.2.

The Jensen’s alpha measure is typically the most difficult to compute because it requires a formal regression analysis. Offsetting that drawback are three substantial advantages relative to the $T$ and $S$ measures. First, it is easier to understand: An alpha value of 0.02 indicates that the manager generated a return of 2 percent per period more than what was expected given the portfolio’s risk level. On the other hand, a Sharpe ratio of 0.409 means that the portfolio manager generated 0.409 units of excess return per unit of total risk, which is more challenging language to interpret. Second, because $\alpha$ is estimated from a formal statistical process, it is possible to make statements about the statistical significance of the manager’s skill level, or the difference in skill between two different managers. Third, Jensen’s alpha can be computed relative to any risk-return model, in contrast to $S$, which focuses on total risk and ignores the return-generating process altogether, and $T$, which is locked into beta as the specific estimate of systematic risk.

Finally, because the information ratio is similar in form to $T$ and $S$, it shares many of the same strengths and weakness of those two ratios. The primary advantage that differentiates $IR$ from the other composite measures is that it provides a direct comparison between the return performance of the portfolio manager and that of the specific benchmark index against which she is competing. Since investors can often own this benchmark portfolio directly—either through index mutual funds or exchange-traded funds—the $IR$ measure calculates the risk-adjusted value added by the active portfolio manager relative to a passive investment alternative. However, Baker, Bradley, and Wurgler (2011) note that tying performance to a single benchmark could lead to missed investment opportunities.

### 25.4 Application of Portfolio Performance Measures

To apply these measures, we selected 30 open-end mutual funds from the nine investment-style classes described in Chapter 16 and used monthly data for the five-year period from July 2005 to June 2010. The monthly rates of return for one of these funds—Janus Twenty (JAVLX)—and the S&P 500 are contained in Exhibit 25.6. The total rate of return for each month is computed as follows:

$$R_{it} = \frac{EP_{it} + Div_{it} + Cap.Gain_{it} - BP_{it}}{BP_{it}}$$

where:

- $R_{it}$ = the total rate of return on Fund $i$ during month $t$
- $EP_{it}$ = the ending price for Fund $i$ during month $t$
- $Div_{it}$ = the dividend payments made by Fund $i$ during month $t$
- $Cap.Gain_{it}$ = the capital gain distributions made by Fund $i$ during month $t$
- $BP_{it}$ = the beginning price for Fund $i$ during month $t$

These return computations do not take into account any sales charges by the funds.

The arithmetic average annual rate of return for JAVLX was 6.50 percent versus 0.64 percent for the market, and the fund’s beta was slightly greater than 1.00 (1.062). Using the average annual rate of T-bills of 2.54 percent as the $RFR$, the Treynor measure for JAVLX ($T_i$) was substantially bigger than the comparable measure for the market $T_M$ (3.725 vs. −1.899), with the latter being negative since the overall market produced returns less than the risk-free asset

Over this five-year period. Likewise, the standard deviation of returns of the Janus fund was greater than the market’s (20.60 vs. 16.81), but the Sharpe measure for the fund ($S$) was positive and larger than the measure for the market ($S_{ret}$) (0.192 vs. -0.113).

Finally, a one-factor regression of the fund’s monthly risk premium ($R_n - R_{FR}$) and the market’s monthly risk premium ($R_{ret} - R_{FR}$) indicated a positive intercept (constant) value of 0.498 but was not statistically significant. If this intercept value had been significant, JAVLX’s risk-adjusted monthly rate of return would have averaged about a half percent above its expected value on a reliable basis.

**Total Sample Results** The overall results in Exhibit 25.7 indicate that active fund managers performed somewhat better than has been documented in earlier performance studies. A primary factor for this outcome was the abnormally poor performance of the index during the

middle of the sample period. Also, our sample was rather casually selected because we intended it for demonstration purposes only. The mean annual return for all the funds was above the market return (2.12 vs. 0.64). Considering only the rate of return, 22 of the 30 funds outperformed the market.

The $R^2$ statistic comparing a portfolio with the market can serve as a measure of diversification. The closer the $R^2$ is to 1.00, the more completely diversified the portfolio. The average $R^2$ for our sample was fairly high at 0.868 and the range was relatively small, from 0.752 to 0.981. This suggests that many of the funds were reasonably well diversified, with 26 of the 30 portfolios having $R^2$ values greater than 0.80. (Recall that a typical individual stock would have an $R^2$ value of around 20–40 percent.)

The two risk measures (standard deviation and beta) also show a wide degree of dispersion but generally are consistent with expectations. Specifically, 27 of the 30 funds had larger standard deviations than the market, and the mean standard deviation was larger (20.35 vs. 16.81). Only 4 of the funds had a beta of less than 1.00; the average beta was 1.126.

The various performance measures ranked the performance of individual funds quite consistently. (These rankings are listed in parentheses beside each measure.) Only 8 out of 30 funds had a lower Treynor ratio than that of the market; only 8 funds had a lower Sharpe as well. Also, 22 of the 30 Jensen’s alpha values using the Single-Index Market Model were positive, with only one of these being statistically significant. One of the funds with a negative alpha was statistically significant. The mean Jensen’s alpha value of 0.143 indicates that the average manager in the sample was able to produce a return of about 14 basis points per month more than what would have been expected given the risk level of the fund. The mean values for the Sharpe and Treynor measures were considerably higher (i.e., less negative) than the aggregate market figure. These results confirm that, overall, this sample of funds produced much better risk-adjusted performance than the market during this time period.

One might expect the best performance by funds with low diversification because they apparently are attempting to beat the market by being unique in their security selection or market timing. This seems to be true for some of the top-performing funds, such as Royce Premier Fund, whereas portfolios that produced returns more closely aligned with overall market, such as the TCW Diversified Value Fund, were among the worst performing funds. It appears that during this period it was often better to not look like the market portfolio, although this is not always the case.

Exhibit 25.8 reports information ratios for these 30 funds. To interpret the display, consider that the Wells Fargo Small Cap Opportunity Fund had a monthly IR value of 0.252, which was calculated by dividing its alpha (0.501) by its regression standard error (1.99). This statistic is then annualized to 0.871 by multiplying the monthly IR by the square root of 12. Notice that 22 of the 30 funds had positive IR levels, which follows directly from the number of funds that had a positive Jensen’s alpha. The mean annualized IR for the sample was 0.205, which falls below the Grinold-Kahn standard for “good” performance of 0.500. Thus, after accounting for tracking error costs, the average fund in this collection added a modest amount of value to its investors.

**Potential Bias of One-Parameter Measures** Friend and Blume (1970) pointed out that the composite measures of performance should be independent of alternative measures of risk because they are risk-adjusted measures. However, their analysis of the relationship between the composite measures and two definitions of risk (standard deviation and beta) for 200 random stock portfolios indicated that the risk-adjusted performance of low-risk portfolios was better than the comparable performance for high-risk portfolios. Klemkosky (1973) examined the relationship between composite performance measures and risk measures using actual mutual fund data. The results showed a positive relationship between the composite performance measures and the risk involved. This was especially true for the Treynor and Jensen measures. He concluded that although a bias might exist, one could not be certain of its
direction. More recently, Leland (1999) has shown that alpha can be biased downward for those portfolios designed to limit downside risk.

**Measuring Performance with Multiple Risk Factors** Equation 25.5 showed in general terms how the Jensen’s alpha measure could be estimated relative to multifactor models of risk and expected return. Exhibit 25.9 shows the Jensen measures calculated for the 30 mutual funds using two different versions of the Fama-French model, discussed in Chapter 9:

\[ R_{it} - R_{FR} = \alpha_i + \left( b_{1i} (R_m - R_{FR}) + b_{2i} SMB_i + b_{3i} HML_i + b_{4i} MOM_i \right) + \epsilon_{it} \]

Specifically, alphas are computed relative to: (1) a three-factor model including the market \((R_m - R_{FR})\), firm size \((SMB)\), and relative valuation \((HML)\) variables; and (2) a four-factor model that also includes the return momentum \((MOM)\) variable.

The performance results in Exhibits 25.7 and 25.8 showed that the vast majority of the active mutual fund managers in the sample were able to outperform the market on a risk-adjusted basis over the July 2005–June 2010 period, although seldom at a statistically significant level. It is possible that some of this superior performance was an illusion because the

Mean: 0.143; Median: 0.155; Standard Error: 2.138; Annualized IR: 0.059; Rank: 205; Median: 0.249
The Jensen’s alpha results for both the three-factor and the four-factor models show some important differences with the comparable findings from the one-factor model reported in Exhibit 25.7. In particular, the mean value for alpha is now slightly negative in each case (−0.065 and −0.076, respectively). Also, 12 (rather than 22) of the funds had positive alpha values, and none of the funds with positive alphas had statistically significant outperformance with the three-factor model. In fact, three of the funds (CSTGX, KDHBX and PSLAX) exhibited statistically significant underperformance when measured against the three-factor model, while two others (HWLIX and TGDVX) also had a significantly negative alpha for the four-factor model. For instance, BUFSX, a small-cap growth fund, had a large positive alpha of 0.319 when its performance was measured relative to a large-cap blend index (i.e., S&P 500), but relative to models that take investment style and momentum into account, its alpha was reduced to −0.022 (three-factor) and −0.055 (four-factor). This highlights the fact that the one-factor and multifactor Jensen measures produce similar but distinct performance rankings and should therefore be considered as different from one another as the Sharpe, Treynor, and Information Ratio measures.

</table>

*aSignificant at the 0.05 level.

S&P 500 Index was not the appropriate benchmark for many of the portfolios. In fact, the style classifications for the 30 funds in Exhibit 25.7 show that only three portfolios followed the large-cap blend style, the category for which the S&P 500 Index applies. Thus, the advantage of measuring a fund’s alpha using a multifactor approach is that it is designed to control for both market (i.e., $R_m$), style (i.e., $SMB$ and $HML$), and momentum (i.e., $MOM$) risk influences. Although not listed in Exhibit 25.9, the average monthly returns (i.e., risk premia) for the $SMB$, $HML$, and $MOM$ factors were 0.26 percent, 0.07 percent, and −0.38 percent, respectively. This indicates that in the stock market as a whole over this investment period, small stocks outperformed large stocks (i.e., a positive mean $SMB$ return), value stocks outperformed growth stocks (i.e., a positive mean $HML$ return), and high-momentum stocks underperformed low-momentum stocks (i.e., a negative mean $MOM$ return). For this particular collection of 30 funds, the mean factor betas—1.020 for the market factor, 0.264 for the $SMB$ factor, −0.041 for the $HML$ factor, and −0.031 for the $MOM$ factor—indicate that the average fund has slightly more systematic market risk than average and is oriented toward holding smaller, more growth-oriented stocks that exhibit negative return momentum.
Evaluating Selectivity

Formally, you can measure the return due to selectivity as follows:

\[
\text{Selectivity} = R_a - R_x(\beta_a)
\]

where:

- \(R_a\) = the actual return on the portfolio being evaluated
- \(R_x(\beta_a)\) = the return on the combination of the riskless asset and the market portfolio \(M\) that has risk \(\beta_x\) equal to \(\beta_a\), the risk of the portfolio being evaluated

As shown in Exhibit 25.11, selectivity measures the vertical distance between the actual return and the \textit{ex post} market line and is quite similar to Treynor’s measure.

Overall performance can be written:

\[
\text{Overall Performance} = \text{Selectivity} + \text{Risk} = \left(\frac{R_a - R_{FR}}{C_{138}}\right) + \left(\frac{R_x(\beta_a) - R_{FR}}{C_{138}}\right)
\]

Exhibit 25.11 shows that overall performance is the total return above the risk-free return and includes the return that should have been received for accepting the portfolio risk (\(\beta_a\)), which is equal to \(R_x(\beta_a) - R_{FR}\). Any excess over this expected return is due to selectivity.

Evaluating Diversification

The selectivity component in Equation 25.7 can also be broken down into two parts. If a portfolio manager attempts to select undervalued stocks and in the process gives up some diversification, it is possible to measure the added return necessary to justify this diversification decision. The portfolio’s gross selectivity is made up of net selectivity plus diversification, as follows:

\[
\text{Selectivity} + \text{Diversification} = R_a - R_x(\beta_a) = \text{Net Selectivity} + \frac{1}{2} R_x(\sigma(R_a)) - \frac{1}{2} R_x(\beta_a)/C_{138}
\]

or

\[
\text{Net Selectivity} = R_a - R_x(\beta_a) - \frac{1}{2} R_x(\sigma(R_a)) + \frac{1}{2} R_x(\beta_a)/C_{138}
\]

where:

- \(R_x(\sigma(R_a))\) = the return on the combination of the riskless asset and the market portfolio that has return volatility equivalent to that of the portfolio being evaluated

The Jensen’s alpha results for both the three-factor and the four-factor models show some important differences with the comparable findings from the one-factor model reported in Exhibit 25.7. In particular, the mean value for alpha is now slightly negative in each case (−0.065 and −0.076, respectively). Also, 12 (rather than 22) of the funds had positive alpha values, and none of the funds with positive alphas had statistically significant outperformance with the three-factor model. In fact, three of the funds (CSTGX, KDHBM and PSLAX) exhibited statistically significant underperformance when measured against the three-factor model, while two others (HXLIX and TGDVX) also had a significantly negative alpha for the four-factor model. For instance, BUFSX, a small-cap growth fund, had a large positive alpha of 0.319 when its performance was measured relative to a large-cap blend index (i.e., S&P 500), but relative to models that take investment style and momentum into account, its alpha was reduced to −0.022 (three-factor) and −0.055 (four factor). This highlights the fact that the one-factor and multifactor Jensen measures produce similar but distinct performance rankings and should therefore be considered as different from one another as the Sharpe, Treynor, and Information Ratio measures.

Relationship among Performance Measures

Exhibit 25.10 contains the matrix of rank correlation coefficients among the Treynor, Sharpe, Jensen (one-factor, three-factor, and four-factor), and Information Ratio measures. The striking feature of the display is that all of these statistics are positively correlated with one another, but not perfectly so. (The Sharpe and Treynor statistics produced virtually identical rankings for this fund sample.) This suggests that although the measures provide a generally consistent assessment of portfolio performance when taken as a whole, they remain distinct at an individual level. The exhibit reinforces our earlier point that it is best to consider these composites collectively and that the user must understand what each means.

25.5 Portfolio Performance Evaluation: Some Extensions

In this section, we will consider five extensions of the basic performance tools that we have just developed: (1) a composite measure that takes the portfolio’s diversification level into account, (2) a composite measure that considers the portfolio’s “downside” risk, (3) techniques that focus on the portfolio’s holdings rather its returns, (4) attribution analysis, which measures why a manager’s portfolio performed the way that it did, and (5) measures of market timing skills.

25.5.1 Components of Investment Performance

Following the work of Treynor, Sharpe, and Fama (1972) suggested that the \textit{overall performance} of a portfolio, in excess of the risk-free rate, can be decomposed into measures of risk-taking and security selection skill:

\[
\text{Overall Performance} = \text{Excess Return} = \text{Portfolio Risk} + \text{Selectivity}
\]

The \textit{selectivity} component represents the portion of the portfolio’s actual return beyond that available to an unmanaged portfolio with identical systematic risk and is used to assess the manager’s investment prowess.
Evaluating Selectivity

Formally, you can measure the return due to selectivity as follows:

\[
\text{Selectivity} = R_a - R_x(\beta_a)
\]

where:

\( R_a \) = the actual return on the portfolio being evaluated
\( R_x(\beta_a) \) = the return on the combination of the riskless asset and the market portfolio \( M \) that has risk \( \beta_x \), equal to \( \beta_a \), the risk of the portfolio being evaluated

As shown in Exhibit 25.11, selectivity measures the vertical distance between the actual return and the \textit{ex post} market line and is quite similar to Treynor’s measure.

Overall performance can be written:

\[
\text{25.7 Overall Performance} = \text{Selectivity} + \text{Risk}
\]

\[
[R_a - RFR] = [R_a - R_x(\beta_a)] + [R_x(\beta_a) - RFR]
\]

Exhibit 25.11 shows that overall performance is the total return above the risk-free return and includes the return that \textit{should} have been received for accepting the portfolio risk \( (\beta_a) \), which is equal to \( [R_x(\beta_a) - RFR] \). Any excess over this expected return is due to selectivity.

Evaluating Diversification

The selectivity component in Equation 25.7 can also be broken down into two parts. If a portfolio manager attempts to select undervalued stocks and in the process gives up some diversification, it is possible to measure the added return necessary to justify this diversification decision. The portfolio’s gross selectivity is made up of net selectivity plus diversification, as follows:

\[
\text{Selectivity} + \text{Diversification} = R_a - R_x(\beta_a) = \text{Net Selectivity} + [R_x(\sigma(R_a)) - R_x(\beta_a)]
\]

or

\[
\text{25.8 Net Selectivity} = R_a - R_x(\beta_a) - [R_x(\sigma(R_a)) - R_x(\beta_a)] = R_a - R_x(\sigma(R_a))
\]

where:

\( R_x(\sigma(R_a)) \) = the return on the combination of the riskless asset and the market portfolio that has return volatility equivalent to that of the portfolio being evaluated

Exhibit 25.11 An Illustration of the Performance Measures

\[
R = R x + \left( \frac{R_a - RFR}{\sigma(R_a)} \right) \beta_x
\]

\[
R FR = \left( \frac{R_a - RFR}{\sigma(R_a)} \right) \beta_x
\]

Downside risk is the volatility of the returns produced by a portfolio that fall below some hurdle rate that the investor chooses, such as zero (i.e., negative returns) or the portfolio’s expected return. Thus, downside risk attempts to measure the volatility associated with the shortfall that occurs if an investment produces a return that is lower than anticipated.

Financial Risk Measures

DR comes closer than measures of total risk (e.g., $\sigma$) to capturing what investors truly consider risky. Harlow (1991) discusses a number of ways to calculate DR in practice. One of the most popular measures is the semi-deviation, which uses the portfolio’s average (expected) return as the hurdle rate:

$$\text{Semi-Deviation} = \sqrt{\frac{1}{n} \sum_{i=1}^{n} (R_i - \bar{R})^2}$$

where:
- $n$ is the number of portfolio returns falling below the expected return

It should be apparent that semi-deviation is closely related to the standard deviation measure of total risk, but does not include those portfolio returns that exceed expectations.

Comparing the Sharpe and Sortino Ratios

Suppose that over the past 10 years, two portfolio managers have produced the following returns:

Average: 4, 4
Std. Dev.: 5.60, 5.92

Both portfolios had an average annual return of 4 percent over this horizon, meaning that it will be how their risk is measured that determines which manager performed the best. Based on the standard deviation coefficients, Portfolio A is the less volatile portfolio. However, a substantial amount of the variation for Portfolio B came from two large positive returns, which are included in the computation of total risk. If the average risk-free rate during this period was 2 percent, the Sharpe ratio calculations confirm that Portfolio A outperformed Portfolio B: $S_A = 0.357 (= \frac{4 - 2}{5.60})$ and $S_B = 0.338 (= \frac{4 - 2}{5.92})$.

The story changes when just the downside risk of the portfolios is considered. In addition to more extreme positive values, Portfolio B also had losses that were limited to 1 percent in any given year, perhaps as a result of a portfolio insurance strategy the manager is using. Using semi-deviation to compute DR for both portfolios leaves:

$$\text{DR}_A = \sqrt{\frac{(0 + 0 + 0 + 0 + 0)}{5} / \sqrt{5}} = 2.80$$
$$\text{DR}_B = \sqrt{\frac{(0 + 0 + 0 + 0 + 0)}{5} / \sqrt{5}} = 2.82$$

Thus, when only the possibility of receiving a less-than-average return is considered, Portfolio A now appears to be the risky alternative due to the fact it has more extreme negative returns than Portfolio B. Assuming a minimum return threshold of 2 percent to match the Sharpe performance, the manager’s performance would plot substantially below the market line in Exhibit 25.11.

25.5.2 Performance Measurement with Downside Risk

The Sortino ratio is a risk-adjusted investment performance statistic that differs from the Sharpe ratio in two ways. First, the Sortino ratio measures the portfolio’s average return in excess of a user-selected minimum acceptable return threshold, which is often the risk-free rate used in the $S$ statistic although it need not be. Second, the Sharpe measure focuses on total risk—effectively penalizing the manager for returns that are both too low and too high—while the Sortino ratio captures just the downside risk (DR) in the portfolio. Sortino and Price (1994) calculate this measure as follows:

$$ST_i = \frac{\bar{R}_i - \tau}{DR_i}$$

where:
- $\tau$ = the minimum acceptable return threshold specified for the time period
- $DR_i$ = the downside risk coefficient for Portfolio $i$ during the specified time period

Like the Sharpe ratio, higher values of the $ST$ measure indicate superior levels of portfolio management.

---

5 Modigliani and Modigliani (1997) present a performance measure (dubbed $M^3$) that is a variation of both the Sharpe measure and Fama’s $R_i [\sigma(R_i)]$ component.
measure, the Sortino ratios for both portfolios indicate that, by limiting the extent of his downside risk, the manager for Portfolio B was actually the superior performer: $ST_A = 0.345$ and $ST_B = 0.415$.

25.5.3 Holdings-Based Performance Measurement

Each of the conventional performance measures just discussed are based on the returns produced by the investment portfolios being compared. There are two distinct advantages to assessing performance based on investment returns. First, returns are usually easy for the investor to observe on a frequent (e.g., daily) basis. Second, they also represent what the investor actually takes away from the portfolio manager’s investing prowess. However, return-based measures are indirect indications of the decision-making ability of a manager that do not reveal the underlying reasons why the portfolio produced the returns it did.

It is also possible to view investment performance in terms of which securities the manager buys or sells from the portfolio. By looking at how the portfolio’s holdings change over time, the investor is able to establish precisely which stock or bond positions were responsible for creating that performance. Thus, using a holdings-based measure can provide additional insights about the quality of the portfolio manager. Two of the most popular holdings-based performance measures are described below.

**Grinblatt-Titman (GT) Performance Measure**

Assuming that an investor knows the exact investment proportions of each security position in her portfolio on two consecutive reporting dates (e.g., quarterly reports for mutual funds), Grinblatt and Titman (1993) showed that the manager’s security selection ability can be established by how he adjusted these weights. For a particular reporting period $t$, their performance measure is:

$$GT_t = \sum_{j} \left( w_{jt} - w_{jt-1} \right) R_{jt}$$

where:

- $\left( w_{jt}, w_{jt-1} \right)$ = the portfolio weights for the $j$th security at the beginning of Period $t$ and Period $t-1$, respectively,
- $R_{jt}$ = the return to the $j$th security during Period $t$, which begins on Date $t-1$ and ends on Date $t$.

A series of $GT_t$ for a manager can be averaged over several periods to create a better indication of the ongoing quality of his decision-making ability.

$$Average\ GT = \frac{\sum_{t} GT_t}{T}$$

where $T$ is the total number of investment periods used in the evaluation.

Exhibit 25.12 illustrates the GT performance measure for two different portfolios: (1) a passive value-weighted index of all the stocks in the market, and (2) an active portfolio manager. Panel A shows the share prices for five stocks representing the investable universe on six different dates relative to the current Date 0. No dividends are paid, and the returns to each stock are also shown for the four full holding periods starting at Date 0 (e.g., Period 1 begins at Date 0 and ends at Date 1).

Panel B shows the total shares outstanding for each stock on Date $-1$, Date 0, Date 1, Date 2, and Date 3, which are the beginning dates for Period 0, Period 1, Period 2, Period 3, and Period 4, respectively. Alongside the shares outstanding, which do not change, Panel B lists the corresponding index weights that would apply at the beginning of each investment period. For instance, the index weight shown for Stock A at the beginning of Period 2 (i.e., $w_{2}$) is 28.0 percent, which is calculated by multiplying the share price at Date 1 (i.e., $14$) by the shares outstanding.

Both portfolios had an average annual return of 4 percent over this horizon, meaning that it will be how their risk is measured that determines which manager performed the best.

Based on the standard deviation coefficients, Portfolio A is the less volatile portfolio. However, a substantial amount of the variation for Portfolio B came from two large positive returns, which are included in the computation of total risk. If the average risk-free rate during this period was 2 percent, the Sharpe ratio calculations confirm that Portfolio A outperformed Portfolio B: $S_A = 0.357 = [4 - 2] / 5.60$ and $S_B = 0.338 = [4 - 2] / 5.92$.

The story changes when just the downside risk of the portfolios is considered. In addition to more extreme positive values, Portfolio B also had losses that were limited to 1 percent in any given year, perhaps as a result of a portfolio insurance strategy the manager is using. Using semi-deviation to compute $DR$ for both portfolios leaves:

$$DR_A = \sqrt{\frac{1}{n} \sum_{R < R_e} (R - R_e)^2} = 5.80$$

and

$$DR_B = \sqrt{\frac{1}{n} \sum_{R < R_e} (R - R_e)^2} = 4.82$$

Thus, when only the possibility of receiving a less-than-average return is considered, Portfolio A now appears to be the risky alternative due to the fact it has more extreme negative returns than Portfolio B. Assuming a minimum return threshold of 2 percent to match the Sharpe
measure, the Sortino ratios for both portfolios indicate that, by limiting the extent of his downside risk, the manager for Portfolio B was actually the superior performer: \( ST_A = 0.345 \) (\( =|4 - 2|/5.80 \)) and \( ST_B = 0.415 \) (\( =|4 - 2|/4.82 \)).

### 25.5.3 Holdings-Based Performance Measurement

Each of the conventional performance measures just discussed are based on the returns produced by the investment portfolios being compared. There are two distinct advantages to assessing performance based on investment returns. First, returns are usually easy for the investor to observe on a frequent (e.g., daily) basis. Second, they also represent what the investor actually takes away from the portfolio manager’s investing prowess. However, \textit{return-based} measures are indirect indications of the decision-making ability of a manager that do not reveal the underlying reasons why the portfolio produced the returns it did.

It is also possible to view investment performance in terms of which securities the manager buys or sells from the portfolio. By looking at how the portfolio’s holdings change over time, the investor is able to establish precisely which stock or bond positions were responsible for creating that performance. Thus, using a \textit{holdings-based measure} can provide additional insights about the quality of the portfolio manager. Two of the most popular holdings-based performance measures are described below.

#### Grinblatt-Titman (GT) Performance Measure

Assuming that an investor knows the exact investment proportions of each security position in her portfolio on two consecutive reporting dates (e.g., quarterly reports for mutual funds), Grinblatt and Titman (1993) showed that the manager’s security selection ability can be established by how he adjusted these weights. For a particular reporting period \( t \), their performance measure is:

\[
GT_t = \sum_j (w_{jt} - w_{j(t-1)}) R_{jt}
\]

where:

\( (w_{jt}, w_{j(t-1)}) \) = the portfolio weights for the \( j \)th security at the beginning of Period \( t \) and Period \( t - 1 \), respectively,

\( R_{jt} \) = the return to the \( j \)th security during Period \( t \), which begins on Date \( t - 1 \) and ends on Date \( t \)

A series of \( GT_t \) for a manager can be averaged over several periods to create a better indication of the ongoing quality of his decision-making ability.

\[
\text{Average GT} = \frac{\sum T \ GT_t}{T}
\]

where \( T \) is the total number of investment periods used in the evaluation.

Exhibit 25.12 illustrates the GT performance measure for two different portfolios: (1) a passive value-weighted index of all the stocks in the market, and (2) an active portfolio manager. Panel A shows the share prices for five stocks representing the investable universe on six different dates relative to the current Date 0. No dividends are paid, and the returns to each stock are also shown for the four full holding periods starting at Date 0 (e.g., Period 1 begins at Date 0 and ends at Date 1).

Panel B shows the total shares outstanding for each stock on Date –1, Date 0, Date 1, Date 2, and Date 3, which are the beginning dates for Period 0, Period 1, Period 2, Period 3, and Period 4, respectively. Alongside the shares outstanding, which do not change, Panel B lists the corresponding index weights that would apply at the beginning of each investment period. For instance, the index weight shown for Stock A at the beginning of Period 2 (i.e., \( w_2 \)) is 28.0 percent, which is calculated by multiplying the share price at Date 1 (i.e., $14) by the shares
outstanding at Date 1 (i.e., 200) and then dividing that product by the total market value of all five stocks at Date 1 (i.e., \(200 \times 14\) + \(200 \times 10\) = $10,000). As the share prices change over time, the value-based index weights will also change, even though the number of shares outstanding do not.

Panel C provides similar data for a hypothetical active portfolio manager. This manager has made two explicit adjustments to his portfolio holdings. First, on Date 0 (i.e., the beginning of Period 1), he has sold half of his share positions in Stocks B and C in order to buy 10 shares of Stock A. Second, on Date 2 (i.e., the beginning of Period 3), he sells the remainder of his Stock B holding to repurchase five shares of Stock C. The portfolio weights of this active manager change because of both explicit stock trades and implicit adjustments due to changing market prices.

The last panel of Exhibit 25.12 calculates the GT measure for both the stock index and the active manager. For the index, the average GT across the four investment periods is virtually zero (i.e., \(-0.03\) percent = \((-0.03\% - 0.57\% + 0.18\% + 0.29\%)/4\)). This should be the case for any passive buy-and-hold portfolio, assuming that the stock returns are not correlated from one period to the next. That is, while index weights will vary with stock prices (e.g., \(w_2 - w_1 = 0.280 - 0.200 = 0.080\), for Stock A), the product of these weight changes with the subsequent stock returns should net out over time if there is no momentum effect present in the returns. This is consistent with viewing the GT measure as the return to a zero-cost hedge portfolio that is long at the current investment weights and short at the previous weights.

In contrast, the GT measure for an active portfolio manager will likely not be zero. Here, the manager’s average GT value is 3.41 percent \(= (15.00 \% - 0.71\% - 0.97\% + 0.34\%)/4\), indicating that he added a substantial amount of value through his stock-picking prowess. In Period 1, the decision to buy Stock A at Date 0, whose price subsequently rose, contributed 10.00 percent \(= (0.250 - 0.000) \times 40\%\), whereas the decisions to sell some of Stocks B and C contributed 2.50 percent each \(= (0.125 - 0.250) \times (-20\%)\) since both stocks declined in value during Period 1. On the other hand, the decision to repurchase Stock C on Date 2 subtracted 1.19 percent of value \(= (0.190 - 0.095) \times (-12.5\%)\) since the price of these shares fell from $8 to $7 during Period 3.

This example demonstrates that it is possible to create a very detailed analysis of how each decision the manager made contributed to his overall performance. Additionally, the GT statistic can be computed without reference to any specific benchmark, which was not the case for returns-based measures such as the Information Ratio. However, the GT measure fails to reward or penalize the manager for portfolio adjustments where the share price change actually occurs in a later period. For instance, the manager received no credit in Period 3 for the decision to sell Stock B because the subsequent share price decline from $8 to $6 did not occur until Period 4. This deficiency can be overcome by calculating portfolio weight adjustments over longer holding periods (e.g., annual vs. quarterly).

outstanding at Date 1 (i.e., 200) and then dividing that product by the total market value of all five stocks at Date 1 (i.e., \([200 \times 14] + \cdots + [200 \times 10] = 10,000\)). As the share prices change over time, the value-based index weights will also change, even though the number of shares outstanding do not.

Panel C provides similar data for a hypothetical active portfolio manager. This manager has made two explicit adjustments to his portfolio holdings. First, on Date 0 (i.e., the beginning of Period 1), he has sold half of his share positions in Stocks B and C in order to repurchase 10 shares of Stock A. Second, on Date 2 (i.e., the beginning of Period 3), he sells the remainder of his Stock B holding to repurchase five shares of Stock C. The portfolio weights of this active manager change because of both explicit stock trades and implicit adjustments due to changing market prices.

The last panel of Exhibit 25.12 calculates the GT measure for both the stock index and the active manager. For the index, the average GT across the four investment periods is virtually zero (i.e., \(-0.03\) percent = \([0.00 - 0.57 + 0.18 + 0.29]/4\)). This should be the case for any passive buy-and-hold portfolio, assuming that the stock returns are not correlated from one period to the next. That is, while index weights will vary with stock prices (e.g., \(w_2 - w_1 = 0.280 - 0.200 = 0.080\), for Stock A), the product of these weight changes with the subsequent stock returns should net out over time if there is no momentum effect present in the returns. This is consistent with viewing the GT measure as the return to a zero-cost hedge portfolio that is long at the current investment weights and short at the previous weights.

In contrast, the GT measure for an active portfolio manager will likely not be zero. Here, the manager’s average GT value is 3.41 percent \([= (15.00 - 0.71 - 0.97 + 0.34)/4\]), indicating that he added a substantial amount of value through his stock-picking prowess. In Period 1, the decision to buy Stock A at Date 0, whose price subsequently rose, contributed 10.00 percent \([= (0.250 - 0.000) \times 40\%]\], whereas the decisions to sell some of Stocks B and C contributed 2.50 percent each \([= (0.125 - 0.250) \times -20\%]\) since both stocks declined in value during Period 1. On the other hand, the decision to repurchase Stock C on Date 2 subtracted 1.19 percent of value \([= (0.190 - 0.095) \times -12.5\%]\) since the price of these shares fell from $8 to $7 during Period 3.

This example demonstrates that it is possible to create a very detailed analysis of how each decision the manager made contributed to his overall performance. Additionally, the GT statistic can be computed without reference to any specific benchmark, which was not the case for returns-based measures such as the Information Ratio. However, the GT measure fails to reward or penalize the manager for portfolio adjustments where the share price change actually occurs in a later period. For instance, the manager received no credit in Period 3 for the decision to sell Stock B because the subsequent share price decline from $8 to $6 did not occur until Period 4. This deficiency can be overcome by calculating portfolio weight adjustments over longer holding periods (e.g., annual vs. quarterly).

**Characteristic Selectivity (CS) Performance Measure** A limitation of the GT measure is that it does not control directly for changes in either risk or investment style that result when a manager revises his portfolio holdings. If a manager sells a risky stock in order to buy a more risky one, he should be rewarded with higher gross returns over time but not necessarily higher risk-adjusted returns. Similarly, GT does not distinguish between stocks that perform well because of security-specific factors and those that merely benefit from broader trends, such as price momentum effects. Daniel et al. (1997) developed an alternative holdings-based measure that compares the returns of each stock held in an actively managed portfolio to the return of a benchmark portfolio that has the same aggregate investment characteristics. Their *characteristic selectivity* (CS) performance statistic is given by:

\[
CS_t = \sum_j w_{jt} (R_{jt} - R_{bjt})
\]
where, in addition to the earlier notation, \( R_{\text{portfolio}} \) is the Period \( t \) (i.e., from Date \( t-1 \) to Date \( t \)) return to a passive portfolio whose investment characteristics are matched at the beginning of Period \( t \) with those of Stock \( j \). Like GT, a series of periodic CS, values can be averaged to indicate the manager’s ability to pick specific stocks within the context of a larger investment style mandate:

\[
\text{Average CS} = \frac{\sum_{i} CS_{i}}{T}
\]

The CS measure credits the active manager whenever he holds a stock that outperforms a style-matched index investment and penalizes him when the opposite is true. The implicit assumption underlying this calculation is that, in lieu of hiring the active manager, investors could always purchase an indexed product with equivalent investment characteristics. Thus, the true test of the active manager’s skill is whether he can pick specific stocks that outperform portfolios that investors could have formed for themselves.

The major obstacle to implementing CS is identifying a set of benchmark portfolios to match the risk and style characteristics of every stock that an active manager might want to hold. Daniel et al. (1997) proposed forming 125 different passive portfolios, based on three investment characteristics: (1) market capitalization (i.e., size), (2) book-to-market ratio, and (3) stock price momentum. They created their benchmarks by sorting every stock listed on the NYSE, AMEX, and NASDAQ exchanges into quintiles based first on size, then on book-to-market ratios, and finally on price momentum. The benchmark returns (i.e., \( R_{\text{portfolio}} \)) were calculated as value-weighted averages of all of the stocks contained in that particular portfolio. The appropriate characteristic-matched benchmark for any given stock position is simply the one that contains that stock.

Exhibit 25.13 summarizes a performance evaluation of almost 2,000 mutual funds with a diverse set of investment objectives from 1975 to 1994. Four different measures are compared: (1) GT, (2) CS, (3) one-factor Jensen, and (4) four-factor Jensen. The GT measure, which captures the net benefit of the broad range of trading strategies employed by active fund managers, shows that the average fund added 1.94 percent of value per year over the 20-year horizon. However, the CS measure—which controls for momentum, size, and value-versus-growth effects—shows that the benefit provided by just the manager’s security selection skills accounted for less than half of this amount (i.e., 0.79 percent per year). Both of the returns-based Jensen performance measures were also positive, but they were statistically insignificant.

25.5.4 Performance Attribution Analysis

Portfolio managers can add value for their investors in two ways: selecting superior securities or demonstrating superior timing skills by allocating funds to different asset or sector classes. Attribution analysis attempts to distinguish which factor is the source of the portfolio’s overall performance. This method compares the manager’s total return to the return for a predetermined benchmark policy portfolio and decomposes the difference into an allocation effect and a selection effect. The most straightforward way to measure these two effects is as follows:

\begin{align*}
\text{Allocation Effect} &= \sum_i \left( (w_{ai} - w_{bi}) \times (R_{bi} - R_b) \right) \\
\text{Selection Effect} &= \sum_i \left( (w_{ai}) \times (R_{ai} - R_b) \right)
\end{align*}

where:

- $w_{ai}, w_{bi}$ = the investment proportions of the $i$th market segment (e.g., asset class, industry group) in the active manager’s portfolio and the benchmark policy portfolio, respectively
- $R_{ai}, R_{bi}$ = the investment return to the $i$th market segment in the active manager’s portfolio and the benchmark portfolio, respectively
- $R_b$ = the total return to the benchmark portfolio

The allocation effect measures the manager’s decision to over- or underweight a particular market segment (i.e., $[w_{ai} - w_{bi}]$) in terms of that segment’s return performance relative to the overall return to the benchmark (i.e., $[R_{bi} - R_b]$). Good timing skill is therefore a matter of investing more money in those market segments that end up producing greater-than-average returns. The selection effect measures the manager’s ability to create specific market segment portfolios that generate superior returns relative to how those market segments are defined in the benchmark (i.e., $[R_{ai} - R_{bi}]$), weighted by the manager’s actual investment proportions. The manager’s total value-added performance is the sum of the allocation and selection effects.

An Example Consider an investor whose top-down portfolio strategy consists of two dimensions. First, he decides on a broad allocation across three asset classes: U.S. stocks, U.S. long-term bonds, and cash equivalents, such as Treasury bills or certificates of deposit. The investor’s second general decision is choosing which specific stocks, bonds, and cash instruments to buy. As a policy benchmark, he selects a hypothetical portfolio with a 60 percent allocation to the Standard and Poor’s 500 Index, a 30 percent investment in the Barclays Aggregate Bond Index, and a 10 percent allocation to three-month Treasury bills.

Suppose that at the start of the investment period, the investor believes equity values are inflated relative to the fixed-income market. Compared to the benchmark, he decides to underweight stocks and overweight bonds and cash with 50 percent in equity, 38 percent in bonds, and 12 percent in cash. Further, he decides to concentrate on equities in the interest rate–sensitive sectors, such as utilities and financial companies, while deemphasizing the technology and consumer durables sectors. Finally, he resolves to buy shorter duration bonds of a higher credit quality than are contained in the benchmark bond index and to buy commercial paper rather than Treasury bills.

The manager has made active investment decisions involving both the allocation of assets and the selection of individual securities. To determine if either (or both) of these decisions proved to be wise, at the end of the investment period he can calculate his overall and

\begin{footnotesize}
\text{Bailey, Richards, and Tierney (2007) argue that a better way to measure the selection effect is to multiply the market segment return differential by the benchmark segment weight, or } \sum_i ((w_{ai} - w_{bi}) \times (R_{ai} - R_{bi})). \text{ A drawback of this approach is that the allocation and selection effects no longer sum to the total value-added return. To balance this, they calculate an interaction effect as } \sum_i ((w_{ai} - w_{bi}) \times (R_{ai} - R_{bi})) \text{ to measure residual performance. Hsu, Kalevick, and Myers (2010) also developed an alternative framework that measures a manager’s dynamic allocation skills. }
\end{footnotesize}
Using a similar procedure, Brinson, Hood, and Beebower (1986) examined the performance of a group of 91 large U.S. pension plans from 1974 to 1983. The mean annual return for this sample was 9.01 percent, compared to 10.11 percent for the benchmark. Thus, active management cost the average plan 110 basis points of return per year. This value-subtracted return increment consisted of a −77-basis-point allocation effect and a −33-basis-point selection effect. They concluded that a plan’s initial strategic asset allocation choice, rather than any of its active management decisions, was the primary determinant of portfolio performance. In a follow-up study, Brinson, Singer, and Beebower (1991) reached a similar conclusion for a different group of 82 pension plans over the 1977–1987 period. For this new sample, the total active return shortfall dropped to −7 basis points, which was divided into an 18-basis-point selection effect and a −25-basis-point allocation effect.

Performance Attribution Extensions

The attribution methodology can also be used to distinguish security selection skills from other decisions that an investor might make. For instance, the manager of an all-equity portfolio must decide which economic sectors (e.g., basic materials, consumer nondurables, transportation) to under- and overweight before she can choose her preferred companies in those sectors. Performance attribution analysis is still applicable, with a “sector rotation” effect replacing the market timing effect. Exhibit 25.15 summarizes the performance of the growth-oriented stock portfolio managed by The MBA Investment Fund, L.L.C., a privately funded investment management company run by a group of graduate students at the University of Texas. Because the Fund’s investment mandate was to beat the return on the Standard and Poor’s 500, the managers had two basic decisions to make: which sectors to emphasize and which individual stocks to buy within those sectors. During the year shown here, the overall returns to the S&P 500 and the MBA Investment Fund were 29.63 percent and 29.54 percent, respectively. The second and third columns of Exhibit 25.15 document the actual and benchmark weights for the 10 economic sectors comprising the S&P 500 Index, with the Fund’s excess weightings (i.e., \( w_{ai} - w_{bi} \)) listed in the fourth column. The last column shows the benchmark sector return relative to the overall S&P return (i.e., \( R_{bi} - R_b \)). The sector allocation effect can be calculated by summing the product of the entries in the last two columns:

\[
\text{Sector Allocation Effect} = (-0.0339 \times -0.0151) + (0.0703 \times -0.0331) + \ldots + (-0.0242 \times -0.1315) = -0.28\%
\]

With an overall return difference of −9 basis points (= 0.2954 − 0.2963), this means that the fund’s managers generated a security selection effect of 19 basis points (= (−0.0009) − (−0.0028)).

Consequently, while the student managers virtually matched the strong performance of the entire stock market, it appears they were better at picking stocks than forecasting broader economic trends.

This general attribution analysis methodology has been extended to other specific asset classes as well. Kuberek (1995) showed that producing fixed-income attributions for bond portfolio managers is quite straightforward once the relevant decision variables are specified, such as allocations to different countries, foreign exchange effects, individual bond selections, and the portfolio's term structure positioning. Karnosky and Singer (1994) and Ankrum and Hensel (1994) have developed a unified framework for attributing performance in a global asset management context. They have added both active and hedged currency allocation returns to the single-currency attribution model of Brinson, Hood, and Beebower to allow for the intricacies of cross-border investing. Comparing the performance of one of their global portfolios relative to the MSCI World Equity Index during 1989, the combined effect of the currency selection decision accounted for 563 basis points of the 7.66 percent return advantage that the portfolio enjoyed.

### 25.5.5 Measuring Market Timing Skills

As we saw in Chapter 16, tactical asset allocation (TAA) attempts to produce active value-added returns solely through allocation decisions. Instead of trying to pick superior individual securities, TAA managers adjust their asset class exposures based on perceived changes in the relative valuations of those classes. The relevant performance measurement criterion for a TAA manager is how well he is able to time broad market movements. There are two reasons why attribution analysis is ill-suited for this task. First, by design, a TAA manager indexes his actual asset class investments and so the selection effect is not relevant. Second, TAA might entail dozens of changes to asset class weightings during an investment period, which could render meaningless an attribution effect computed on the average holdings. Because of these problems, many analysts consider a regression-based method for measuring timing skills to be a superior approach.

Weigel (1991) tested the market timing skills of a group of 17 U.S.-based TAA managers. His methodology was motivated by the pioneering work of Merton (1981) and Hendriksson and Merton (1981) and assumed that perfect market timing ability was equivalent to owning a lookback call option that pays at expiration the return to the best-performing asset class among stocks, bonds, and cash. That is, in Period $t$, a manager with perfect market timing skills would have a return ($R_{at}$) equal to:

$$R_{at} = RFR_t + \max[R_{at} - RFR_t, 0]$$

where $R_{at}$ and $R_{bt}$ are the Period $t$ returns to the stock and bond benchmark portfolios, respectively. Controlling for stock and bond price movements in a manner comparable to Jensen's method, the following regression equation can be calculated:

$$(R_{at} - RFR_t) = \alpha + \beta_{si}(R_{bi} - RFR_i) + \beta_{si}(R_{bi} - RFR_i) + \gamma[\max|R_{at} - RFR_t, 0|] + \epsilon_t$$

The average value for $\gamma$, which measures the proportion of the perfect timing option that the TAA managers were able to capture, was 0.30. This value was statistically significant, meaning that these managers had reliable, although not perfect, market timing skills. Also, the average alpha was −0.5 percent per quarter, indicating that these same managers had negative nonmarket timing skills (e.g., hedging strategies).

Many other studies have examined the market timing ability of portfolio managers who are not exclusively TAA practitioners. Kon (1983) and Chang and Lewellen (1984) concluded that mutual fund managers generally possess negative market timing skills, a position supported by Bayer and Dahlquist (2001). Cogggin, Fabozzi, and Rahman (1993) carried this analysis further...
by looking at both the timing and the selectivity skills of a group of U.S. equity pension fund managers. Their sample of managers possessed positive, but small, selection skills and negative timing skills. From these studies, it is reasonable to conclude that only those managers explicitly trying to time market movements have a chance of doing so.

### 25.6 Factors That Affect Use of Performance Measures

All the performance measures just described are only as good as their data inputs. Of course, an analyst should use judgment and be patient in the evaluation process. It is not possible to evaluate a portfolio manager on the basis of a quarter or even a year. An evaluation should extend over several years and cover at least a full market cycle, which allows one to determine whether the manager’s performance differs during rising and declining markets as Ferson and Schadt (1996) demonstrate.

Many of the equity portfolio performance measures we have discussed are derived from the CAPM and assume the existence of a market portfolio at the point of tangency on the Markowitz efficient frontier. Theoretically, the market portfolio is an efficient, completely diversified portfolio that must contain all risky assets in the economy and be market-value weighted. The problem arises in finding a realistic proxy for this theoretical market portfolio. Analysts typically use the Standard and Poor’s 500 index as the proxy for the market portfolio because it contains a fairly diversified portfolio of stocks, and the sample is market-value weighted. Unfortunately, it does not represent the true composition of the market portfolio since it includes only common stocks that mostly are listed on the NYSE. Notably, it excludes many other risky assets that theoretically should be considered, such as numerous domestic stocks, foreign stocks, foreign and domestic bonds, real estate, alternative assets, and collectibles.

This lack of completeness was highlighted in several articles by Roll (1977a, 1978, 1980, 1981), who detailed the problem with the market proxy and pointed out its implications for measuring portfolio performance. Although a detailed discussion of Roll’s critique will not be repeated here, we need to consider his major problem with the measurement of the market portfolio, which he refers to as a **benchmark error**. He showed that if the proxy for the market portfolio is not a truly efficient portfolio, then the SML using this proxy may not be the true SML. In such a case, a portfolio plotted above the SML and derived using a poor benchmark could actually plot below the SML that uses the true market portfolio.

Another problem is that the beta could differ from that computed using the true market portfolio. For example, if the true beta were larger than the beta computed using the proxy, the true position of the portfolio would shift to the right. In an empirical test, Brown and Brown (1987) documented a considerable amount of ranking reversal when the definition of the market portfolio was changed in a Jensen’s alpha analysis of a sample of well-established mutual funds. Terhaar (2001) also showed how the benchmark error problem can affect attribution analysis.

### 25.6.1 Demonstration of the Global Benchmark Problem

As an illustration of the impact of the benchmark problem in global capital markets, consider how individual measures of risk change when the world equity market is employed as the market portfolio proxy in the SML. Exhibit 25.16 contains beta estimates for the 30 stocks in the Dow Jones Industrial Average (DJIA) using the S&P 500, the typical proxy for stocks of companies domiciled in the United States, and the Morgan Stanley Capital International (MSCI) World Stock Index, which is a market-value-weighted index that contains stocks from around the world. These findings were calculated using weekly returns from two different three-year periods: 2005–2007 and 2008–2010. The percentage difference between the U.S. beta and the World beta is also shown, using the higher of the two risk estimates as the base.
Four country-specific benchmarks— the S&P 500 (United States), the Nikkei (Japan), the FTAll Shares (England), and the FAZ (Germany)— and two aggregate benchmarks— M-S World and Brinson GSMI— were used in the analysis. Their results show that using alternative market proxies for different countries generates SMLs that differ substantially during a given time period and are very unstable over time. For instance, the Nikkei SML had the largest risk premium during 1983–1988 but a negative risk premium during 1989–1994, which clearly is contrary to capital market theory. The S&P 500 provided investors with the biggest performance hurdle over the whole sample period, due to the high-risk premiums in the United States during 1989–1994.

25.6.2 Implications of the Benchmark Problems

Several points are significant regarding this benchmark criticism. First, the problems noted by Roll, which are increased with global investing, do not negate the value of the CAPM as a normative model of equilibrium pricing; the theory is still viable. The problem is one of measurement when using the theory to evaluate portfolio performance. You need to find a better proxy for the market portfolio or to adjust measured performance for benchmark errors. Roll (1981) and Grinold (1992) have made several suggestions to help overcome this problem. Alternatively, the analyst might consider giving greater weight to the Sharpe and Sortino portfolio performance measures because they do not depend on the market portfolio. Although the evaluation process based on these statistics generally uses a benchmark portfolio as an example of an unmanaged portfolio for comparison purposes, the risk measure for the portfolio being evaluated does not directly depend on a market portfolio. Also, recall that the portfolio rank from the Sharpe measure typically correlates highly with the ranks derived from alternative performance measures.

25.6.3 Required Characteristics of Benchmarks

Concurrent with the search for a global market portfolio, there has also been a search for appropriate normal portfolios, which are customized benchmarks that reflect the specific styles of alternative managers. Bailey, Richards, and Tierney (2007) consider this a critical need of pension plans and endowments that hire multiple managers with widely divergent styles. If a broad market index is used rather than a specific benchmark portfolio, it is implicitly assumed that the portfolio manager does not have an investment style, which is quite unrealistic. Also, it does not allow the plan sponsors to determine if the money manager is consistent with his or her stated investment style. The authors contend that any useful benchmark should have the following characteristics:

- **Unambiguous.** The names and weights of securities comprising the benchmark are clearly delineated.
- **Investable.** The option is available to forgo active management and simply hold the benchmark.
- **Measurable.** It is possible to calculate the return on the benchmark on a reasonably frequent basis.
- **Appropriate.** The benchmark is consistent with the manager’s investment style or biases.
- **Reflective of current investment opinions.** The manager has current investment knowledge (be it positive, negative, or neutral) of the securities that make up the benchmark.
- **Specified in advance.** The benchmark is constructed prior to the start of an evaluation period.
- **Owned.** The manager should accept accountability for benchmark performance.

There are two major differences in the various beta statistics. First, for many stocks, the beta estimates change a great deal over time. For example, Boeing’s U.S. and World betas during 2005–2007 were 0.87 and 0.78, respectively. However, during 2008–2010, both of these values substantially increased (to 1.21 and 1.10, respectively). Second, although the mean and median values for the U.S. and World beta estimates appear to be somewhat similar during both time periods, the “% Diff” columns show that there are some substantial differences in betas estimated for the same stock over the same time period when two different definitions of the benchmark portfolio are employed. For instance, the U.S. and World beta estimates for Travelers differed by more than 18 percent in 2005–2007 and then by over 13 percent in 2008–2010. Overall, the median size of this discrepancy itself changed over time—from 13.0 percent to 6.8 percent—indicating that the specification of the proper benchmark remains a critical issue in the performance evaluation process.

Reilly and Akhtar (1995) examined the effect of the choice of a benchmark on global performance measurement by plotting SMLs for six different indexes over three time horizons:
If a benchmark does not possess all of these properties, it is considered flawed as an effective management tool. One example of a flawed benchmark is the use of the median manager from a broad universe of managers or even a limited universe of managers. This criticism is spelled out in detail by Bailey (1992), who argues that the manager universe is inadequate on almost every characteristic. Finally, Dialynas (2001) considers the special problems of creating benchmarks for fixed-income portfolios.

25.7.1 Returns-Based Bond Performance Measurement

Early attempts to analyze fixed-income performance often involved peer group comparisons of the returns generated by bond portfolio managers with comparable investment styles. Kritzman (1983) examined the ranking for 32 bond managers over two five-year periods. He determined each manager’s percentile ranking in each period and correlated the rankings. There was no relationship between levels of performance in the two periods and no relationship between past and future performance, even when comparing the best and worst performers. He concluded that it is necessary to look at something besides past performance to determine superior bond portfolio managers.

Of course, peer group comparisons are potentially flawed because they do not account for investment risk directly. In principle, the Jensen’s alpha approach described in previous sections can be employed to measure the performance of any asset portfolio. In practice, however, when the assets in the portfolio change from stocks to bonds, it is likely that a straightforward application of the conventional risk models will not produce the most meaningful results. Fama and French (1993) addressed this issue by expanding their three-factor equation to include two additional factors specifically related to how returns are generated for fixed-income securities:

\[
R_{jt} - R_{FRt} = \alpha_j + \beta_{j1}(R_{mt} - R_{FRt}) + \beta_{j2}SMB_t + \beta_{j3}HML_t + \beta_{j4}TERM_t + \beta_{j4}DEF_t + \epsilon_{jt}
\]

A good overview of this area and a discussion of the historical development of the various performance measures are contained in Fong (2001) and Colin (2005).

25.6.2 Implications of the Benchmark Problems

Several points are significant regarding this benchmark criticism. First, the problems noted by Roll, which are increased with global investing, do not negate the value of the CAPM as a normative model of equilibrium pricing; the theory is still viable. The problem is one of measurement when using the theory to evaluate portfolio performance. You need to find a better proxy for the market portfolio or to adjust measured performance for benchmark errors. Roll (1981) and Grinold (1992) have made several suggestions to help overcome this problem.

Alternatively, the analyst might consider giving greater weight to the Sharpe and Sortino portfolio performance measures because they do not depend on the market portfolio. Although the evaluation process based on these statistics generally uses a benchmark portfolio as an example of an unmanaged portfolio for comparison purposes, the risk measure for the portfolio being evaluated does not directly depend on a market portfolio. Also, recall that the portfolio rank from the Sharpe measure typically correlates highly with the ranks derived from alternative performance measures.

25.6.3 Required Characteristics of Benchmarks

Concurrent with the search for a global market portfolio, there has also been a search for appropriate normal portfolios, which are customized benchmarks that reflect the specific styles of alternative managers. Bailey, Richards, and Tierney (2007) consider this a critical need of pension plans and endowments that hire multiple managers with widely divergent styles. If a broad market index is used rather than a specific benchmark portfolio, it is implicitly assumed that the portfolio manager does not have an investment style, which is quite unrealistic. Also, it does not allow the plan sponsors to determine if the money manager is consistent with his or her stated investment style. The authors contend that any useful benchmark should have the following characteristics:

- **Unambiguous.** The names and weights of securities comprising the benchmark are clearly delineated.
- **Investable.** The option is available to forgo active management and simply hold the benchmark.
- **Measurable.** It is possible to calculate the return on the benchmark on a reasonably frequent basis.
- **Appropriate.** The benchmark is consistent with the manager’s investment style or biases.
- **Reflective of current investment opinions.** The manager has current investment knowledge (be it positive, negative, or neutral) of the securities that make up the benchmark.
- **Specified in advance.** The benchmark is constructed prior to the start of an evaluation period.
- **Owned.** The manager should accept accountability for benchmark performance.
The two additional risk factors are (1) **TERM**, which is the term premium in the slope of the Treasury yield curve and is calculated as the difference between the long-term and short-term government bond yields, and (2) **DEF**, which is the default premium calculated by the credit spread between the long-term corporate and government bond yields.

The model was tested using seven different bond portfolios over the 342-month period from July 1963 to December 1991. These portfolios were formed with the following securities: 1- to 5-year Treasuries (1–5G), 6- to 10-year Treasuries (6–10G), Aaa-rated corporates, Aa-rated corporates, A-rated corporates, Baa-rated corporates, and low-grade corporates rated below Baa (LG). The findings are summarized in Exhibit 25.17.

Although both stock and bond risk factors were included, the two bond factors provide the dominant explanation for how these bond portfolio returns varied over time. While all of the portfolios groups had significant positive exposures to **TERM** and **DEF**, only a few of the categories also had significant loadings on the stock market variables. Further, the reported alpha coefficients in the last row are quite small and were insignificant for all of the corporate bond portfolios. Since these portfolios represent the performance of indexed fixed-income investments, these results are what you would expect. However, the same process can be used to assess the value added by active bond managers as well.

### 25.7 Evaluation of Bond Portfolio Performance

The analysis of risk-adjusted performance for equity portfolios began in the late 1960s, following the development of portfolio theory and the CAPM. No such development has simplified analysis for the bond market, where numerous and complex factors can influence portfolio returns. Prior to the 1970s, most bond portfolio managers followed buy-and-hold strategies, so their performance probably did not differ much. In this era, interest rates were relatively stable, so one could gain little from the active management of bond portfolios.

The environment in the bond market changed considerably in the late 1970s when interest rates increased dramatically and became more volatile. This created an incentive to trade bonds actively, which led to more diverse performance by bond portfolio managers. This trend also created demand for techniques that would help investors evaluate the performance of bond portfolio managers. The historic decline in interest rates that began in the early 1990s and the attendant increase in the level of rate volatility fostered a renewed interest in measuring the risk-adjusted performance of bond portfolios as well as attempts to explain the causes of that performance.

As it was for stocks, bond performance measurement can also be divided into attempts to assess how portfolio managers performed relative to investor expectations and why the managers produced the performance they did. We now consider techniques that address both of these questions.⁷

#### 25.7.1 Returns-Based Bond Performance Measurement

Early attempts to analyze fixed-income performance often involved peer group comparisons of the returns generated by bond portfolio managers with comparable investment styles. Kritzman (1983) examined the ranking for 32 bond managers over two five-year periods. He determined each manager’s percentile ranking in each period and correlated the rankings. There was no relationship between levels of performance in the two periods and no relationship between past and future performance, even when comparing the best and worst performers. He concluded that it is necessary to look at something besides past performance to determine superior bond portfolio managers.

Of course, peer group comparisons are potentially flawed because they do not account for investment risk directly. In principle, the Jensen’s alpha approach described in previous sections can be employed to measure the performance of any asset portfolio. In practice, however, when the assets in the portfolio change from stocks to bonds, it is likely that a straightforward application of the conventional risk models will not produce the most meaningful results. Fama and French (1993) addressed this issue by expanding their three-factor equation to include two additional factors specifically related to how returns are generated for fixed-income securities:

\[
R_{jt} - R_{FR} = \alpha_j + \left[ b_{1j} (R_{mt} - R_{FR}) + b_{2j} SMB_j + b_{3j} HML_j \right] + \left[ b_{4j} TERM_j + b_{5j} DEF_j \right] + e_{jt}
\]

⁷A good overview of this area and a discussion of the historical development of the various performance measures are contained in Fung (2001) and Colin (2005).
in the index. Given the bond market line, this technique divides the portfolio return that differs from the return on the benchmark into four components: (1) a policy effect, (2) a rate anticipation effect, (3) an analysis effect, and (4) a trading effect. When the latter three effects are combined, they are referred to as the management effect.

The policy effect measures the difference in the expected return portfolio because of a difference in policy regarding its duration compared to the duration of the index. For example, assume the duration and return for the Barclays Index is 9.0 years and 8.25 percent, respectively. If the manager’s policy portfolio has a duration of 9.5 years, according to the prevailing bond market line, the return should be about 8.60 percent. Thus, the policy effect is 0.5 year and 0.35 percent (35 basis points). The higher duration implies that the portfolio should have a higher average return of 0.35 percent (this positive relationship assumes the typical upward-sloping yield curve).

Given the expected return and duration for this long-term portfolio, all deviations from the index portfolio are attributable to the remaining management effect components. The interest rate anticipation effect captures the differential return from changing the duration during this period. The analysis effect, attributable to the selection of issues with better-than-average long-term prospects, is the difference between the actual return of the buy-and-hold portfolio at the beginning of the quarter and the expected return of that buy-and-hold portfolio. The trading effect is the result of the current quarter’s trading, either through effective trade-desk operation or through short-term selection abilities. It is the difference between total management effect and the effects attributable to analysis and interest rate anticipation.

The two additional risk factors are (1) TERM, which is the term premium in the slope of the Treasury yield curve and is calculated as the difference between the long-term and short-term government bond yields, and (2) DEF, which is the default premium calculated by the credit spread between the long-term corporate and government bond yields.

The model was tested using seven different bond portfolios over the 342-month period from July 1963 to December 1991. These portfolios were formed with the following securities: 1- to 5-year Treasuries (1–5G), 6- to 10-year Treasuries (6–10G), Aaa-rated corporates, A-rated corporates, A-rated corporates, Baa-rated corporates, and low-grade corporates rated below Baa (LG). The findings are summarized in Exhibit 25.17.

Although both stock and bond risk factors were included, the two bond factors provide the dominant explanation for how these bond portfolio returns varied over time. While all of the portfolios groups had significant positive exposures to TERM and DEF, only a few of the categories also had significant loadings on the stock market variables. Further, the reported alpha coefficients in the last row are quite small and were insignificant for all of the corporate bond portfolios. Since these portfolios represent the performance of indexed fixed-income investments, these results are what you would expect. However, the same process can be used to assess the value added by active bond managers as well.

### 25.7.2 Bond Performance Attribution

In this section, we present one attempt to develop a bond portfolio performance attribution model that considers multiple risk factors.

**The Bond Market Line** Wagner and Tito (1977) applied asset pricing techniques to the evaluation of bond performance. The main factor necessary for a proper bond performance attribution is the development of an appropriate index, and for this a measure of risk is necessary, similar to the beta coefficient for equities. A bond’s duration statistic captures the net effect of the volatility inherent in the underlying coupon and maturity structure.

Using this as a measure of risk, the authors derived a bond market line much like the security market line used to evaluate equity performance. Duration simply replaces beta as the risk variable. The bond market line in Exhibit 25.18 is drawn from points defined by returns on Treasury bills to the Barclays Government-Corporate Bond Index rather than the S&P 500 Index. This benchmark gives the market's average annual rate of return during some common period, and the duration for the index is the value-weighted duration for the individual bonds.

in the index. Given the bond market line, this technique divides the portfolio return that differs from the return on the benchmark into four components: (1) a policy effect, (2) a rate anticipation effect, (3) an analysis effect, and (4) a trading effect. When the latter three effects are combined, they are referred to as the management effect.

The policy effect measures the difference in the expected return portfolio because of a difference in policy regarding its duration compared to the duration of the index. For example, assume the duration and return for the Barclays Index is 9.0 years and 8.25 percent, respectively. If the manager’s policy portfolio has a duration of 9.5 years, according to the prevailing bond market line, the return should be about 8.60 percent. Thus, the policy effect is 0.5 year and 0.35 percent (35 basis points). The higher duration implies that the portfolio should have a higher average return of 0.35 percent (this positive relationship assumes the typical upward-sloping yield curve).

Given the expected return and duration for this long-term portfolio, all deviations from the index portfolio are attributable to the remaining management effect components. The interest rate anticipation effect captures the differential return from changing the duration during this

---

\[ \text{Duration} \] is a measure of the average time to receipt of cash flows from an investment. It is a measure of the sensitivity of a bond's price to changes in interest rates.

---

### Exhibit 25.18 Bond Market Line and Performance Breakdown

**Management effect** is the improvement in investment performance of a passive strategy through active bond management. It is the difference between total bond portfolio return and the expected return at the long-term average duration.

**Policy effect** is the difference between long-term duration of a bond portfolio and the duration of a bond market index resulting from long-term investment policy. Measured as the return at the long-term average less the return on the Barclays Index.

**Bond market line** is a straight line drawn through the return/duration of Treasury bills and the return/duration of the Barclays Index. The buy-and-hold portfolio is the composition of the portfolio at the beginning of the quarter. Used to differentiate between trading gains secured within a quarter and long-term analysis gains.

**Trading effect** is the result of the current quarter's trading, either through effective trade desk operation or through short-term selection abilities. It is the difference between total management effect and the effects attributable to analysis and interest rate anticipation.

**Analysis effect**, attributable to the selection of issues with better-than-average long-term prospects, is the difference between the actual return of the buy-and-hold portfolio at the beginning of the quarter and the expected return of that buy-and-hold portfolio.

**Interest rate anticipation effect** is attributable to changes in portfolio duration resulting from attempts to profit from and ability to predict bond market movements. It is the difference between the expected return at the actual portfolio duration and the expected return at the long-term duration.

---

---

\[ \text{Notably, the duration of the various bond market indexes has changed over time (i.e., the duration of the corporate bond series has declined, whereas the duration of the government bond series has increased slightly). See Reilly and Wright (2001).} \]
period compared to the portfolio’s long-term duration. Assume the policy duration for the long-term portfolio is 9.5 years, which implies an expected return of 8.60 percent, and that the actual prevailing duration for the portfolio being evaluated is 10.0 years, which implies an expected return of 9.00 percent using the bond market line. Therefore, the rate anticipation effect during this period is 0.40 percent (9.00 – 8.60).

The difference between this duration-based expected return and the actual return for the portfolio during this period is a combination of an analysis effect and a trading effect. The analysis effect is the differential return attributable to acquiring bonds that are temporarily mispriced and is measured by the expected return for the portfolio held at the beginning of the period (using the bond market line) to the actual return of this same portfolio. An actual return greater than the expected return suggests that the portfolio manager acquired some underpriced issues that provided excess returns during the period. For example, if the portfolio at the beginning of the period had a duration of 10 years, this might indicate that the portfolio’s expected return was 9.00 percent for the period. In turn, if the actual return for this buy-and-hold portfolio was 9.40 percent, it would indicate an analysis effect of 0.40 basis points.

Finally, the trading effect occurs because of short-run changes in the portfolio during the period. It is measured as the residual after taking account of the analysis effect from the total excess return based on duration. Suppose the total actual return is 10.50 percent with a duration of 10.0 years. The prevailing bond market line indicates an expected return of 9 percent for a portfolio with a 10-year duration. Thus, the combination of the analysis and trading effects is 1.50 percent (= 10.50 – 9.00). Since the analysis effect was 0.40 percent, the trading effect must be 1.10 percent. In summary, for this portfolio manager, the actual return was 10.50 percent, compared to a return for the index of 8.25 percent. This total excess of 2.25 percent would be divided as follows:

- 0.35 percent policy effect, due to higher long-term duration
- 0.40 percent interest rate anticipation effect, due to increasing the duration of the current portfolio above the long-term portfolio duration
- 0.40 percent analysis effect—the impact of superior selection of individual issues in the beginning portfolio
- 1.10 percent trading effect—the impact of trading the issues during the period

This technique breaks down the return based on the duration as a comprehensive risk measure. However, it does not consider differences in the risk of default (e.g., it does not differentiate between an Aaa bond and a Baa bond with the same duration). A portfolio manager who invested in Baa bonds, for example, could experience a very positive analysis effect simply because the bonds were lower quality than the average quality implicit in the benchmark. The only way to avoid this would be to construct differential market lines for alternative ratings or construct a benchmark line that matches the quality makeup of the portfolio being evaluated.

Layard-Liesching (2001) used the information ratio to assess the relative impact of each possible decision that a bond manager could make on the return to the overall portfolio. His analysis showed that while large-scale duration “bets” could certainly be taken, their payoffs were likely to be low once the high degree of tracking error they created was taken into account. He argued that credit quality bets were more likely to be fruitful, particularly as the global movement to privatizing companies that were previously under governmental control continues to create new investment opportunities.9

9 Other attribution models that decompose bond returns in somewhat different ways can be found in Fong, Pearson, and Vasicek (1983) and Campisi (2000). For more detailed discussions of bond performance measurement, see Reilly and Sidhu (1980) and Kahle, Maxwell, and Xu (2007).
25.8 Reporting Investment Performance

The performance measures described in this chapter represent the essential elements of how any investor’s performance should be evaluated. However, before the various composite statistics can be calculated, a more fundamental question must be addressed: How should the returns used in the evaluation process be reported to the investor? We conclude our discussion by exploring two dimensions of this problem. First, we consider the issue of how returns should be computed for a portfolio that experiences infusions and withdrawals of cash during the investment period. Second, we will briefly summarize the performance presentation standards (PPS) created by the CFA Institute, an international organization of more than 100,000 investment practitioners and educators in more than 100 countries.

25.8.1 Time-Weighted and Money-Weighted Returns

As we saw in Chapter 1, the holding period yield (HPY) for any investment position was determined by that position’s market value at the end of the period divided by its initial value:

\[
HPY = \frac{\text{Ending Value of Investment}}{\text{Beginning Value of Investment}} - 1
\]

For any security or portfolio, there are two basic reasons why the ending and beginning values could differ: the receipt of cash payments (e.g., dividends) or a change in price (e.g., capital gains) during the period. For most investment positions, calculating returns during any given time frame is a reasonably straightforward matter.

For professional money managers and management companies, however, the beginning and ending value of a portfolio can differ for a reason that has nothing to do with the manager’s investment prowess. If the investor either withdraws or adds to her initial investment capital during the period, the ending value of the position will reflect these changes. Of course, it would be unfair to credit the manager with having produced high returns that were due to additional capital commitments or penalize him for reductions in the ending value of the investment caused by the investor removing funds from her account. Consequently, an evaluation of the manager’s true performance must take these contributions and withdrawals into account.

Consider two portfolio managers (A and B) who have exactly identical investment styles and stockpicking abilities. Indeed, we will assume that over a two-period investment horizon, they produce exactly the same capital gains with the investment capital entrusted to them: 25 percent in Period 1, and 5 percent in Period 2. Further, suppose that each manager receives from his respective investor $500,000 to invest. The difference is that Manager A receives all of these funds immediately, whereas Manager B’s investor commits only $250,000 initially and the remaining $250,000 at the end of the first period.

This investment timing difference can be seen by calculating the terminal (Period 2) value of each portfolio:

Portfolio A: \[500,000[(1 + 0.25)(1 + 0.05)] = 656,250\]

and

Portfolio B: \[250,000[(1 + 0.25)(1 + 0.05)] + 250,000(1 + 0.05) = 590,625\]

Obviously, Manager B’s portfolio is worth less than Manager A’s, but this is a result of the way the investment funds were committed rather than of any difference in the performance of the two managers. The managers’ performance evaluation should not be affected by the investors’ decisions concerning the timing of their capital commitments. In other words, Manager B should not be held accountable for the fact that Investor B did not have all of her funds invested during the high-return environment of the first period.
One common method of computing average returns that we have seen is to use a discounted cash flow approach to calculate an investment’s internal rate of return. For the two managers in this example, these calculations generate the following returns:

Manager A: \[ 500,000 = \frac{656,250}{(1 + r_{dA})^2}, \] or \( r_{dA} = 14.56 \) percent

and

Manager B: \[ 250,000 = -\frac{250,000}{(1 + r_{dB})} = \frac{590,625}{(1 + r_{dB})^2}, \] or \( r_{dB} = 11.63 \) percent

These returns \( r_{dA} \) and \( r_{dB} \) are sometimes called **money-weighted returns** because they are the discount rates that set the present value of future cash flows (including future investment contributions and withdrawals) equal to the level of the initial investment. In this case, money-weighted returns give an inaccurate impression of Manager B’s ability; he did not actually perform 2.93 percent \((= 0.1456 - 0.1163)\) worse than Manager A. Thus, while this internal rate of return method gives an accurate assessment of Investor B’s return, it is a misleading measure of Manager B’s talent.

A better way of evaluating a manager’s performance would be to consider how well he did regardless of the size or timing of the investment funds involved. For both managers in this example, the **time-weighted return** is simply the geometric average of (one plus) the periodic returns:

\[ r_{dA} = r_{dB} = \sqrt{(1 + 0.25)(1 + 0.05)} - 1 = 14.56 \] percent

Money-weighted and time-weighted returns are only the same when there are no interim investment contributions within the evaluation period. This was the case for Manager A. For Manager B, the money-weighted return understates the true (time-weighted) performance because of the way the investor deployed her funds. When there are contributions, Dietz and Kirschman (1990) have suggested a method for adjusting holding period yields:

\[ \text{Adjusted HPY} = \frac{\text{Ending Value of Investment} - (1 - DW)(\text{Contribution})}{\text{Beginning Value of Investment} + (DW)(\text{Contribution})} - 1 \]

where the contribution can be either positive (a new commitment) or negative (a withdrawal). This adjustment process alters the initial and terminal values of the portfolios by the weighted amount of the contribution made during the holding period. The day-weight \((DW)\) factor represents the portion of the period that the contribution is actually held in the account. For example, if a contribution were placed in the portfolio halfway through a 30-day month, \( DW \) would be 0.5 \((= 30 - 15)/30)\.

### 25.8.2 Performance Presentation Standards

The preceding example underscores the fact that there may not always be a straightforward answer to a seemingly simple question. Although Portfolio B had a money-weighted return of 11.63 percent, its manager generated an average return of 14.56 percent. Which should be reported to the investor? The Securities and Exchange Commission has established regulations to guard against the publication of outright fraudulent claims, but Lawton and Remington (2007) point out that the following reporting practices have been historically permissible:

- Present returns only for the best-performing portfolios as though those returns were fully representative of the manager’s expertise in a given strategy or style.
- Base portfolio market values on unsubstantiated estimates of asset prices or present simulated returns as though they had actually been earned.
Inflated returns by annualizing partial-period returns.
Select the most favorable measurement period, calculating returns from a low point to a high point.
Choose as a benchmark the particular index the selected portfolios have outperformed by the greatest margin during the measurement period.
Portray growth in AUM in a way that masks the difference between investment returns and client contributions.

Largely as a result of such abuses, the investment community has recently begun to demand the adoption of a more rigorous set of reporting guidelines.

In an effort to fulfill the call for uniform, accurate, and consistent performance reporting, CFA Institute has developed a comprehensive set of performance presentation standards (PPS). Introduced in 1987 and formally adopted in 1993, the PPS quickly became the accepted practice within the investment management community. However, early versions of these standards tended to have country-specific elements that made them difficult to translate to a fully global platform. Consequently, in 1999 the CFA Institute also adopted a companion set of Global Investment Performance Standards (GIPS), which were intended to accomplish the following goals:

- To establish investment industry best practices for calculating and presenting investment performance that promote investor interests and instill investor confidence;
- To obtain worldwide acceptance of a single standard for the calculation and presentation of investment performance based on the principles of fair representation and full disclosure;
- To promote the use of accurate and consistent investment performance data;
- To encourage fair, global competition among investment firms without creating barriers to entry; and
- To foster the notion of industry “self-regulation” on a global basis.10

By 2010, the GIPS had been adopted by 32 countries throughout North America, Europe, Africa, and the Asia Pacific region. They are now considered the definitive set of standards for reporting investment performance.

A detailed analysis of these standards (which are revised frequently) is beyond our current scope, but several of the fundamental principles on which they are based include:

- Total return, including realized and unrealized gains plus income, must be used when calculating investment performance.
- Time-weighted rates of return must be used.
- Portfolios must be valued at least monthly, and periodic returns must be geometrically linked.
- If composite return performance is presented, this composite must contain all actual fee-paying accounts, including all terminated accounts for periods up through the last full reporting period the account was under management. Composite results may not link simulated or model portfolios with actual performance.
- Performance must be calculated after the deduction of actual trading expenses (e.g., broker commissions and SEC fees), if any.
- For taxable clients, taxes on income and realized capital gains must be recognized in the same period they were incurred and must be subtracted from results, regardless of whether taxes are paid from assets outside the account.
- Annual returns for all years must be presented. Performance of less than one year must not be annualized. A 10-year performance record (or a record for the period since firm inception if less than 10 years) must be presented.

---

The first major goal of portfolio management is to derive returns that equal or exceed the returns on a naively selected portfolio with equal risk. The second goal is to attain complete diversification relative to a suitable benchmark. Several techniques have been derived to evaluate equity portfolios in terms of both risk and return (composite measures). The Treynor measure considers the excess returns earned per unit of systematic risk. The Sharpe measure indicates the excess return per unit of total risk. The Jensen and Information Ratio measures likewise evaluate performance in terms of systematic risk and tracking error relative to a benchmark, respectively. Additional work in equity portfolio evaluation has been concerned with models that focus on downside risk, how a portfolio's security holdings change, and those that indicate which components of the management process contributed to the results. Finally, attribution analysis seeks to establish whether market timing or security selection skills (or both) are the source of a manager's performance.

Richard Roll challenged the validity of all techniques that assume a market portfolio theoretically includes all risky assets but which then use a proxy such as the S&P 500 that is limited to U.S. common stocks. This criticism does not invalidate the normative asset pricing model, only its application because of measurement problems related to the proxy for the market portfolio. The measurement problem is increased in an environment where global investing is the norm.

Although techniques for evaluating equity portfolio performance have been in existence for 50 years, comparable measures for examining bond portfolio performance are more recent. While it is possible to adapt equity risk models for the evaluation of bond managers, it is often necessary to consider separately the decision variables related to bonds: the overall market factor, the impact of maturity-duration decisions, the influence of sector and quality factors, and the impact of individual bond selection.

The various techniques discussed provide theoretically justifiable measures that differ from one another. Although there is high rank correlation among the alternative measures, all the measures should be used because they provide different insights regarding the performance of managers. Also, portfolio managers should be evaluated over different market environments before a final judgment is reached regarding their strengths and weaknesses.

Sample 1 Investment Firm claims compliance with the Global Investment Performance Standards (GIPS) and has prepared and presented this report in compliance with the GIPS standards. Sample 1 Investment Firm has been independently verified for the periods 1 January 2000 through 31 December 2010. The verification report is available upon request. Verification assesses whether (1) the firm has complied with all the composite construction requirements of the GIPS standards on a firm-wide basis and (2) the firm's policies and procedures are designed to calculate and present performance in compliance with the GIPS standards. Verification does not ensure the accuracy of any specific composite presentation.

**Notes:**
1. Sample 1 Investment Firm is a balanced portfolio investment manager that invests solely in U.S.-based securities. Sample 1 Investment Firm is defined as an independent investment management firm that is not affiliated with any parent organization. Policies for valuing portfolios, calculating performance, and preparing compliant presentations are available upon request.
2. The Balanced Growth Composite includes all institutional balanced portfolios that invest in large-cap U.S. equities and investment-grade bonds with the goal of providing long-term capital growth and steady income from a well-diversified strategy. Although the strategy allows for equity exposure ranging between 50–70%, the typical allocation is between 55–65%. The account minimum for the composite is $5 million.
3. The custom benchmark is 60% YYY U.S. Equity Index and 40% ZZZ U.S. Aggregate Bond Index. The benchmark is rebalanced monthly.
4. Valuations are computed and performance is reported in U.S. dollars.
5. Gross-of-fees returns are presented before management and custodial fees but after all trading expenses. Composite and benchmark returns are presented net of non-reclaimable withholding taxes. Net-of-fees returns are calculated by deducting the highest fee of 0.83% from the monthly gross composite return. The management fee schedule is as follows: 1.00% on the first $25 million; 0.60% thereafter.
6. This composite was created in February 2000. A complete list of composite descriptions is available upon request.
7. Internal dispersion is calculated using the equal-weighted standard deviation of annual gross returns of those portfolios that were included in the composite for the entire year.
8. The three-year annualized standard deviation measures the variability of the composite and the benchmark returns over the preceding 36-month period. The standard deviation is not presented for 2002 through 2010 because monthly composite and benchmark returns were not available and is not required for periods prior to 2011.

**Source:** Copyright 2010, CFA Institute. Reproduced and republished from *Global Investment Performance Standards (GIPS)*, 2010, with permission of the CFA Institute. All rights reserved.
The first major goal of portfolio management is to derive returns that equal or exceed the returns on a naively selected portfolio with equal risk. The second goal is to attain complete diversification relative to a suitable benchmark. Several techniques have been derived to evaluate equity portfolios in terms of both risk and return (composite measures). The Treynor measure considers the excess returns earned per unit of systematic risk. The Sharpe measure indicates the excess return per unit of total risk. The Jensen and Information Ratio measures likewise evaluate performance in terms of systematic risk and tracking error relative to a benchmark, respectively. Additional work in equity portfolio evaluation has been concerned with models that focus on downside risk, how a portfolio’s security holdings change, and those that indicate which components of the management process contributed to the results. Finally, attribution analysis seeks to establish whether market timing or security selection skills (or both) are the source of a manager’s performance.

Richard Roll challenged the validity of all techniques that assume a market portfolio that theoretically includes all risky assets but which then use a proxy such as the S&P 500 that is limited to U.S. common stocks. This criticism does not invalidate the normative asset pricing model, only its application because of measurement problems related to the proxy for the market portfolio. The measurement problem is increased in an environment where global investing is the norm.

Although techniques for evaluating equity portfolio performance have been in existence for 50 years, comparable measures for examining bond portfolio performance are more recent. While it is possible to adapt equity risk models for the evaluation of bond managers, it is often necessary to consider separately the decision variables related to bonds: the overall market factor, the impact of maturity-duration decisions, the influence of sector and quality factors, and the impact of individual bond selection.

The various techniques discussed provide theoretically justifiable measures that differ from one another. Although there is high rank correlation among the alternative measures, all the measures should be used because they provide different insights regarding the performance of managers. Also, portfolio managers should be evaluated over different market environments before a final judgment is reached regarding their strengths and weaknesses.
3. The Sharpe and Treynor performance measures both calculate a portfolio’s average excess return per unit of risk. Under what circumstances would it make sense to use both measures to compare the performance of a given set of portfolios? What additional information is provided by a comparison of the rankings achieved using the two measures?

4. Describe how the Jensen measure of performance is calculated. Under what conditions should it give a similar set of portfolio rankings as the Sharpe and Treynor measures? Is it possible to adjust the Jensen measure so that a portfolio’s alpha value is measured relative to an empirical form of the arbitrage pricing theory rather than the capital asset pricing model? Explain.

5. The information ratio (IR) has been described as a benefit-cost ratio. Explain how the IR measures portfolio performance and whether this analogy is appropriate.

6. Assessing the performance of an investment portfolio can be accomplished with either returns-based measures or holdings-based measures. What are the major advantages and major disadvantages of each approach to performance measurement?

7. Performance attribution analysis is an attempt to divide a manager’s “active” residual return into an allocation effect and a selection effect. Explain how these two effects are measured and why their sum must equal the total value-added return for the manager. Is this analysis valid if the actual portfolio in question is riskier than the benchmark portfolio to which it is being compared?

8. During the annual review of Acme’s pension plan, several trustees questioned Lucy Graham, a pension consultant, about various aspects of performance measurement and risk assessment. In particular, one trustee asked about the appropriateness of using each of the following benchmarks:

   • Market index
   • Benchmark normal portfolio
   • Median of the manager universe

   a. Explain two different weaknesses of using each of the three benchmarks to measure the performance of a portfolio.

   Another trustee asked how to distinguish among the following performance measures:

   • The Sharpe ratio
   • The Treynor measure
   • Jensen’s alpha

   b. (1) Describe how each of the three performance measures is calculated.

   (2) State whether each measure assumes that the relevant risk is systematic, unsystematic, or total. Explain how each measure relates excess return and the relevant risk.

9. Richard Roll, in an article on using the capital asset pricing model (CAPM) to evaluate portfolio performance, indicated that it may not be possible to evaluate portfolio management ability if there is error in the benchmark used.

   a. In evaluating portfolio performance, describe the general procedure, with emphasis on the benchmark employed.

   b. Explain what Roll meant by the benchmark error, and identify the specific problem with this benchmark.

   c. Draw a graph that shows how a portfolio that has been judged as superior relative to a “measured” security market line (SML) can be inferior relative to the “true” SML.

   d. Assume that you are informed that a given portfolio manager has been evaluated as superior when compared to the DJIA, the S&P 500, and the NYSE Composite Index. Explain whether this consensus would make you feel more comfortable regarding the portfolio manager’s true ability.
e. While conceding the possible problem with benchmark errors as set forth by Roll, some contend this does not mean the CAPM is incorrect, but only that there is a measurement problem when implementing the theory. Others contend that because of benchmark errors, the whole technique should be scrapped. Take and defend one of these positions.

10. It has been contended that the derivation of an appropriate model for evaluating the performance of a bond manager is more difficult than an equity portfolio evaluation model because more decisions are required. Discuss some of the specific decisions that need to be considered when evaluating the performance of a bond portfolio manager.

PROBLEMS

1. The following portfolios are being considered for investment. During the period under consideration, \( RFR = 0.07 \).

<table>
<thead>
<tr>
<th>Portfolio</th>
<th>Return</th>
<th>( \alpha )</th>
<th>( \beta )</th>
<th>( \sigma_\beta )</th>
</tr>
</thead>
<tbody>
<tr>
<td>P</td>
<td>0.15</td>
<td>1.0</td>
<td>0.05</td>
<td></td>
</tr>
<tr>
<td>Q</td>
<td>0.20</td>
<td>1.5</td>
<td>0.10</td>
<td></td>
</tr>
<tr>
<td>R</td>
<td>0.10</td>
<td>0.6</td>
<td>0.03</td>
<td></td>
</tr>
<tr>
<td>S</td>
<td>0.17</td>
<td>1.1</td>
<td>0.06</td>
<td></td>
</tr>
<tr>
<td>Market</td>
<td>0.13</td>
<td>1.0</td>
<td>0.04</td>
<td></td>
</tr>
</tbody>
</table>

a. Compute the Sharpe measure for each portfolio and the market portfolio.
b. Compute the Treynor measure for each portfolio and the market portfolio.
c. Rank the portfolios using each measure, explaining the cause for any differences you find in the rankings.

2. An analyst wants to evaluate Portfolio X, consisting entirely of U.S. common stocks, using both the Treynor and Sharpe measures of portfolio performance. The following table provides the average annual rate of return for Portfolio X, the market portfolio (as measured by the Standard and Poor's 500 Index), and U.S. Treasury bills (T-bills) during the past eight years.

<table>
<thead>
<tr>
<th>Portfolio</th>
<th>Annual Average Rate of Return</th>
<th>Standard Deviation of Return</th>
<th>Beta</th>
</tr>
</thead>
<tbody>
<tr>
<td>Portfolio X</td>
<td>10%</td>
<td>18%</td>
<td>0.60</td>

<tr>
<td>S&amp;P 500</td>
<td>12</td>
<td>13</td>
<td>1.00</td>
</tr>
<tr>
<td>T-bills</td>
<td>6</td>
<td>n/a</td>
<td>n/a</td>
</tr>
</tbody>
</table>

\( n/a = \text{not applicable} \)

a. Calculate both the Treynor measure and the Sharpe measure for both Portfolio X and the S&P 500. Briefly explain whether Portfolio X underperformed, equaled, or outperformed the S&P 500 on a risk-adjusted basis using both the Treynor measure and the Sharpe measure.
b. Based on the performance of Portfolio X relative to the S&P 500 calculated in Part a, briefly explain the reason for the conflicting results when using the Treynor measure versus the Sharpe measure.

3. You have been assigned the task of comparing the investment performance of five different pension fund managers. After gathering 60 months of excess returns (i.e., returns in excess of the monthly risk-free rate) on each fund as well as the monthly excess returns on the entire stock market, you perform the regressions of the form:

\[
(R_{\text{fund}} - RFR)_t = \alpha + \beta(R_{\text{market}} - RFR)_t + \epsilon_t
\]
You have prepared the following summary of the data, with the standard errors for each of the coefficients listed in parentheses.

<table>
<thead>
<tr>
<th>Portfolio</th>
<th>$\alpha$</th>
<th>$\beta$</th>
<th>$R^2$</th>
<th>$(R_{FUND} - R_{FRA})$ Mean</th>
<th>$(R_{FUND} - R_{FRA})$ $\sigma$</th>

</tr>
</tbody>
</table>

a. Which fund had the highest degree of diversification over the sample period? How is diversification measured in this statistical framework?
b. Rank these funds’ performance according to the Sharpe, Treynor, and Jensen measures.
c. Since you know that according to the CAPM the intercept of these regressions (i.e., $\alpha$) should be zero, this coefficient can be used as a measure of the value added provided by the investment manager. Which funds have statistically outperformed and underperformed the market using a two-sided 95 percent confidence interval? (Note: The relevant $t$-statistic using 60 observations is 2.00.)

4. You have just gathered the following performance data for three different money managers, based on a regression of their excess returns relative to those for the S&P 500 Index. Each manager’s performance was measured over the same three-year period, but the return period for each was different.

<table>
<thead>
<tr>
<th>Manager</th>
<th>Alpha</th>
<th>Beta</th>
<th>Std. Error of Regression</th>
<th>Return Period</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>0.058%</td>
<td>0.95</td>
<td>0.533%</td>
<td>Weekly</td>
</tr>
<tr>
<td>B</td>
<td>0.115</td>
<td>1.12</td>
<td>5.884</td>
<td>Biweekly</td>
</tr>
<tr>
<td>C</td>
<td>0.250</td>
<td>0.78</td>
<td>2.165</td>
<td>Monthly</td>
</tr>
</tbody>
</table>

a. Calculate the information ratio for each manager, ignoring the difference in return reporting periods.
b. Calculate the annualized information ratio for each manager.
c. Rank the managers’ performance according to your answers in Parts a and b. Which manager performed the best? Explain.

5. Consider the following historical performance data for two different portfolios, the Standard and Poor’s 500, and the 90-day T-bill.

<table>
<thead>
<tr>
<th>Investment Vehicle</th>
<th>Average Rate of Return</th>
<th>Standard Deviation</th>
<th>Beta</th>
<th>$R^2$</th>
</tr>
</thead>
<tbody>
<tr>
<td>Fund 1</td>
<td>26.40%</td>
<td>20.67%</td>
<td>1.351</td>
<td>0.751</td>
</tr>
<tr>
<td>Fund 2</td>
<td>13.22%</td>
<td>14.20%</td>
<td>0.905</td>
<td>0.713</td>
</tr>
<tr>
<td>S&amp;P 500</td>
<td>15.71%</td>
<td>13.25%</td>
<td></td>
<td></td>
</tr>
<tr>
<td>90-day T-bill</td>
<td>6.20%</td>
<td>0.50</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

a. Calculate the Fama overall performance measure for both funds.
b. What is the return to risk for both funds?
c. For both funds, compute the measures of (1) selectivity, (2) diversification, and (3) net selectivity.
d. Explain the meaning of the net selectivity measure and how it helps you evaluate investor performance. Which fund had the best performance?

6. You are evaluating the performance of two portfolio managers, and you have gathered annual return data for the past decade:

<table>
<thead>
<tr>
<th>Year</th>
<th>Manager X Return (%)</th>
<th>Manager Y Return (%)</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>−1.5</td>
<td>−6.5</td>
</tr>
<tr>
<td>2</td>
<td>−1.5</td>
<td>−3.5</td>
</tr>
<tr>
<td>3</td>
<td>−1.5</td>
<td>−1.5</td>
</tr>
<tr>
<td>4</td>
<td>−1.0</td>
<td>3.5</td>
</tr>
<tr>
<td>5</td>
<td>0.0</td>
<td>4.5</td>
</tr>
<tr>
<td>6</td>
<td>4.5</td>
<td>6.5</td>
</tr>
<tr>
<td>7</td>
<td>6.5</td>
<td>7.5</td>
</tr>
<tr>
<td>8</td>
<td>8.5</td>
<td>8.5</td>
</tr>
<tr>
<td>9</td>
<td>13.5</td>
<td>12.5</td>
</tr>
<tr>
<td>10</td>
<td>17.5</td>
<td>13.5</td>
</tr>
</tbody>
</table>

a. For each manager, calculate (1) the average annual return, (2) the standard deviation of returns, and (3) the semi-deviation of returns.
b. Assuming that the average annual risk-free rate during the 10-year sample period was 1.5 percent, calculate the Sharpe ratio for each portfolio. Based on these computations, which manager appears to have performed the best?
c. Calculate the Sortino ratio for each portfolio, using the average risk-free rate as the minimum acceptable return threshold. Based on these computations, which manager appears to have performed the best?
d. When would you expect the Sharpe and Sortino measures to provide (1) the same performance ranking, or (2) different performance rankings? Explain.

7. Consider the following performance data for two portfolio managers (A and B) and a common benchmark portfolio:

<table>
<thead>
<tr>
<th>BENCHMARK</th>
<th>MANAGER A</th>
<th>MANAGER B</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Weight</td>
<td>Return</td>
</tr>
<tr>
<td>Stock</td>
<td>0.6</td>
<td>−5.0%</td>
</tr>
<tr>
<td>Bonds</td>
<td>0.3</td>
<td>−3.5%</td>
</tr>
<tr>
<td>Cash</td>
<td>0.1</td>
<td>0.3%</td>
</tr>
</tbody>
</table>

a. Calculate (1) the overall return to the benchmark portfolio, (2) the overall return to Manager A’s actual portfolio, and (3) the overall return to Manager B’s actual portfolio. Briefly comment on whether these managers have under- or outperformed the benchmark fund.
b. Using attribution analysis, calculate (1) the selection effect for Manager A, and (3) the allocation effect for Manager B. Using these numbers in conjunction with your results from Part a, comment on whether these managers have added value through their selection skills, their allocation skills, or both.

8. A U.S. pension plan hired two offshore firms to manage the non-U.S. equity portion of its total portfolio. Each firm was free to own stocks in any country market included in Morgan Stanley/Capital International’s Europe, Australia, and Far East Index (EAFE), and free to use
a. Evaluate the performance of each of these three firms relative to its appropriate index and to the manager universe. Use only the data from the descriptions and the preceding table, even though other information would be required for a more complete and accurate appraisal.

To provide additional guidance to the Committee, you decide to do an attribution analysis on the returns produced by Firm A and Firm C and have prepared the following table:

<table>
<thead>
<tr>
<th>PERFORMANCE ATTRIBUTION ANALYSIS</th>
</tr>
</thead>
<tbody>
<tr>
<td>(P A S T FIVE YEARS)</td>

<td>0.03</td>
<td>0.30</td>
<td>0.01</td>
<td>-0.04</td>
</tr>
</tbody>
</table>

b. Evaluate the performance of Firm A and of Firm C based on all the information previously provided and your interpretation of the data in this new table.

c. Based solely on the attribution analysis you performed in Part b, state which firm produced the better result and justify your conclusion.

You are a member of the plan sponsor’s Pension Committee, which will soon meet with the plan’s consultant to review manager performance. In preparation for this meeting, you go through the following analysis:

a. Briefly describe the strengths and weaknesses of each manager, relative to the EAFE Index data.

b. Briefly explain the meaning of the data in the “Currency” column.

9. To illustrate for the Investment Committee of the profit-sharing plan to which you are a consultant on some of the issues that arise in measuring performance, you have identified three U.S. fixed-income management firms whose investment approaches are representative of general practice. Each firm’s approach follows.

Firm A: An enhanced index fund manager that seeks to add value by superior security selection while maintaining portfolio duration and sector weights equal to the overall bond market.

Firm B: An active duration manager investing only in the government and corporate bond sectors. The firm uses futures to manage portfolio duration.

Firm C: An active manager seeking to add value by correctly anticipating changes in the shape of the yield curve, while maintaining portfolio duration and sector weights roughly equal to the overall bond market.

You have provided the Committee with the following additional information about these firms, derived from a consultant’s database.

<table>
<thead>
<tr>
<th>ANNUALIZED TOTAL RETURN DATA (PAST FIVE YEARS)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Firm A</td>
</tr>

For each manager, calculate:

a. her money-weighted return;

b. her time-weighted return; and,

c. estimates of her quarterly performance returns using the Dietz approximation method, assuming contributions/withdrawals are made exactly halfway through the quarter.
How to Become a CFA® Charterholder

As mentioned in the section on career opportunities, the professional designation of Chartered Financial Analyst (CFA) is becoming a significant requirement for a career in investment analysis and/or portfolio management. For that reason, this section presents the history and objectives of CFA Institute and general guidelines for acquiring the CFA designation. If you are interested in the program, you can write or email CFA Institute for more information.

The CFA examinations were first offered in 1963 by the Institute of Chartered Financial Analysts (ICFA), which was formed in 1959 to enhance the professionalism of those involved in various aspects of the investment decision-making process and to recognize those who achieve a high level of professionalism. The ICFA combined with the Financial Analysts Federation in 1990 to form the Association for Investment Management and Research, which became CFA Institute in early 2004.

The mission of CFA Institute is to lead the investment profession globally by setting the highest standards of ethics, education, and professional excellence. As applied to the CFA program, the focus of CFA Institute is:

• To develop and keep current a "body of knowledge" applicable to the investment decision-making process. The principal components of this knowledge are financial accounting, economics, both debt and equity securities analysis, portfolio management, ethical and professional standards, and quantitative techniques.

• To administer a study and examination program for eligible candidates, the primary objectives of which are to assist the candidate in mastering and applying the body of knowledge and to test the candidate's competency in the knowledge gained.

• To award the professional CFA designation to those candidates who have passed three examination levels (encompassing a total of 18 hours of testing over a minimum of two years), who meet stipulated standards of professional conduct, and who otherwise are eligible for membership in CFA Institute.

• CFA Institute also provides a useful and informative program of continuing education through seminars, publications, and other formats that enable members, candidates, and others in the investment constituency to be more aware of and to better utilize the changing and expanding body of knowledge.

• Importantly, CFA Institute also sponsors and enforces a Code of Ethics and Standards of Professional Conduct that apply to enrolled candidates and to all members.

To enter the CFA program an applicant must have a bachelor's degree (or the equivalent work experience). Students who confirm they are in their final year of a degree program may register and enroll for Level I of the CFA program. Student candidates can take the CFA Level I exam and receive results but will not be allowed to enroll for the Level II exam until confirmation of a degree has been provided. A candidate may sit for all three examinations without having had investment experience per se or having joined a member society or chapter of CFA Institute. However, after passing the three examination levels, the CFA Charter will not be awarded unless or until the candidate:

• has at least four years of acceptable work experience and
• has been accepted for regular membership in CFA Institute and has applied for regular membership in an affiliated society.

The curriculum of the CFA study program covers:

1. Ethical and Professional Standards
2. Quantitative Methods
3. Economics
4. Financial Statement Analysis
5. Corporate Finance
6. Analysis of Debt Investments
7. Analysis of Equity Investments
8. Analysis of Derivatives
9. Analysis of Alternative Investments

Members and candidates are typically employed in the investment field. From 1963 to July 2008, over 100,000 charters have been awarded. There were more than 175,000 candidate registrations for the 2008 CFA Program. If you are interested in learning more about the CFA Program, CFA Institute has a booklet that describes the program and includes an application form. The address is: CFA Institute, Attn: Information Central, PO Box 3668, Charlottesville, Virginia, 22903, USA. You may also find more information at the CFA Institute website, http://www.cfainstitute.org, or by requesting a booklet by email to info@cfainstitute.org.

Appendix B: Code of Ethics and Standards of Professional Conduct

The CFA Institute Code of Ethics and Standards of Professional Conduct are fundamental to the values of CFA Institute and essential to achieving its mission to lead the investment profession globally by setting high standards of education, integrity, and professional excellence. High ethical standards are critical to maintaining the public's trust in financial markets and in the investment profession. Since their creation in the 1960s, the Code and Standards have promoted the integrity of CFA Institute members and served as a model for measuring the ethics of investment professionals globally, regardless of job function, cultural differences, or local laws and regulations. All CFA Institute members (including holders of the Chartered Financial Analyst® [CFA®] designation) and CFA candidates must abide by the Code and Standards and are encouraged to notify their employer of this responsibility. Violations may result in disciplinary sanctions by CFA Institute. Sanctions can include revocation of membership, revocation of candidacy in the CFA Program, and revocation of the right to use the CFA designation.

The Code of Ethics

Members of CFA Institute (including CFA charterholders) and candidates for the CFA designation (“Members and Candidates”) must:

• Act with integrity, competence, diligence, respect, and in an ethical manner with the public, clients, prospective clients, employers, employees, colleagues in the investment profession, and other participants in the global capital markets.
• Place the integrity of the investment profession and the interests of clients above their own personal interests.
• Use reasonable care and exercise independent professional judgment when conducting investment analysis, making investment recommendations, taking investment actions, and engaging in other professional activities.
• Practice and encourage others to practice in a professional and ethical manner that will reflect credit on themselves and the profession.
• Promote the integrity of and uphold the rules governing capital markets.
• Maintain and improve their professional competence and strive to maintain and improve the competence of other investment professionals.

Standards of Professional Conduct

I. Professionalism

A. Knowledge of the Law. Members and Candidates must understand and comply with all applicable laws, rules, and regulations (including the CFA Institute Code of Ethics and Standards of Professional Conduct) of any government, regulatory organization, licensing agency, or professional association governing their professional activities. In the event of conflict, Members and Candidates must comply with the more strict law, rule, or regulation. Members and Candidates must not knowingly participate or assist in and must dissociate from any violation of such laws, rules, or regulations.

B. Independence and Objectivity. Members and Candidates must use reasonable care and judgment to achieve and maintain independence and objectivity in their professional activities. Members and Candidates must not offer, solicit, or accept any gift, benefit, compensation, or consideration that reasonably could be expected to compromise their own or another’s independence and objectivity.

C. Misrepresentation. Members and Candidates must not knowingly make any misrepresentations relating to investment analysis, recommendations, actions, or other professional activities.

D. Misconduct. Members and Candidates must not engage in any professional conduct involving dishonesty, fraud, or deceit or commit any act that reflects adversely on their professional reputation, integrity, or competence.

II. Integrity of Capital Markets

A. Material Nonpublic Information. Members and Candidates who possess material nonpublic information that could affect the value of an investment must not act or cause others to act on the information.

B. Market Manipulation. Members and Candidates must not engage in practices that distort prices or artificially inflate trading volume with the intent to mislead market participants.

III. Duties to Clients

A. Loyalty, Prudence, and Care. Members and Candidates have a duty of loyalty to their clients and must act with reasonable care and exercise prudent judgment. Members and Candidates must act for the benefit of their clients and not place their own interests above those of their clients.

B. Fiduciary Duty. Members and Candidates must place the interests of their clients above their own personal interests.

The curriculum of the CFA study program covers:

1. Ethical and Professional Standards
2. Quantitative Methods
3. Economics
4. Financial Statement Analysis
5. Corporate Finance
6. Analysis of Debt Investments
7. Analysis of Equity Investments
8. Analysis of Derivatives
9. Analysis of Alternative Investments

Members and candidates are typically employed in the investment field. From 1963 to July 2008, over 100,000 charters have been awarded. There were more than 175,000 candidate registrations for the 2008 CFA Program. If you are interested in learning more about the CFA Program, CFA Institute has a booklet that describes the program and includes an application form. The address is: CFA Institute, Attn: Information Central, PO Box 3668, Charlottesville, Virginia, 22903, USA. You may also find more information at the CFA Institute website, http://www.cfainstitute.org, or by requesting a booklet by email to info@cfainstitute.org.

APPENDIX B

Code of Ethics and Standards of Professional Conduct

Preamble
The CFA Institute Code of Ethics and Standards of Professional Conduct are fundamental to the values of CFA Institute and essential to achieving its mission to lead the investment profession globally by setting high standards of education, integrity, and professional excellence. High ethical standards are critical to maintaining the public’s trust in financial markets and in the investment profession. Since their creation in the 1960s, the Code and Standards have promoted the integrity of CFA Institute members and served as a model for measuring the ethics of investment professionals globally, regardless of job function, cultural differences, or local laws and regulations. All CFA Institute members (including holders of the Chartered Financial Analyst® [CFA®] designation) and CFA candidates must abide by the Code and Standards and are encouraged to notify their employer of this responsibility. Violations may result in disciplinary sanctions by CFA Institute. Sanctions can include revocation of membership, revocation of candidacy in the CFA Program, and revocation of the right to use the CFA designation.

The Code of Ethics
Members of CFA Institute (including CFA charterholders) and candidates for the CFA designation (“Members and Candidates”) must:

- Act with integrity, competence, diligence, respect, and in an ethical manner with the public, clients, prospective clients, employers, employees, colleagues in the investment profession, and other participants in the global capital markets.
- Place the integrity of the investment profession and the interests of clients above their own personal interests.
- Use reasonable care and exercise independent professional judgment when conducting investment analysis, making investment recommendations, taking investment actions, and engaging in other professional activities.
- Practice and encourage others to practice in a professional and ethical manner that will reflect credit on themselves and the profession.
- Promote the integrity of and uphold the rules governing capital markets.
- Maintain and improve their professional competence and strive to maintain and improve the competence of other investment professionals.

Standards of Professional Conduct

I. Professionalism
A. Knowledge of the Law. Members and Candidates must understand and comply with all applicable laws, rules, and regulations (including the CFA Institute Code of Ethics and Standards of Professional Conduct) of any government, regulatory organization, licensing agency, or professional association governing their professional activities. In the event of conflict, Members and Candidates must comply with the more strict law, rule, or regulation. Members and Candidates must not knowingly participate or assist in and must dissociate from any violation of such laws, rules, or regulations.

B. Independence and Objectivity. Members and Candidates must use reasonable care and judgment to achieve and maintain independence and objectivity in their professional activities. Members and Candidates must not offer, solicit, or accept any gift, benefit, compensation, or consideration that reasonably could be expected to compromise their own or another’s independence and objectivity.

C. Misrepresentation. Members and Candidates must not knowingly make any misrepresentations relating to investment analysis, recommendations, actions, or other professional activities.

D. Misconduct. Members and Candidates must not engage in any professional conduct involving dishonesty, fraud, or deceit or commit any act that reflects adversely on their professional reputation, integrity, or competence.

II. Integrity of Capital Markets
A. Material Nonpublic Information. Members and Candidates who possess material nonpublic information that could affect the value of an investment must not act or cause others to act on the information.

B. Market Manipulation. Members and Candidates must not engage in practices that distort prices or artificially inflate trading volume with the intent to mislead market participants.

III. Duties to Clients
A. Loyalty, Prudence, and Care. Members and Candidates have a duty of loyalty to their clients and must act with reasonable care and exercise prudent judgment. Members and Candidates must act for the benefit of their clients.
and place their clients’ interests before their employer’s or their own interests.

B. Fair Dealing. Members and Candidates must deal fairly and objectively with all clients when providing investment analysis, making investment recommendations, taking investment action, or engaging in other professional activities.

C. Suitability.

1. When Members and Candidates are in an advisory relationship with a client, they must:
   a. Make a reasonable inquiry into a client’s or prospective client’s investment experience, risk and return objectives, and financial constraints prior to making any investment recommendation or taking investment action and must reassess and update this information regularly.
   b. Determine that an investment is suitable to the client’s financial situation and consistent with the client’s written objectives, mandates, and constraints before making an investment recommendation or taking investment action.
   c. Judge the suitability of investments in the context of the client’s total portfolio.

2. When Members and Candidates are responsible for managing a portfolio to a specific mandate, strategy, or style, they must make only investment recommendations or take only investment actions that are consistent with the stated objectives and constraints of the portfolio.

D. Performance Presentation. When communicating investment performance information, Members and Candidates must make reasonable efforts to ensure that it is fair, accurate, and complete.

E. Preservation of Confidentiality. Members and Candidates must keep information about current, former, and prospective clients confidential unless:

1. The information concerns illegal activities on the part of the client or prospective client,
2. Disclosure is required by law, or
3. The client or prospective client permits disclosure of the information.

IV. Duties to Employers

A. Loyalty. In matters related to their employment, Members and Candidates must act for the benefit of their employer and not deprive their employer of the advantage of their skills and abilities, divulge confidential information, or otherwise cause harm to their employer.

B. Additional Compensation Arrangements. Members and Candidates must not accept gifts, benefits, compensation, or consideration that competes with or might reasonably be expected to create a conflict of interest with their employer’s interest unless they obtain written consent from all parties involved.

C. Responsibilities of Supervisors. Members and Candidates must make reasonable efforts to detect and prevent violations of applicable laws, rules, regulations, and the Code and Standards by anyone subject to their supervision or authority.

V. Investment Analysis, Recommendations, and Actions

A. Diligence and Reasonable Basis. Members and Candidates must:

1. Exercise diligence, independence, and thoroughness in analyzing investments, making investment recommendations, and taking investment actions.
2. Have a reasonable and adequate basis, supported by appropriate research and investigation, for any investment analysis, recommendation, or action.

B. Communication with Clients and Prospective Clients. Members and Candidates must:

1. Disclose to clients and prospective clients the basic format and general principles of the investment processes they use to analyze investments, select securities, and construct portfolios and must promptly disclose any changes that might materially affect those processes.
2. Use reasonable judgment in identifying which factors are important to their investment analyses, recommendations, or actions and include those factors in communications with clients and prospective clients.
3. Distinguish between fact and opinion in the presentation of investment analysis and recommendations.

C. Record Retention. Members and Candidates must develop and maintain appropriate records to support their investment analyses, recommendations, actions, and other investment-related communications with clients and prospective clients.

VI. Conflicts of Interest

A. Disclosure of Conflicts. Members and Candidates must make full and fair disclosure of all matters that could reasonably be expected to impair their independence and objectivity or interfere with respective duties to their clients, prospective clients, and employer. Members and Candidates must ensure that such disclosures are prominent, are delivered in plain language, and communicate the relevant information effectively.

B. Priority of Transactions. Investment transactions for clients and employers must have priority over investment transactions in which a Member or Candidate is the beneficial owner.

C. Referral Fees. Members and Candidates must disclose to their employer, clients, and prospective clients, as appropriate, any compensation, consideration, or benefit received from or paid to others for the recommendation of products or services.

VII. Responsibilities as a CFA Institute Member or CFA Candidate

A. Conduct as Members and Candidates in the CFA Program. Members and Candidates must not engage in any conduct that compromises the reputation or integrity of CFA Institute or the CFA designation or the integrity, validity, or security of the CFA examinations.

B. Reference to CFA Institute, the CFA Designation, and the CFA Program. When referring to CFA Institute, CFA Institute membership, the CFA designation, or candidacy in the CFA Program, Members and Candidates must not misrepresent or exaggerate the meaning or implications of membership in CFA Institute, holding the CFA designation, or candidacy in the CFA program.

Rueschhoff, Nozolin, and David Struppeck. 2000. "Equity Returns: Local GAAP versus US GAAP for Foreign Issuers from Developing Countries." Journal of International Accounting 33, no. 3 (Spring).

A
Abnormal rate of return  The amount by which a security’s actual return differs from its expected rate of return, which is based on the market’s rate of return and the security’s relationship with the market.
Accumulation phase  Phase in the investment life cycle during which individuals in the early to middle years of their working career attempt to accumulate assets to satisfy short-term needs and longer term goals.
Actuarial rate of return  The discount rate used to find the present value of a defined benefit pension plan’s future obligations and thus determine the size of the firm’s annual contribution to the plan.
Agency conflict  An ethical problem that can arise any time one person (i.e., agent) is hired to perform a service or act in the interest of another (i.e., principal).
Algorithmic trading  Trading carried out based upon computer programs (algorithms) that specify trading instructions determined by either fundamental events (e.g., earning announcements or earnings revisions) or technical signals (momentum patterns or other technical rules). Trades implemented using the computer algorithms can react significantly faster than human traders—the algorithmic traders can be in and out of a stock in micro-seconds. The result is higher trading volume but also the potential for greater volatility (see “Flash Crash”).
Alpha  A term commonly used to describe a manager’s abnormal rate of return, which is the difference between the return the portfolio actually produced and the expected return given its risk level.
Alternative asset  A nontraditional (i.e., not common stocks or bonds) asset class investment, including hedge funds, private equity, real estate, and commodities.
Alternative trading system (ATS)  A nontraditional, computerized trading system that competes with or supplements dealer markets and traditional stock exchanges. They are typically crossing networks in which buy and sell orders are matched and executed at a single price. While they facilitate trading in shares, they do not provide listing services.
American Depository Receipts (ADRs)  Certificates of ownership issued by a U.S. bank that represent indirect ownership of a certain number of shares of a specific foreign firm. Shares are held on deposit in a bank in the firm’s home country.
American option  An option contract that can be exercised at any time until its expiration date.
Analysis effect  The difference in performance of a security portfolio from that of a chosen index due to acquisition of temporarily mispriced issues that then move to their correct prices.
Anomalies  Security price relationships that appear to contradict a well-regarded hypothesis—in this case, the efficient market hypothesis.
Arbitrage  A trading strategy designed to generate a guaranteed profit from a transaction that requires no capital commitment or risk bearing on the part of the trader. A simple example of an arbitrage trade would be the simultaneous purchase and sale of the same security in different markets at different prices.
Arbitrage pricing theory (APT)  A theory that posits that the expected return to a financial asset can be described by its relationship with several common risk factors. The multifactor APT can be contrasted with the single-factor CAPM.
Arithmetic mean (AM)  A measure of mean annual rates of return equal to the sum of annual holding period rates of return divided by the number of years.
Asset allocation  The process of deciding how to distribute an investor’s wealth among different asset classes for investment purposes.
Asset-backed securities (ABS)  Securitized debt that can be backed by a range of assets beyond the traditional mortgage assets. The other assets include car loans, credit card debt, student loans, or home equity loans.
Asset class  Securities that have similar characteristics, attributes, and risk/return relationships.
Asset-liability management  A matched-funding approach to portfolio management where the characteristics (e.g., cash flow amount, duration) of the assets are coordinated with those of the liabilities that the investor faces.
Assets under management (AUM)  The total market value of the assets managed by an investment firm.
At the money  A special case of an option where the exercise price and the price of the underlying asset are identical.
Attribution analysis  An assessment technique designed to establish whether a manager’s performance relative to a benchmark resulted from market timing or security selection skills.
Auction-rate securities (ARS)  Securities issued by municipalities, hospitals, and museums in an attempt to pay short-term rates for long-term capital. Specifically, these securities have long-term maturities (20–30 years), but they act like short-term securities in terms of required yield because the coupon is constantly being reset during frequent auctions every week to 35 days. The risk (that became reality in 2007–2008) is that the auctions can “fail” when there are not enough bids to sell all the bonds available (i.e., for various reasons holders do not want to renew their positions).
**Autocorrelation test** A test of the efficient market hypothesis that compares security price changes over time to check for predictable correlation patterns.

**Average tax rate** A person’s total tax payment divided by his or her total income.

**B**

**Backtest** A method of testing a quantitative model in which computers are used to examine the composition and returns of portfolios based on historical data to determine if the selected strategy would have worked in the past.

**Backwarddated** A condition in a futures market where the current contract price is less than the current spot price for the underlying asset.

**Balance sheet** A financial statement that shows what assets the firm controls at a fixed point in time and how and when it has financed these assets.

**Balanced fund** A mutual fund with, generally, a three-part investment objective: (1) to conserve the investor’s principal, (2) to pay current income, and (3) to increase both principal and income. The fund aims to achieve this by owning a mixture of bonds, preferred stocks, and common stocks.

**Basis** The difference between the spot price of the underlying asset and the futures contract price at any point in time (e.g., the initial basis at the time of contract origination, the cover basis at the time of contract termination).

**Basis of an asset** For tax purposes, the cost of an asset.

**Basis risk** The residual exposure to the price volatility of an underlying asset that results from a cross hedge transaction.

**Bearer bond** An unregistered bond for which ownership is determined by possession. The holder receives interest payments by clipping coupons attached to the security and sending them to the issuer for payment.

**Behavioral finance** Involves the analysis of various psychological traits of individuals and how these traits affect how they act as investors, analysts, and portfolio managers.

**Benchmark error** Situation where an inappropriate or incorrect benchmark is used to compare and assess portfolio returns and management.

**Benchmark portfolio** A comparison standard of risk and assets included in the policy statement and similar to the investor’s risk preference and investment needs, which can be used to evaluate the investment performance of the portfolio manager.

**Beta** A standardized measure of systematic risk based upon an asset’s covariance with the market portfolio.

**Binomial option pricing model** A valuation equation that assumes the price of the underlying asset changes through a series of discrete upward or downward movements.

**Black-Scholes option pricing model** A valuation equation that assumes the price of the underlying asset changes continuously through the option’s expiration date by a statistical process known as geometric Brownian motion.

**Bond insurance** Insurance policies written by commercial insurance companies wherein the insurance company agrees to pay the bondholder principal and/or coupon interest that is due on a bond that is not paid by the issuer. These policies were originally issued only on municipal bonds, but have subsequently been written for corporate bonds and collateralized issues. Insured bond issues generally receive the bond rating equal to that held by the insurance company.

**Bond ladder** A strategy for managing a fixed-income portfolio where the investment funds are divided evenly among bonds that mature at regular intervals surrounding the desired time horizon.

**Bond price volatility** The percentage changes in bond prices over time.

**Bond swap** An active bond portfolio management strategy that exchanges one position for another to take advantage of some difference between them.

**Business risk** The variability of operating income arising from the characteristics of the firm’s industry. Two sources of business risk are sales variability and operating leverage.

**Buy-and-hold strategy** A passive portfolio management strategy in which securities (bonds or stocks) are bought and held to maturity.

**C**

**Call market** A market in which trading for individual stocks only takes place at specified times. All the bids and asks available at the time are combined and the market administrators specify a single price that will possibly clear the market at that time.

**Call option** Option to buy an asset within a certain period at a specified price called the exercise price.

**Call premium** Amount above par that an issuer must pay to a bondholder for retiring the bond before its stated maturity.

**Call provisions** Specifies when and how a firm can issue a call for bonds outstanding prior to their maturity.

**Cap agreement** A contract that on each settlement date pays the holder the greater of the difference between the reference rate and the cap rate or zero; it is equivalent to a series of call options at the reference rate.

**Capital appreciation** A return objective in which the investor seeks to increase the portfolio value, primarily through capital gains, over time to meet a future need rather than dividend yield.

**Capital asset pricing model (CAPM)** A theory concerned with deriving the expected or required rates of return on risky assets based on the assets’ systematic risk relative to a market portfolio.

**Capital market instruments** Fixed-income or equity investments that trade in the secondary market.

**Capital market line (CML)** The line from the intercept point that represents the risk-free rate tangent to the original efficient frontier; it becomes the new efficient frontier since investments on this line dominate all the portfolios on the original Markowitz efficient frontier.

**Capital preservation** A return objective in which the investor seeks to minimize the risk of loss; generally a goal of the risk-averse investor.

**Certificates of deposit (CDs)** Instruments issued by banks and S&Ls that require minimum deposits for specified terms and that pay higher rates of interest than deposit accounts.

**Characteristic line** Regression line that indicates the systematic risk (beta) of a risky asset.

**Closed-end investment company** An investment company that issues only a limited number of shares, which it does not redeem (buy back). Instead, shares of a closed-end fund are traded in securities markets at prices determined by supply and demand.
Coefficient of variation (CV) A measure of relative variability that indicates risk per unit of return. It is equal to: standard deviation divided by the mean value. When used in investments, it is equal to: standard deviation of returns divided by the expected rate of return.

Coincident indicators A set of economic variables whose values reach peaks and troughs at about the same time as the aggregate economy.

Collar agreement A hedging arrangement where an underlying asset is protected against decreases in value by the simultaneous purchase of a put option and sale of a call option.

Collateral trust bonds A mortgage bond wherein the assets backing the bond are financial assets like stocks and bonds.

Collateralized debt obligations (CDOs) Considered part of the asset-backed securities (ABSs) market because they are backed by the cash flows from a portfolio of securities. In contrast to the specific securities such as mortgages, credit card debt, and auto loans, CDOs are unique because they will generally include a variety of debt with a diversity of credit ratings. Finally, there are typically several tranches with different credit ratings from AAA to non-investment grade.

Collateralized mortgage obligation (CMO) A debt security based on a pool of mortgage loans that provides a relatively predictable term by paying of tranches in specified order.

Commission brokers Employees of a member firm who buy or sell securities for the customers of the firm.

Common stock An equity investment that represents ownership of a firm, with full participation in its success or failure. The firm’s directors must approve dividend payments.

Common-size statements The normalization of balance sheet and income statement items to allow for more meaningful comparison of different-sized firms. Balance sheet items are divided by total assets; income statement items are divided by total sales.

Competitive bid An underwriting alternative wherein an issuing entity (governmental body or a corporation) specifies the type of security to be offered (bonds or stocks) and the general characteristics of the issue, and the issuer solicits bids from competing investment banking firms with the understanding that the issuer will accept the highest bid from the bankers.

Competitive environment The level of intensity of competition among firms in an industry, determined by an examination of five competitive forces.

Competitive strategy The search by a firm for a favorable competitive position within an industry within the known competitive environment.

Competently diversified portfolio A portfolio in which all unsystematic risk has been eliminated by diversification.

Completeness fund A specialized index used to form the basis of a passive portfolio whose purpose is to provide diversification to a client’s total portfolio by excluding those segments in which the client’s active managers invest.

Composite Leading Indicator Index An index that reflects the composite performance of 10 economic series that have historically experienced peaks and troughs before corresponding peaks and troughs in aggregate economic activity. Results for this composite index are published monthly by The Conference Board.

Composite measure An investment performance statistic that considers both the return and risk associated with a portfolio (e.g., Sharpe measure, Treynor measure, Jensen measure).

Computer-Assisted Execution System (CAES) A service created by Nasdaq that automates order routing and execution for securities listed on domestic stock exchanges and involved on the Intermarket Trading System (ITS).

Consolidated Quotation System (CQS) An electronic quotation service for issues listed on the NYSE, the AMEX, or regional exchanges and traded on the Nasdaq InterMarket.

Consolidation phase Phase in the investment life cycle during which individuals who are typically past the midpoint of their career have earnings that exceed expenses and invest them for future retirement or estate planning needs.

Construct the portfolio Given the strategy and economic outlook, what specific stocks and/or bonds will be put into the portfolio at the present time that are consistent with the client’s policy statement.

Contango A situation in a futures market where the current contract price is greater than the current spot price for the underlying asset.

Contingent deferred sales load A mutual fund that imposes a sales charge when the investor sells or redeems shares; also referred to as rear-end loads or redemption charges.

Continual monitoring The constant evaluation of the economic environment, the policy statement, and the portfolio to ensure that it is consistent with the policy statement. Also involves evaluating performance to determine if changes are required in the portfolio, the strategy, or the policy statement.

Continuous market A market where stocks are priced and traded continuously by an auction process or by dealers when the market is open.

Contract price The transaction price specified in a forward or futures contract.

Contrarian An investment strategy that attempts to buy (or sell) securities on which the majority of other investors are bearish (or bullish).

Convenience yield An adjustment made to the theoretical forward or futures contract delivery price to account for the preference that consumers have for holding spot positions in the underlying asset.

Conversion factors The adjustments made to Treasury bond futures contract terms to allow for the delivery of an instrument other than the standardized underlying asset.

Conversion parity price The price at which common stock can be obtained by surrendering the convertible instrument at par value.

Conversion premium The excess of the market value of the convertible security over its equity value if immediately converted into common stock. Typically expressed as a percentage of the equity value.

Conversion ratio The number of shares of common stock for which a convertible security may be exchanged.

Conversion value The value of the convertible security if converted into common stock at the stock’s current market price.

Convertible bonds A bond with the added feature that the bondholder has the option to turn the bond back to the firm in exchange for a specified number of common shares of the firm.

Convexity A measure of the degree to which a bond’s price-yield curve departs from a straight line. This characteristic affects estimates of a bond’s price volatility for a given change in yields.

Core-plus bond portfolio management This is a combination approach to bond portfolio management wherein a significant (core)
part of the portfolio (e.g., 70–75 percent) is managed passively in a widely recognized sector of the bond market, such as an aggregate bond index or a U.S. government/corporate sector. The rest of the portfolio would be actively managed in one or several “plus” sectors that are less efficient than the core component—for example, high-yield bonds, foreign bonds, or emerging market debt.

**Correlation coefficient** A standardized measure of the relationship between two variables that ranges from −1.00 to +1.00.

**Cost of carry** The net amount that would be required to store a commodity or security for future delivery, usually calculated as physical storage costs plus financial capital costs less dividends paid to the underlying asset.

**Counterparty** A participant to a derivative transaction.

**Country risk** Uncertainty due to the possibility of major political or economic change in the country where an investment is located; also called political risk.

**Coupon** Indicates the interest payment on a debt security. It is the coupon rate times the par value that indicates the interest payments on a debt security.

**Coupon reinvestment risk** The component of interest rate risk due to the uncertainty of the rate at which coupon payments will be reinvested.

**Covariance** A measure of the degree to which two variables, such as rates of return for investment assets, move together over time relative to their individual mean returns.

**Covered call** A trading strategy in which a call option is sold as a supplement to a long position in an underlying asset or portfolio of assets.

**Covered interest arbitrage** A trading strategy involving borrowing money in one country and lending it to another designed to exploit price deviations from the interest rate parity model.

**Credit analysis** An active bond portfolio management strategy designed to identify bonds that are expected to experience changes in rating. This strategy is critical when investing in high-yield bonds.

**Credit default swap** An agreement in which the protection buyer makes periodic premium payments in exchange for the protection seller’s obligation to make a settlement payment that is contingent on the occurrence of a credit-related event to a predetermined reference entity, usually a specific bond or bond index.

**Cross hedge** A trading strategy in which the price volatility of a commodity or security position is hedged with a forward or futures contract based on a different underlying asset or different settlement terms.

**Crossover price** The price at which the yield to maturity equals the yield to call. Above this price, yield to call is the appropriate yield measure; below this price, yield to maturity is the appropriate yield measure.

**Cross-sectional analysis** An examination of a firm’s performance in comparison to other firms in the industry with similar characteristics to the firm being studied.

**Cross-sectional return studies** Studies wherein investigators look for public information that can be used to predict the cross-sectional distribution of risk-adjusted returns—for example, is there an inverse relationship between market-value size of a firm and future risk-adjusted rates of return for its stock?

**Current income** A return objective in which the investor seeks to generate income rather than capital gains. This is generally a goal of an investor who wants to supplement earnings with income to meet living expenses.

**Current yield** A bond’s yield as measured by its current income (coupon) as a percentage of its market price.

**Cyclical change** An economic trend arising from the ups and downs of the business cycle.

**Cyclical company** A firm whose earnings rise and fall with general economic activity.

**Cyclical stock** A stock with a high beta; its gains typically exceed those of a rising market and its losses typically exceed those of a falling market.
DuPont system  A method of examining ROE by breaking it down into three component parts: (1) profit margin, (2) total asset turnover, and (3) financial leverage.

Duration  A measure of the interest rate sensitivity of a bond’s market price taking into consideration its coupon and term to maturity; the percent change in price for 100-basis point change in yield.

Duration strategy  A portfolio management strategy employed to reduce the interest rate risk of a bond portfolio by matching the modified duration of the portfolio with its investment horizon. For example, if the investment horizon is 10 years, the portfolio manager would construct a portfolio that has a modified duration of 10 years. This strategy is referred to as immunization of the portfolio.

E  Earnings momentum  A strategy in which portfolios are constructed of stocks of firms with rising earnings.

Earnings multiplier model  A technique for estimating the value of a stock issue as a multiple of its future earnings per share.

Earnings surprise  A company announcement of earnings that differ from analysts’ prevailing expectations.

EBITDA  Earnings before interest, taxes, depreciation, and amortization.

Economic value added (EVA)  Internal management performance measure that compares net operating profit to total cost of capital. Indicates how profitable company projects are as a sign of management performance.

Effective duration  Direct measure of the interest rate sensitivity of a bond (or any financial instrument) based upon price changes derived from a pricing model.

Efficient capital market  A market in which security prices rapidly reflect all information about securities.

Efficient frontier  The set of portfolios that has the maximum rate of return for every given level of risk, or the minimum risk for every potential rate of return.

Electronic Communication Network (ECN)  A computerized trading system that matches buy and sell orders, usually for retail and small institutional trading. ECNs act as customers as a broker—they do not buy or sell from their own accounts. Put another way, they are electronic order books without designated market makers.

Electronic Crossing System (ECS)  An electronic trading system that matches large buy and sell orders.

Empirical duration  Measures directly the interest rate sensitivity of an asset by examining the percentage price change for an asset in response to a change in yield during a specified period of time.

Ending-wealth value  The total amount of money derived from investment in a bond until maturity, including principal, coupon payments, and income from reinvestment of coupon payments.

Enhanced indexing  A portfolio management strategy that attempts to outperform a designated benchmark on a risk-adjusted basis by combining passive (i.e., indexed) and active management approaches.

Equipment trust certificates  Mortgage bonds that are secured by specific pieces of transportation equipment like boxcars and planes.

Equity collar  An option-based hedging strategy that protects a stock position from price declines by purchasing a put option that is paid for by the sale of a call option.

Equity swap  A swap transaction in which one cash flow is tied to the return to an equity portfolio position, often an index such as the Standard and Poor’s 500, while the other is based on a floating-rate index.

Equivalent taxable yield (ETY)  A yield on a tax-exempt bond that adjusts for its tax benefits to allow comparisons with taxable bonds.

Estimated rate of return  The rate of return an investor anticipates earning from a specific investment over a particular future holding period.

Eurobonds  Bonds denominated in a currency other than the currency in which they are issued.

European option  An option contract that can only be exercised on its expiration date.

Event study  Research that examines the reaction of a security’s price to a specific company, world event, or news announcement.

Exchange clearinghouse  The functional unit attached to a futures exchange that guarantees contract performance, oversees delivery, serves as a bookkeeper, and calculates settlement transactions.

Exchange rate risk  Uncertainty due to the denomination of an investment in a currency other than that of the investor’s own country.

Exchange-traded fund (ETF)  A tradable depository receipt that gives investors a pro rata claim to the returns associated with a portfolio of securities (often designed to mimic an index, such as the Standard and Poor’s 500) held in trust by a financial institution.

Exercise price  The transaction price specified in an option contract; also known as the strike price.

Expected rate of return  The return that analysts’ calculations suggest a security should provide, based on the market’s rate of return during the period and the security’s relationship to the market.

Expense ratio  The percentage of a fund’s assets deducted annually for expenses, including management fees, administrative fees, and operating costs, but not including security trading fees.

Expiration  The expiration date of a derivative security.

Extended DuPont System  A method of examining ROE by breaking it down into five component parts.

External efficiency  A market in which prices adjust quickly to new information regarding supply or demand. Also referred to as informational efficiency.

F  Fiduciary  A person who supervises or oversees the investment portfolio of a third party, such as in a trust account, and makes investment decisions in accordance with the owner’s wishes.

Filter rule  A trading rule that recommends security transactions when price changes exceed a previously determined percentage.

Financial risk  The variability of future income arising from the firm’s fixed financing costs, for example, interest payments. The effect of fixed financial costs is to magnify the effect of changes in operating profit on net income or earnings per share.

Fixed-income investments  Loans with contractually mandated payment schedules from firms or governments to investors.

Flash crash  A major decline in stock prices that occurred on May 6, 2010, caused by a group of sell transactions imbedded in an algorithmic trading program. The sudden decline caused several other trading programs to withdraw from the market that resulted in
significant illiquidity and the crash. Subsequently the market recovered almost as fast and many of the drastic market trades were cancelled.

**Flat trend channel** The range defined by security prices as they maintain a relatively steady level.

**Flexible portfolio fund** Mutual fund that allows managers to shift assets between stocks, bonds, and cash according to changing market conditions; also known as *asset allocation* fund.

**Floating-rate note (FRN)** Short- to intermediate-term bonds with regularly scheduled coupon payments linked to a variable interest rate, most often LIBOR.

**Floor agreement** A contract that on each settlement date pays the holder the greater of the difference between the floor rate and the reference rate or zero; it is equivalent to a series of put options on the reference rate.

**Floor brokers** Independent members of an exchange who act as brokers for other members.

**Foreign bonds** Bond issues sold primarily in one country and currency by a borrower of a different nationality. For example, a U.S. dollar bond sold in the United States by a Japanese firm (referred to as Yankee bonds).

**Forward contract** An agreement between two counterparties that requires the exchange of a commodity or security at a fixed time in the future at a predetermined price.

**Forward discount** A situation where, from the perspective of the domestic country, the spot exchange rate is smaller than the forward exchange rate with a foreign country.

**Forward premium** A situation where, from the perspective of the domestic country, the spot exchange rate is larger than the forward exchange rate with a foreign country.

**Forward rate** A short-term yield for a future holding period implied by the spot rates of two securities with different maturities.

**Forward rate agreement (FRA)** A transaction in which two counterparties agree to a single exchange of cash flows based on a fixed and floating rate, respectively.

**Franchise factor** A firm’s unique competitive advantage that makes it possible for a firm to earn excess returns (rates of return above a firm’s cost of capital) on its capital projects. In turn, these excess returns and the franchise factor cause the firm’s stock price to have a P/E ratio above its base P/E ratio that is equal to 1/k.

**Free cash flow to equity** This cash flow measure equals cash flow from operations minus capital expenditures and debt payments.

**Full replication** A technique for constructing a passive index portfolio in which all securities in an index are purchased in proportion to their weights in the index.

**Futures contract** An agreement that provides for the future exchange of a particular asset at a specified delivery date in exchange for a specified payment at the time of delivery.

**G**

**General obligation bond (GO)** A municipal issue serviced from and guaranteed by the issuer’s full taxing authority.

**Generally accepted accounting principles (GAAP)** Accounting principles formulated by the Financial Accounting Standards Board and used to construct financial statements.

**Geometric mean (GM)** The nth root of the product of the annual holding period returns for n years minus 1.

**Gifting phase** Phase in the investment life cycle during which individuals use excess assets to financially assist relatives or friends, establish charitable trusts, or construct trusts to minimize estate taxes.

**Government sponsored enterprises (GSEs)** Entities set up by the government to provide support for specific segments of the economy considered important by the government. Prime examples are the Federal National Mortgage Association (referred to as Fannie Mae) and Federal Home Loan Corporation (Freddie Mac) that were set up to reduce the cost of borrowing by home owners. They issue securities directly in the market at rates that are generally higher than Treasuries because they are not backed by the full credit of the government, but lower than corporations. Funds from the sale of securities are used to acquire mortgages that are securitized and sold to institutions and individual investors.

**Growth company** A company that consistently has the opportunities and ability to invest in projects that provide rates of return that exceed the firm’s cost of capital. Because of these investment opportunities, it retains a high proportion of earnings, and its earnings grow faster than those of average firms.

**Growth stock** A stock issue that generates a higher rate of return than other stocks in the market with similar risk characteristics.

**H**

**Hedge** A trading strategy in which derivative securities are used to reduce or completely offset a counterparty’s risk exposure to an underlying asset.

**Hedge fund** An investment vehicle designed to manage a private, unregistered portfolio of assets according to any of several strategies. The investment strategy often employs arbitrage trading and significant financial leverage (e.g., short selling, borrowing, derivatives), while the compensation arrangement for the manager typically specifies considerable profit participation.

**Hedge ratio** The number of derivative contracts that must be transacted to offset the price volatility of an underlying commodity or security position.

**High Frequency Trading (HFT)** Numerous short term trades by firms or institutions that are initiated and determined by computer algorithms as discussed under “algorithmic trading.” The result can be thousands of daily trades with round trip transactions completed in microseconds.

**High-yield bond** A bond rated below investment grade; also referred to as speculative-grade bonds or junk bonds.

**Holdings-base measure** A performance measure based on how a manager changes the portfolio’s security holdings over time, often in comparison to a benchmark portfolio.

**Holding period return (HPR)** The total return from an investment, including all sources of income, for a given period of time. A value of 1.0 indicates no gain or loss. Equal to ending wealth/beginning wealth.

**Holding period yield (HPY)** The total return from an investment for a given period of time stated as a percentage; equal to HPR-1.

**Immunization** A bond portfolio management technique of matching modified duration to the investment horizon of the portfolio to eliminate interest rate risk.

**Implied volatility** The standard deviation of changes in the price of the underlying asset that can be inferred from an option’s market price in relation to a specific valuation model.
In the money  An option that has positive intrinsic value.
Incentive compensation  A scheme for paying investment managers according to the performance of the portfolio, often based on the level of assets under management.
Income bonds  Debentures that stipulate interest payments only if the issuer earns the income to make the payments by specified dates.
Income statement  A financial statement that shows the flow of the firm’s sales, expenses, and earnings over a period of time.
Indenture  The legal agreement that lists the obligations of the issuer of a bond to the bondholder, including payment schedules, call provisions, and sinking funds.
Indexing  A passive bond portfolio management strategy that seeks to match the composition, and therefore the performance, of a selected market index.
Industry life cycle analysis  An analysis that focuses on the industry's stage of development.
Information  An attribute of a good market that includes providing buyers and sellers with timely, accurate information on the volume and prices of past transactions and on all currently outstanding bids and offers.
Information ratio  Statistic used to measure a portfolio’s average return in excess of a comparison, benchmark portfolio divided by the standard deviation of this excess return.
Informationally efficient market  A more technical term for an efficient capital market that emphasizes the role of information in setting the market price.
Initial public offering (IPO)  A new issue by a firm that has no existing public market.
Interest rate anticipation  An active bond portfolio management strategy designed to preserve capital or take advantage of capital gains opportunities by predicting interest rates and their effects on bond prices.
Interest rate collar  The combination of a long position in a cap agreement and a short position in a floor agreement, or vice versa; it is equivalent to a series of range forward positions.
Interest rate parity  The relationship that must exist in an efficient market between the spot and forward foreign exchange rates between two countries and the interest rates in those countries.
Interest rate risk  The uncertainty of returns on an investment due to possible changes in interest rates over time.
Interest rate swap  An agreement calling for the periodic exchange of cash flows, one based on an interest rate that remains fixed for the life of the contract and the other that is linked to a variable-rate index.
Interest-on-interest  Bond income from reinvestment of coupon payments.
Intermarket Trading System (ITS)  A computerized system that connects competing exchanges and dealers who trade stocks listed on an exchange. Its purpose is to help customers find the best market for these stocks at a point in time.
Internal liquidity (solvency) ratios  Financial ratios that measure the ability of the firm to meet future short-term financial obligations.
Internal rate of return (IRR)  The discount rate at which cash outflows of an investment equal cash inflows.
International domestic bonds  Bonds issued by a foreign firm, denominated in the firm’s native currency, and sold within its own country.
Intrinsic value  The portion of a call option's total value equal to the greater of either zero or the difference between the current value of the underlying asset and the exercise price; for a put option, intrinsic value is the greater of either zero or the exercise price less the underlying asset price; for a stock, it is the value derived from fundamental analysis of the stock's expected returns or cash flows.
Investment  The current commitment of dollars for a period of time in order to derive future payments that will compensate the investor for the time the funds are committed, the expected rate of inflation, and the uncertainty of future payments.
Investment company  A firm that sells shares of the company and uses the proceeds to buy portfolios of stock, bonds, or other financial instruments.
Investment decision process  Estimation of intrinsic value for comparison with market price to determine whether or not to invest.
Investment horizon  The time period used for planning and forecasting purposes or the future time at which the investor requires the invested funds.
Investment management company  A company separate from the investment company that manages the portfolio and performs administrative functions.
Investment strategy  A decision by a portfolio manager regarding how he or she will manage the portfolio to meet the goals and objectives of the client. This will include either active or passive management and, if active, what style in terms of top-down or bottom-up or fundamental versus technical.

J
January effect  A frequent empirical anomaly where risk-adjusted stock returns in the month of January are significantly larger than those occurring in any other month of the year.
J-curve effect  The tendency for the returns to private equity funds to be negative initially and then positive in later years as the more profitable investments are realized.
Jensen measure  An absolute measure of a portfolio's risk-adjusted performance, computed as the intercept in a regression equation where the excess returns to a manager's portfolio and the market index are, respectively, the dependent and independent variables.

L
Lagging indicators  A set of economic variables whose values reach peaks and troughs after the aggregate economy.
Leading indicators  A set of economic variables whose values reach peaks and troughs in advance of the aggregate economy.
Limit order  An order that lasts for a specified time to buy or sell a security when and if it trades at a specified price.
Limited partnership  A business organization with one or more general partners who manage the business and assume legal debts and obligations, and one or more limited partners who are liable only to the extent of their investments.
Liquid  Term used to describe an asset that can be quickly converted to cash at a price close to fair market value.
Liquidity  The ability to buy or sell an asset quickly and at a reasonable price based on information.
Liquidity preference hypothesis  One of the alternative explanations for the different shapes of the term structure of interest rates. This hypothesis holds that long-term securities should provide
higher promised yields than short-term securities because of the higher price volatility of long-maturity (high duration) bonds.

**Liquidity risk** Uncertainty due to the ability to buy or sell an investment in the secondary market.

**Long hedge** A long position in a forward or futures contract used to offset the price volatility of a short position in the underlying asset.

**Long position** The buyer of a commodity or security or, for a forward contract, the counterparty who will be the eventual buyer of the underlying asset.

**Long-term, high-priority goal** A long-term financial investment goal of personal importance that typically includes achieving financial independence, such as being able to retire at a certain age.

**Lower-priority goal** A financial investment goal of lesser personal importance, such as taking a luxurious vacation or buying a car every few years.

**Low-load fund** A mutual fund that imposes a moderate front-end sales charge when the investor buys the fund, typically 3 to 4 percent.

**M**

**Macaulay duration** A measure of the time flow of cash from a bond where cash flows are weighted by present values discounted by the yield to maturity.

**Maintenance margin** The required proportion that the investor’s equity value must be to the total market value of the stock. If the proportion drops below this percent, the investor will receive a margin call.

**Management and advisory firm** A firm that provides a range of services from standard banking transactions (savings accounts, personal loans) to advising individual and institutional investors on structuring their portfolios and managing investment funds.

**Management effect** A combination of the interest rate anticipation effect, the analysis effect, and the trading effect.

**Management fee** The compensation an investment company pays to the investment management company for its services. The average annual fee is about 0.5 percent of fund assets.

**Margin** The percent of cost a buyer pays in cash for a security, borrowing the balance from the broker. This introduces leverage, which increases the risk of the transaction.

**Margin account** The collateral posted with the futures exchange clearinghouse by an outside counterparty to insure its eventual performance; the initial margin is the deposit required at contract origination while the maintenance margin is the minimum collateral necessary at all times.

**Margin call** A request by an investor’s broker for additional capital for a security bought on margin if the investor’s equity value declines below the required maintenance margin.

**Marginal tax rate** The part of each additional dollar in income that is paid as tax.

**Marked to market** The settlement process used to adjust the margin account of a futures contract for daily changes in the price of the underlying asset.

**Market** The means through which buyers and sellers are brought together to aid in the transfer of goods and/or services.

**Market order** An order to buy or sell a security immediately at the best price available.

**Market portfolio** The portfolio that includes all risky assets with relative weights equal to their proportional market values.

**Market risk premium** The amount of return above the risk-free rate that investors expect from the market in general as compensation for systematic risk.

**Market value added (MVA)** External management performance measure to compare the market value of the company’s debt and equity with the total capital invested in the firm.

**Maturity strategy** A portfolio management strategy employed to reduce the interest rate risk of a bond portfolio by matching the maturity of the portfolio with its investment horizon. For example, if the investment horizon is 10 years, the portfolio manager would construct a portfolio that will mature in 10 years.

**Mean rates of return** The average of an investment’s returns over an extended period of time.

**Modified duration** A measure of Macaulay duration divided by one plus the bond’s periodic yield used to approximate the bond’s price volatility.

**Money market** The market for short-term debt securities with maturities of less than one year.

**Money market fund** A fund that invests in short-term securities sold in the money market. (Large companies, banks, and other institutions also invest their surplus cash in the money market for short periods of time.) In the entire investment spectrum, these are generally the safest, most stable securities available. They include Treasury bills, certificates of deposit of large banks, and commercial paper (short-term IOUs of large corporations).

**Money-weighted return** The discount rate that sets the present value of a future set of cash flows equal to the investment’s current value; also known as the internal rate of return.

**Mortgage bonds** Bonds that pledge specific assets such as buildings and equipment. The proceeds from the sale of these assets are used to pay off bondholders in case of bankruptcy.

**Moving average** The continually recalculating average of security prices for a period, often 200 days, to serve as an indication of the general trend of prices and also as a benchmark price.

**Multifactor model** An empirical version of the APT where the investor chooses the exact number and identity of the common risk factors used to describe an asset’s risk-return relationship. Risk factors are often designated as *macroeconomic* variables (e.g., inflation, changes in gross domestic product) or *microeconomic* variables (e.g., security-specific characteristics like firm size or book-to-market ratios).

**Municipal bond insurance** See Bond insurance.

**Mutual fund** An investment company that pools money from shareholders and invests in a variety of securities, including stocks, bonds, and money market securities. A mutual fund ordinarily stands ready to buy back (redeem) its shares at their current net asset value, which depends on the market value of the fund’s portfolio of securities at the time. Mutual funds generally continuously offer new shares to investors.

**N**

**Nasdaq InterMarket** A trading system that includes Nasdaq market makers and ECNs that quote and trade stocks listed on the NYSE and the AMEX. It involves dealers from the Nasdaq market and the Intermarket Trading System (ITS). In many ways, this has become what had been labeled the third market.

**National Association of Securities Dealers Automated Quotation ( NASDAQ ) system** An electronic system for providing bid-ask quotes on OTC securities.
Near-term, high-priority goal A short-term financial investment goal of personal importance, such as accumulating funds for making a house down payment or buying a car.

Negotiated sales An underwriting arrangement wherein the sale of a security issue by an issuing entity (governmental body or a corporation) is done using an investment banking firm that maintains an ongoing relationship with the issuer. The characteristics of the security issue are determined by the issuer in consultation with the investment banker.

Net asset value (NAV) per share The market value of an investment company’s assets (securities, cash, and any accrued earnings) after deducting liabilities, divided by the number of shares outstanding.

Net present value (NPV) A measure of the excess cash flows expected from an investment proposal. It is equal to the present value of the cash inflows from an investment proposal, discounted at the required rate of return for the investment, minus the present value of the cash outflows required by the investment, also discounted at the investment’s required rate of return. If the derived net present value is a positive value (i.e., there is an excess net present value), the investment should be acquired since it will provide a rate of return above its required returns.

New issue Common stocks or bonds offered by companies for public sale.

No-load fund A mutual fund that sells its shares at net asset value without adding sales charges.

Nominal yield A bond’s yield as measured by its coupon rate.

Normal portfolio A specialized or customized benchmark constructed to evaluate a specific manager’s investment style or philosophy.

Notes Intermediate-term debt securities with maturities longer than 1 year but less than 10 years.

Notional principal The principal value of a swap transaction, which is not exchanged but is used as a scale factor to translate interest rate differentials into cash settlement payments.

O

Objectives The investor’s goals expressed in terms of risk and return and included in the policy statement.

Offensive competitive strategy A strategy whereby a firm attempts to use its strengths to affect the competitive forces in the industry and, in so doing, improves the firm’s relative position in the industry.

130/30 strategy An active equity portfolio management approach that allows short positions up to a certain percentage (e.g., 30) of capital and an equal percentage of leveraged long positions.

Open-end investment company The more formal name for a mutual fund, which derives from the fact that it continuously offers new shares to investors and redeems them (buys them back) on demand.

Operating efficiency ratios Financial ratios intended to indicate how efficiently management is utilizing the firm’s assets in terms of dollar sales generated per dollar of assets. Primary examples would be: total asset turnover, fixed asset turnover, or equity turnover.

Operating leverage The use of fixed-production costs in the firm’s operating cost structure. The effect of fixed costs is to magnify the effect of a change in sales on operating profits.

Operating profitability ratios Financial ratios intended to indicate how profitable the firm is in terms of the percent of profit generated from sales. Alternative measures would include operating profit (EBIT)/net sales, pretax profit (EBT)/net sales, and net profit/sales.

Optimal portfolio The portfolio on the efficient frontier that has the highest utility for a given investor. It lies at the point of tangency between the efficient frontier and the curve with the investor’s highest possible utility.

Option-adjusted duration An estimate of the duration of a bond that specifically adjusts for the existence of an embedded put and/or call option in the bond. It can be envisioned as the duration of a noncallable bond minus the duration of an embedded call option or plus the duration of an embedded put option.

Options Clearing Corporation (OCC) A company designed to guarantee, monitor margin accounts, and settle exchange-traded option transactions.

Option contract An agreement that grants the owner the right, but not the obligation, to make a future transaction in an underlying commodity or security at a fixed price and within a predetermined time in the future.

Option premium The initial price that the option buyer must pay to the option seller to acquire the contract.

Option-adjusted spread A type of yield spread that considers changes in the term structure and alternative estimates of the volatility of interest rates. It is spread after adjusting for embedded options.

Options Clearing Corporation (OCC) A company designed to guarantee, monitor margin accounts, and settle exchange-traded option transactions.

OTC Electronic Bulletin Board (OTCBB) A regulated quotation service that displays real-time quotes, last-sale prices, and volume information for a specified set of over-the-counter (OTC) securities that are not traded on the formal Nasdaq market.

Out of the money An option that has no intrinsic value.

Overfunded plan A defined benefit pension plan in which the present value of the pension liabilities is less than market value of the plan’s assets.

Overweighted A condition in which a portfolio, for whatever reason, includes more of a class of securities than the relative market value alone would justify.

P

Par value See Principal.

Payback The time required for the added income from the convertible security relative to the stock to offset the conversion premium.

Peak The culmination of a bull market when prices stop rising and begin declining.

Peer group comparison A method of measuring portfolio performance by collecting the returns produced by a representative universe of investors over a specific period of time.

Performance presentation standards (PPS) A comprehensive set of reporting guidelines created by the Association for Investment Management and Research (AIMR) (now the CFA Institute), in an effort to fulfill the call for uniform, accurate, and consistent performance reporting.
Perpetuity  An investment without any maturity date. It provides returns to its owner indefinitely.

Personal trust  An amount of money set aside by a grantor and often managed by a third party, the trustee. Often constructed so one party receives income from the trust’s investments and another party receives the residual value of the trust after the income beneficiaries’ death.

Policy effect  The difference in performance of a bond portfolio from that of a chosen index due to differences in duration, which result from a fund’s investment policy.

Policy statement  A statement in which the investor specifies investment goals, constraints, and risk preferences.

Portfolio  A group of investments. Ideally, the investments should have different patterns of returns over time.

Portfolio turnover  The total dollar value of securities sold from a portfolio in a year divided by the average assets under management for the fund during the same period.

Preferred stock  An equity investment that stipulates the dividend payment either as a coupon or a stated dollar amount. The firm’s directors may withhold dividend payments.

Premium  A bond selling at a price above par value due to capital market conditions.

Price continuity  A feature of a liquid market in which there are small price changes from one transaction to the next due to the depth of the market.

Price momentum  A portfolio strategy in which you acquire stocks that have enjoyed above-market stock price increases.

Price risk  The component of interest rate risk due to the uncertainty of the market price of a bond caused by changes in market interest rates.

Price/earnings (P/E) ratio  The number by which expected earnings per share is multiplied to estimate a stock’s value; also called the earnings multiplier.

Price-weighted index  An index calculated as an arithmetic mean of the current prices of the sampled securities.

Price-yield curve  Created by plotting the set of computed prices for a specific bond against an alternative set of potential yields. It generally shows the convexity of the curve.

Primary market  The market in which newly issued securities are sold by their issuers, who receive the proceeds.

Principal (par value)  The original value of the debt underlying a bond that is payable at maturity.

Private equity  An ownership interest in a company or collection of assets that is not publicly traded on an exchange or in the over-the-counter market.

Private placement  A new issue sold directly to a small group of investors, usually institutions.

Promised yield to call (YTC)  A bond’s yield if held until the first available call date, with reinvestment of all coupon payments at the yield-to-call rate.

Promised yield to maturity (YTM)  The most widely used measure of a bond’s yield that states the fully compounded rate of return on a bond bought at market price and held to maturity with reinvestment of all coupon payments at the yield to maturity rate.

Protective put  A trading strategy in which a put option is purchased as a supplement to a long position in an underlying asset or portfolio of assets; the most straightforward form of portfolio insurance.

Public bond  A long-term, fixed-obligation debt security in a convenient, affordable denomination for sale to individuals and financial institutions.

Pure auction market  A trading system in which interested buyers and sellers submit bid and ask prices for given stocks to a central location where the orders are matched by a broker who does not own the stock but acts as a facilitating agent. In the current environment the facilitator can be a computer as well as an individual.

Pure cash-matched dedicated portfolio  A conservative dedicated portfolio management technique aimed at developing a bond portfolio that will provide cash payments that exactly match the specified liability schedules.

Put options  Options to sell a security (stock or bond) within a certain period at a specified price.

Put-call parity  The relationship that must exist in an efficient market between the prices for put and call options having the same underlying asset, exercise price, and expiration date.

Q

Quadratic optimization  A technique that relies on historical correlations in order to construct a portfolio that seeks to minimize tracking error with an index.

Quality financial statements  Financial statements that most knowledgeable observers (analysts, portfolio managers) would consider conservatively prepared in terms of sales, expenses, earnings, and asset valuations. The results reported would reflect reasonable estimates and indicate what truly happened during the period and the legitimate value of assets and liabilities on the balance sheet.

R

Range forward  A trading strategy based on a variation of the put-call parity model where, for the same underlying asset but different exercise prices, a call option is purchased and a put option is sold (or vice versa).

Rate anticipation effect  The difference in return because of changing the duration of the portfolio during a period as compared with the portfolio’s long-term policy duration.

Real estate investment trusts (REITs)  Investment funds that hold portfolios of real estate investments.

Real options  Options embedded in a firm’s real assets that give managers valuable decision-making flexibility, such as the right to either undertake or abandon an investment project.

Real risk-free rate (RRFR)  The basic interest rate with no accommodation for inflation or uncertainty; the pure time value of money.

Realized capital gains  Capital gains that result when an appreciated asset is sold; realized capital gains are taxable.

Realized yield  The expected compounded yield on a bond that is sold before it matures assuming the reinvestment of all cash flows at an explicit rate. Also called horizon yield for the yield realized during an investment horizon period.

Refunding issue  Bonds that provide funds to prematurely retire another bond issue. These bonds can be either a junior or senior issue.

Registered bond  A bond for which ownership is registered with the issuer. The holder receives interest payments by check directly from the issuer.
Registered competitive market makers (RCMMs)  Members of an exchange who are allowed to use their memberships to buy or sell for their own account within the specific trading obligations set down by the exchange.

Registered traders  Members of the stock exchange who are allowed to use their memberships to buy and sell for their own account, which means they save commissions on their trading but they provide liquidity to the market, and they abide by exchange regulations on how they can trade.

Relative-strength (RS) ratio  The ratio of a stock price or an industry index value to a market indicator series, indicating the stock’s or the industry’s performance relative to the overall market.

Required rate of return  The return that compensates investors for their time, the expected rate of inflation, and the uncertainty of the return.

Resistance level  A price at which a technician would expect a substantial increase in the supply of a stock to reverse a rising trend.

Return prediction studies  Studies wherein investigations attempt to predict the time series of future rates of return using public information. An example would be predicting above-average returns for the stock market based on the aggregate dividend yield—for example, a high dividend yield indicates above average future market returns.

Revenue bond  A bond that is serviced by the income generated from specific revenue-producing projects of the municipality such as toll roads or athletic stadiums.

Rising trend channel  The range defined by security prices as they move progressively higher.

Risk  The uncertainty that an investment will earn its expected rate of return.

Risk averse  The assumption about investors that they will choose the least risky alternative, all else being equal.

Risk premium (RP)  The increase over the nominal risk-free rate that investors demand as compensation for an investment’s uncertainty.

Risk-free asset  An asset with returns that exhibit zero variance.

Risky asset  An asset with uncertain future returns.

Runs test  A test of the weak-form efficient market hypothesis that checks for trends that persist longer in terms of positive or negative price changes than one would expect for a random series.

S

Sampling  A technique for constructing a passive index portfolio in which the portfolio manager buys a representative sample of stocks that comprise the benchmark index.

Seasoned equity issues  New equity shares offered by firms that already have stock outstanding.

Secondary market  The market in which outstanding securities are bought and sold by owners other than the issuers. Purpose is to provide liquidity for investors.

Sector rotation strategy  An active strategy that involves purchasing stocks in specific industries or stocks with specific characteristics (low P/E, growth, value) that are anticipated to rise in value more than the overall market.

Secured (senior) bond  A bond backed by a legal claim on specified assets of the issuer.

Security market index  An index created as a statistical measure of the performance of an entire market or segment of a market based on a sample of securities from the market or segment of a market.

Security market indicator series  An index created as a statistical measure of the performance of an entire market or segment of a market based on a sample of securities from the market or segment of a market.

Security market line (SML)  The line that reflects the combination of risk and return of alternative investments. In CAPM, risk is measured by systematic risk (beta).

SelectNet  An order-routing and trade-execution system for institutional investors (brokers and dealers) that allows communication through the Nasdaq system rather than by phone.

Semistrong-form efficient market hypothesis  The belief that security prices fully reflect all publicly available information, including information from security transactions and company, economic, and political news.

Separation theorem  The proposition that the investment decision, which involves investing in the market portfolio on the capital market line, is separate from the financing decision, which targets a specific point on the CML based on the investor’s risk preference.

Serial obligation bond  A bond issue that has a series of maturity dates. Typical for municipal bonds.

Settlement price  The price determined by the exchange clearinghouse with which futures contract margin accounts are marked to market.

Sharpe measure  A relative measure of a portfolio’s benefit-to-risk ratio, calculated as its average return in excess of the risk-free rate divided by the standard deviation of portfolio returns.

Short hedge  A short position in a forward or futures contract used to offset the price volatility of a long position in the underlying asset.

Short position  The seller of a commodity or security or, for a forward contract, the counterparty who will be the eventual seller of the underlying asset.

Short sale  The sale of borrowed securities with the intention of repurchasing them later at a lower price and earning the difference.

Sinking fund  Bond provision that requires the issuer to redeem some or all of the bond systematically over the term of the bond rather than in full at maturity.

Small-firm effect  A frequent empirical anomaly where risk-adjusted stock returns for companies with low market capitalization (i.e., share price multiplied by number of outstanding shares) are significantly larger than those generated by high market capitalization (large cap) firms.

Small-Order Execution System (SOES)  A quotation and execution system for retail (nonprofessional) investors who place orders with brokers who must honor their prevailing bid-ask for automatic execution up to 1,000 shares.

Soft dollars  A form of compensation to a money manager generated when the manager commits the investor to paying higher brokerage fees in exchange for the manager receiving additional services (e.g., stock research) from the broker.

Sortino measure  A relative measure of a portfolio’s performance, calculated as its average return in excess of minimum acceptable return threshold, divided by its downside risk coefficient.
Specialist  The major market maker on U.S. stock exchanges who acts as a broker or dealer to ensure the liquidity and smooth functions of the secondary stock market.
Speculative company  A firm with a great degree of business and/or financial risk, with commensurate high earnings potential.
Speculative stock  A stock that appears to be highly overpriced compared to its intrinsic valuation.
Spending phase  Phase in the investment life cycle during which individuals' earning years end as they retire. They pay for expenses with income from social security and returns from prior investments and invest to protect against inflation.
Spot rate  The required yield for a cash flow to be received at some specific date in the future—for example, the spot rate for a flow to be received in one year, for a cash flow in two years, and so on.
Spread  A trading strategy where long and short positions in two call (or two put) option contracts having the same underlying asset but different exercise prices or expiration dates are combined to create a customized return distribution.
Standard deviation  A measure of variability equal to the square root of the variance.
Statement of cash flows  A financial statement that shows the effects on the firm's cash flow of income flows and changes in its balance sheet.
Static yield spread  Yield spreads over the total term structure.
Stock index arbitrage  A trading strategy involving a long position in a stock portfolio and a short position in a stock index futures contract (or vice versa) designed to exploit a mispricing in the futures contract relative to the underlying index.
Straddle  A trading strategy requiring the simultaneous purchase of a call option and a put option having the same exercise price, underlying asset, and expiration date. Variations of this theme include strips, straps, strangles, and chooser options.
Strong-form efficient market hypothesis  The belief that security prices fully reflect all information from both public and private sources.
Structural change  Economic trend occurring when the economy is undergoing a major change in organization or in how it functions.
Structured note  A bond with an embedded derivative designed to create a payoff distribution that satisfies the needs of a specific investor clientele.
Style analysis  An attempt to explain the variability in the observed returns to a security portfolio in terms of the movements in the returns to a series of benchmark portfolios designed to capture the essence of a particular security characteristic such as size, value, and growth.
Style grid  A graph used to classify and display the investment style that best defines the nature of a security portfolio.
Subordinate (junior) bonds  Debentures that, in case of default, entitle holders to claims on the issuer's assets only after the claims of holders of senior debentures and mortgage bonds are satisfied.
Superior analyst  An individual who consistently is able to identify undervalued and overvalued securities that will provide excess risk-adjusted returns. This requires two attributes: the first is being correct regarding estimates of major valuation variables; the second is being different from most other analysts and investors. The result is the prediction of significant "surprises" related to the securities involved.
Support level  A price at which a technician would expect a substantial increase in price and volume for a stock to reverse a declining trend that was due to profit taking.
Sustainable growth potential  A measure of how fast a firm can grow using internal equity and debt financing and a constant capital structure; equal to retention rate × ROE.
Swap spread  A measure of the risk premium for an interest rate swap, calculated as the difference between the agreement's fixed rate and the yield on a Treasury bond with the same maturity.
SWOT analysis  An examination of a firm's Strengths, Weaknesses, Opportunities, and Threats. This analysis helps an analyst evaluate a firm's strategies to exploit its competitive advantages or defend against its weaknesses.
Systematic risk  The variability of returns that is due to macroeconomic factors that affect all risky assets. Because it affects all risky assets, it cannot be eliminated by diversification.
Tactical asset allocation  An investment strategy that adjusts the investor's mix of stocks and bonds by increasing the allocation to the asset class that is relatively undervalued.
Tax cost ratio  Based on the ratio of the portfolio's tax-adjusted and pretax returns, the measure indicates the average annual percentage of a taxable investor's assets that have been consumed by taxes over the measurement period.
Tax efficiency  The extent to which the investor controls the tax consequences of the security trades in a portfolio by balancing capital gains and capital losses.
Technical analysis  Estimation of future security price movements based on past price and volume movements.
Term bond  A bond that has a single maturity date.
Term premium  See Liquidity preference hypothesis.
Term structure of interest rates  The relationship between term to maturity and yield to maturity for a sample of comparable bonds at a given time. Popularly known as the yield curve.
Term to maturity  Specifies the date or the number of years before a bond matures or expires.
Third market  Over-the-counter trading of securities listed on an exchange.
Tick  The minimum price movement for the asset underlying a forward or futures contract; for Treasury bonds, one tick equals 1/32 of 1 percent of par value.
Time premium  The difference between an option's total market value and its intrinsic value.
Time-series analysis  An examination of a firm's performance data over a period of time.
Time-weighted return  The geometric average of (one plus) the holding period yields to an investment portfolio.
Total return  A return objective in which the investor wants to increase the portfolio value to meet a future need by both capital gains and current income reinvestment.
Total return swap  An agreement providing for the periodic exchange of cash flows based on a floating-rate index and the total return (i.e., interest plus capital gain or loss) to a predetermined reference entity, usually a specific bond or bond index.
Tracking error  The standard deviation of the difference in returns between an active investment portfolio and its benchmark portfolio; also called tracking error volatility.

Trading effect  The difference in performance of a bond portfolio from that of a chosen index due to short-run changes in the composition of the portfolio.

Trading rule  A formula for deciding on current transactions based on historical data.

Trading turnover  The percentage of outstanding shares traded during a period of time.

Transaction cost  The cost of executing a trade. Low costs characterize an operationally efficient market.

Treasury bill  A negotiable U.S. government security with a maturity of less than one year that pays no periodic interest but yields the difference between its par value and its discounted purchase price.

Treasury bond  A U.S. government security with a maturity of more than 10 years that pays interest periodically.

Treasury inflation-protected securities (TIPS)  Treasury bonds backed by the faith and credit of the Treasury that provide a promised yield in real terms—that is, the principal and interest payments are indexed to the Consumer Price Index (CPI) published by the Bureau of Labor Statistics.

Treasury note  A U.S. government security with maturities of 1 to 10 years that pays interest periodically.

Treaty composite measure  A relative measure of a portfolio’s performance calculated as its average return in excess of the risk-free rate divided by its beta coefficient.

Trough  The culmination of a bear market at which prices stop declining and begin rising.

12b-1 plan  A fee charged by some funds, named after the SEC rule that permits it. Such fees pay for distribution costs, such as advertising, or for brokers’ commissions. The fund’s prospectus details any 12b-1 charges that apply.

U

Underfunded plan  A defined benefit pension plan in which the present value of the fund’s liabilities to employees exceeds the value of the fund’s assets.

Underweight  A condition in which a portfolio, for whatever reason, includes less of a class of securities than the relative market value alone would justify.

Unrealized capital gains  Capital gains that reflect the price appreciation of currently held unsold assets.

Unsecured bonds  Bonds that promise payments of interest and principal but pledge no specific assets. Holders have first claim on the issuer’s income and unpledged assets. Also known as debentures.

Unsystematic risk  Risk that is unique to an asset, derived from its particular characteristics. It can be eliminated in a diversified portfolio.

Unweighted index  An indicator series affected equally by the performance of each security in the sample regardless of price or market value. Also referred to as an equal-weighted series.

Unwind  The negotiated termination of a forward or futures position before contract maturity.

V

Valuation analysis  An active bond portfolio management strategy designed to capitalize on expected price increases in temporarily undervalued issues.

Valuation process  Part of the investment decision process in which you estimate the value of a security.

Value stocks  Stocks that appear to be undervalued for reasons besides earnings growth potential. These stocks are usually identified based on high dividend yields, low P/E ratios, or low price-to-book ratios.

Value-weighted index  An index calculated as the total market value of the securities in the sample. Market value is equal to the number of shares or bonds outstanding times the market price of the security.

Variable-rate note  A debt security for which the interest rate changes to follow specified short-term rate, for example, the T-bill rate; see Floating rate note.

Variable principal redemption (VPR)  A class of debt securities whose principal redemption at maturity is not fixed but tied to changes in the value of another economic entity, such as a stock index or commodity price.

Volatility index (VIX)  A measure of investor expectations of near-term volatility in the stock market calculated as a weighted average of the implied volatilities estimated from Standard and Poor’s 500 option contracts.

W

Warrant  An instrument that allows the holder to purchase a specified number of shares of the firm’s common stock from the firm at a specified price for a given period of time.

Weak-form efficient market hypothesis  The belief that security prices fully reflect all security market information.

Y

Yankee bonds  Bonds sold in the United States and denominated in U.S. dollars but issued by a foreign firm or government.

Yield  The promised rate of return on an investment under certain assumptions.

Yield illusion  The erroneous expectation that a bond will provide its stated yield to maturity without recognizing the implicit reinvestment assumption related to coupon payments.

Yield spread  The difference between the promised yields of alternative bond issues or market segments at a given time relative to yields on Treasury issues of equal maturity.

Yield to worst  Given a bond with multiple potential maturity dates and prices due to embedded call options, the practice is to calculate a yield to maturity for each of the call dates and prices and select the lowest yield (the most conservative possible yield) as yield to worst.

Z

Zero coupon bond  A bond that pays its par value at maturity but no periodic interest payments. Its yield is determined by the difference between its par value and its discounted purchase price. Also called original issue discount (OID) bonds.
